Yield of gas and by-products. The volume of gas obtained varies naturally to a considerable extent, according to the quality of the coal carbonised, to the conditions of carbonisation, and also to the extent to which the furnace gases, consisting chiefly of nitrogen, are drawn into the gas through the porous retorts. At the present day the volume of gas produced from a ton of coal, without steaming the retorts, measured moist at 60°F. and 30 inches bar., usually falls within the limits of 9000 and 13,000 cub. ft., and, except in small works, or where gas of high illuminating power is produced, the yield does not often fall below about 11,000 cub. ft. From the same classes of coal, the higher the yield of gas the lower is the illuminating power and calorific power, but, in general, the total yield of light represented by the multiple of make per ton \times illuminating power, becomes higher as the make of gas increases, and this is the case to a still greater extent with the yield of heat units per ton of coal, as the calorific power falls off with increasing gas production to a much smaller extent than is the case with the illuminating power; and, in view of the fact that the heating value of the gas is now by far the most important factor, there is a constant endeavour to obtain, as high a yield as possible.

The constituents present in purified coal gas obtained by the simple carbonisation of coal in more than minute quantity are carbon dioxide, ethylene, benzene, oxygen, carbon monoxide, methane, hydrogen, and nitrogen. Their relative proportions naturally vary considerably, but for the most part fall within the following limits:—

Carbon dioxide	.	.	.	0.0-3.0	p.c.
Ethylene	.	.	.	2.0-4.0	"
Benzene	.	.	.	0.5-1.0	"
Oxygen	.	.	.	0.0-1.5	"
Carbon monoxide	.	.	.	4.0-15.0	"
Methane	.	.	.	22.0-25.0	"
Hydrogen	.	.	.	38.0-55.0	"
Nitrogen	.	.	.	2.0-20.0	"

The ethylene and benzene are usually estimated together and recorded as 'unsaturated hydrocarbons,' no very satisfactory quick method for their separate determination being available. In addition to methane, the richer coal gases contain small amounts of ethane, which is, however, also difficult of estimation in ordinary analyses. The nitrogen is usually taken as the difference between the sum of the other constituents and 100. The sp.gr. of coal gas falls mostly within the limits 0.4 and 0.55 (air=1).

The yield of coal tar with horizontal and inclined retorts varies commonly from 9 to 13 gallons per ton of coal, averaging about 10 gallons, or some 5.5 p.c. of the weight of the original coal. Its sp.gr. varies from about 1.10 to 1.25, this depending largely on the temperature of carbonisation. The higher the temperature to which the volatile products are exposed, the higher is the average carbon percentage, and the lower the hydrogen percentage of the tar, and the greater the amount of the so-called 'free carbon' formed; the latter, although in appearance resembling amorphous carbon, always contains hydrogen, and consists of derivatives of very complex hydrocarbons, which are infusible and insoluble in the remaining tar. The yield of tar from vertical retorts is higher and is increased by steaming, the tar being much thinner, and having a sp.gr. of 1.07-1.13, and only contains 40-55 p.c. of pitch instead of the 60-70 p.c. in tar from horizontal retorts, and also only small amounts of 'free carbon.'

The ammoniacal liquor contains a quantity of ammonia calculated as sulphate, equivalent generally to a yield of from 22 to 30 lbs. of the latter per ton of coal, but is usually higher (up to 45 lbs.) in continuous vertical retorts, and is considerably increased by steaming. The composition of ammoniacal liquor and its working up into ammonium salts, are described in the article AMMONIA.

The yield of coke averages about 14 cwt. per ton of coal, but a considerable amount of this is used for heating the retort setting and other purposes on the works, so that the amount available for sale is much less than this, and a sale of 10 cwt. per ton is not often exceeded.

Manufacture of carburetted water gas. In order to obtain a gas of high illuminating power to mix with the gas from ordinary coal, and increase the illuminating power of the latter, canal coal was formerly used, rich varieties of which give a gas of as high an illuminating power as 35 or even 40 candles. Owing to the increasing scarcity and cost of canal, about 1890 recourse was had to oil, as a source of rich gas, this being either carbonised in retorts making oil gas of 60 candle power or higher, or used in the preparation of carburetted water gas, i.e. a mixture of water gas and oil gas, which during the previous 20 years had been largely manufactured in the United States, and had, to a large extent, displaced coal gas, and which can readily be made of 20-25 candle power. The carburetted water gas was adopted in a large number of cases, as this plant has the advantage that the volume of gas produced is much greater than with an oil-gas plant, and the apparatus, starting cold, can be put to work in a very short time, and forms a valuable means of quickly increasing the supply in times of sudden great

consumption, such as are brought about by fogs or very cold weather. Owing to the now almost general reduction of illuminating power to a quality the ordinary gas coal is capable of yielding, the use of oil gas has been almost entirely given up, but carburetted water gas of a calorific power similar to that of the coal gas is made in many undertakings to a large extent, and mixed with the coal gas before storage, about 10 p.c. of the total gas made in the United Kingdom in 1913 consisting of this gas. As mentioned above, water gas alone is now also frequently admixed with the coal gas in many cases.

The manufacture of water gas itself (commonly known as 'blue' water gas, owing to its burning with a blue non-luminous flame) is dealt with in a separate article (see GAS, WATER), and will only be considered here so far as it concerns the manufacture of the carburetted gas. Fig. 25 shows the general arrangement of the Humphreys and Glasgow plant largely employed in the manufacture. The generator A is filled with coke, the latter being ignited at the bottom and raised to incandescence by blowing in air from a fan, the amount of air being regulated so that the gases coming away from the generator contain sufficient carbon monoxide to burn readily. These pass to the top of the 'carburettor' B, which is filled with fire-brick checker work, a secondary stream of air being added to the gas at the top, when the carbon monoxide burns and raises the fire-brick checker work to a red heat. The gases pass away from the bottom and enter the bottom of the 'superheater' C, where they meet with more air, and the remaining carbon monoxide burns to the dioxide, and raises the checker work in the superheater also to a red heat. The waste gases escape into the air from the 'stack-valve' on the top of the superheater, which is open during this operation. When the coke in the generator is sufficiently hot, and the checker work in the carburettor and superheater raised to the required temperature, all three air valves and the stack valve are closed, and steam turned on to the generator, water gas being produced, which passes to the top of the carburettor. At this point oil is sprayed into the gas, and passes with the latter over the hot checker work, and is first volatilised, the vapours then undergoing decomposition, which is completed in passing through the superheater, the oil being thus converted into permanent gas and condensable tar vapours. The stack valve being now closed, the mixed gas passes through a seal pot, H (which prevents gas returning up the stand pipe when the stack valve is open), thence through scrubbers filled with boards and tubular water-cooled condensers to reduce the gas to atmospheric temperature and condense the tar vapours and excess of steam from the gas. As the formation of water gas takes place with absorption of heat, the temperature of the coke in the generator steadily falls, and eventually reaches a point at which the amount of carbon dioxide produced becomes excessive, and the steam is then shut off, the oil having been also shut off from the carburettor a short time previously; the generator air valve is then again opened, and also the secondary air-valves and stack valve, and the coke and checker

work raised to a suitable temperature as before, this period of working being known as the 'blow.' When this is effected, the air and stack valves are again closed, steam and oil turned on, and carburetted water gas made for a further period, known as the 'run,' until the temperature in the generator again falls too low, when steam and oil are again shut off and the blow recommenced. This sequence of operations is then maintained continuously, except during the intervals necessary for adding fresh coke to the generator, and for removing the clinker produced from the ash of the coke. The periods adopted for the length of the blow and run vary somewhat according to the nature of the coke and the available air

pressure, a blow and run of 3 and 5 minutes and of 4 and 7 minutes being frequently adopted. The steam supply must be regulated so as not to allow a large excess of undecomposed steam to pass the fuel bed, as in that case a high percentage of carbon dioxide is formed. The checker work temperatures required vary with the class of oil used, the best results being obtained at somewhat different temperatures with different oils, as well as with the quantity of oil used per 1000 cub. ft. of gas made; an average temperature of working is about 750°.

The oil employed is mostly that fraction of petroleum lying between the burning oils and the lubricating oils, frequently termed 'solar' oil, which can be obtained at the lowest price.

Fig. 25.

This is heated before introduction into the carburettor by passing through a coil in the gas main over which hot gas is passing. The amount of oil used depends upon the quality of gas which is desired, and is regulated according to the requirements in this respect.

As the gas production is intermittent, a balancing reservoir is required for the gas if this is to be passed through the purifiers at a uniform rate. For this purpose a relief gas holder is placed at the condenser outlet into which the gas passes intermittently as made, and is drawn from it continuously by an exhaustor and forced forward to the purifiers. The gas is purified from tar fog and sulphuretted hydrogen, and from carbon dioxide, if necessary, by the same methods as adopted with coal gas. Usually separate purifiers are employed for this gas, the purified streams of coal gas and carburetted

water gas mixing together at the outlet of their respective meters before reaching the holders, but in some cases the crude carburetted water gas is mixed with the coal gas before the purifiers, and the mixed stream purified in the same boxes.

The only by-product obtained in the manufacture, other than spent oxide or spent lime from the purifiers, is the oil tar, no ammonia being produced in the process. The oil tar is a comparatively thin oil of sp.gr. 1.0-1.05, consisting mainly of aromatic hydrocarbons. It only contains about 30-35 p.c. of pitch, and scarcely any 'free carbon,' the solid matter found in it consisting chiefly of fine coke ash carried over from the generator with the stream of water gas. It is mostly sold to distillers, but is sometimes used as fuel, and also for washing the crude coal gas to remove naphthalene, of

which it normally contains only small amounts. Sometimes the tar separates as an emulsion with water, from which the latter only separates with great difficulty.

The amount of coke employed in the manufacture, including that used for raising steam, amounts to from 40 to 50 lbs. per 1000 cub. ft. made, whilst the consumption of oil varies considerably, according to the quality of gas required. With good working each gallon of oil of good quality used per 1000 cub. ft. will give an illuminating power of 7-8 candles if

the carbon dioxide is removed. The quantity of oil tar produced amounts to 12-15 p.c. of the oil used.

Carburetted water gas contains the same constituents as coal gas, but their relative amounts differ considerably, the percentages of carbon monoxide and ethylene being higher, and those of hydrogen and methane lower; it only contains small amounts of sulphur compounds other than sulphuretted hydrogen.

The following analyses of coal gas, carburetted water gas, and of a mixed gas containing

SECTION THROUGH TANK AND - GAS HOLDER

FIG. 26.

about 20 p.c. of the latter, are fairly typical for gases of relatively high calorific power, and show the general character of the difference:—

	Coal gas	Carb. water gas	Mixed gas
Carbon dioxide . . .	1.2	3.8	1.6
Ethylene and benzene . . .	3.2	11.4	4.1
Oxygen . . .	0.4	0.2	0.5
Carbon monoxide . . .	9.1	31.0	12.2
Methane . . .	30.2	15.0	28.1
Hydrogen . . .	48.5	32.9	46.2
Nitrogen . . .	7.4	5.7	7.3

Carburetted water gas usually contains small amounts of ethane as well as methane.

The sp.gr. of carburetted water gas is much higher than that of coal gas of the same illuminating power, owing especially to its smaller percentage of hydrogen. It varies considerably, according to the percentage of oil gas in it, but usually falls within the limits of 0.6 and 0.75 (air=1).

Measurement, storage, and distribution of the gas. The gas, leaving the purifiers, passes to the station meters in which its volume is measured, and thence to the gas holders, where it is stored ready for distribution as required. The meters

employed are usually wet meters, similar to those used as consumers' meters, but of very much larger size. The temperature of the gas passing and the height of the barometer is noted, and the volume recorded by the meter corrected to standard temperature and pressure, which is, however, not the 0° and 760 mm. barometer employed for scientific purposes, but that of the gas at 60°F. and 30 inches bar. saturated with moisture, this being approximately the average condition of the gas when sold to consumers, whose payment is made by volume.

The gas holders (Fig. 26), consisting of a large bell with suitable guide framing floating in a tank of water, are often of very large size, the largest being capable of holding about 15,000,000 cub. ft. In order to reduce the necessary depth of the tank, the bell is usually constructed in a number of lifts which slide into each other in a somewhat similar manner to the cylinders of a telescope. The weight of the holder keeps the gas within it under a pressure equivalent generally to the weight of a water column of 4-10 inches, according to the weight and diameter of the holder.

In order to control the pressure of the gas in

the mains in the district of supply, a governor is fixed between the holder and the trunk mains, whereby the pressure in the distribution mains is reduced to that most suitable, after which it is automatically maintained at that pressure. Fig. 27 gives a section of a governor in frequent use. The gas, entering in the direction shown by the arrows, must, in order to reach the outlet, pass through a device consisting of a hollow vertical cylinder closed at the top and having a

which, under the atmospheric pressure, falls, increasing the size of the gas openings, allowing more gas to pass and restoring the pressure in the outlet main. If the consumption decreases and pressure increases, the bell rises and reduces the size of the gas openings, and in this manner the pressure once set remains constant. When it is desired to alter the pressure in the outlet main to allow for the periods of higher or lower consumption on the district, water is either added to or run off from the annular chamber in the bell.

Formerly the holders gave more pressure than was required on the district, but at the present time, owing to the greater consumption and the higher pressures which are required for the efficient working of incandescent burners, gas fires, and gas engines, it frequently happens, especially in large works, that the pressure given by the smaller holders and the upper lifts of the larger ones is insufficient. In such cases the gas is drawn from the holder by means of fans, and forced forward at higher pressure to the works governor, or carried into the district by separate high-pressure mains, the gas from which is passed into the ordinary distribution mains at suitable points for maintaining good and uniform pressure throughout the area of supply.

Determination of calorific power. Several calorimeters are in use for this purpose, all of which are in principle identical with the form proposed by Hartley (J. Gas Lighting, 1884, 1142), the gas being burned at a constant rate in a chamber through which water also flows at a constant rate. The instrument in most frequent use in all parts of the world is the Junkers' calorimeter, a section of which is given in Fig. 28. The gas, after passing through a governor and meter, is burned in a large Bunsen burner, *E*, in the central portion of an annular copper chamber, the annular space of which is traversed by a large number of copper tubes down which the products of combustion pass and escape into the atmosphere by the side opening *F*, which is provided with a damper regulating the amount of air passing through the apparatus. The water of a temperature closely approximating to that of the normal is run into the upper small reservoir *A*, provided with an outlet proper to the calorimeter, and a constant level overflow *B*, the rate at which the water enters being maintained above that passing through the calorimeter, the excess passing away by the overflow, thus maintaining a constant head of water. The water flows down, past the regulating cock and inlet thermometer, to the bottom of the annular chamber, and flows upwards to the top around the tubes conveying the products of combustion in the reverse direction, and cools the latter to the temperature of the incoming water. The water leaves the annular chamber at the top and passes through a series of baffle plates to ensure thorough mixing, over the outlet thermometer to the overflow funnel *C*. The water condensed from the gas collects at the bottom of the annular chamber and flows out through a small tube into a collecting cylinder.

The gas and water supplies are adjusted so that the difference in the readings of the inlet and outlet water thermometers is 10° – 15° , and

FIG. 27.

number of slots cut in the vertical side, the width of which increases towards the top of the cylinder. The top of this cylinder is connected by a rod with the bell above, and is capable of moving freely up and down with this bell which is sealed in water. When water is allowed to run into the annular chamber in the bell, the latter increases in weight, and with the attached cylindrical device sinks, increasing the size of the openings through which the gas can pass, and by adjustment of the amount of water the desired pressure at the outlet can be obtained. If, then, owing to increased consumption, the pressure of the gas in the outlet main falls, this lessened pressure is transmitted to the bell,

when equilibrium is attained and the condensed water is also dripping regularly from the small tube, D, at the bottom of the calorimeter, the water from the calorimeter is diverted into a collecting vessel as the meter hand passes a point which is noted, and a small measuring

FIG. 28.

cylinder placed to collect the condensed water. Frequent readings of the inlet and outlet thermometers are made, until a sufficient amount of water has been collected (from 2 to 5 litres are mostly taken); to conclude the test, the gas may be shut off when the collecting vessel is filled to a definite point, or the water may be diverted from the measuring vessel as the meter hand passes a noted point. The volume of gas is taken from the meter readings and corrected to that of the moist gas at 60°F. and 30 inches bar., the weight of water passed determined by measurement or by weighing, and the average increase in temperature of the water found from the readings taken during the test. The calorific power of 1 cub. ft. of the gas, expressed in large calories, is equal to :

$$\frac{\text{weight of water in kilos.} \times \text{temperature C.}^\circ}{\text{volume of gas consumed}}$$

In this country the value is usually expressed in British thermal units, i.e. the amount of heat required to raise 1 lb. of water 1°F., each calorie being equal to 3.968 B.Th.U., and to obtain the result in these units the number of calories found must be multiplied by that factor.

The calorific value thus obtained includes the latent heat evolved by the condensation of the steam produced by the combustion of the

hydrogen contained in the gas, and is termed the *gross* calorific power. In almost all the practical applications of gas, the products of combustion pass away at temperature above which the condensation of the steam occurs, so that this latent heat cannot be utilised either for the production of high temperature in the flame of the burning gas, or for development of power in the cylinder of a gas engine. A deduction of this amount of latent heat is therefore made from the gross calorific power, the difference, excluding this heat, being termed the *net* calorific power. The amount of such latent heat is ascertained by collecting the condensed water which flows from the calorimeter during the test, a larger volume of gas than that required for the determination of the gross value being burned for this determination (about 1 cub. ft.). Each c.c. of water evolves, in condensation, 0.536 cal., and the amount to be deducted is found by multiplying 0.536 by the number of c.c. of condensed water per cub. foot of gas burned. The usual practice is, however, to deduct 0.6 cal. for each c.c. of condensed water, this representing not only the latent heat, but also the sensible heat lost by the condensed steam in cooling from 100° to atmospheric temperature, and the 'net' figures then obtained are rather lower than the true net value, which has to be employed in thermodynamic calculations.

FIG. 29.

The Boys calorimeter, prescribed by the Metropolitan Gas Referees, is shown in section in Fig. 29. The base R carries the pair of union jet burners B, which are supplied with the

gas to be tested through a governor and meter; the calorimeter vessel proper D, after lighting the gas, is then placed in position over the flame, and rests on three centering and lifting plates C, leaving a space through which the air required for combustion enters. The products pass up the copper chimney and thence into the annular space between the chimney and the outer side of the calorimeter vessel. This annular space is divided into two portions by a brattice of thin sheet brass filled with non-conducting material such as cork-dust, which causes the combustion products to pass first down the inner portion of the annular space, and then up on the outer side to the top, where they escape into the atmosphere through holes bored in the wooden top. A tube of copper, to the outside of which is sweated a helix of copper wire, giving it a large conducting surface, is led in a spiral, first from top to bottom of the outer annular chamber, then around the bottom below the brattice, and finally up the inner annular chamber. The water is led over the inlet thermometer through this tube, passing first through the outer annular chamber, then along the bottom, into which water is placed before commencing a test, and up the inner annular chamber, and in its travel absorbs the heat of the products of combustion. Before reaching the outlet thermometer, the water passes through the central temperature-equalising chamber.

The general method of working is similar to that of the Junkers calorimeter, full details of construction and working being given in the official notification of the Gas Referees (Wyman and Sons, Ltd.).

With both these forms of calorimeter, an appreciable error is introduced into the determination of the gross value, if the air supply to the calorimeter is not at least 90 p.c. saturated with moisture, inasmuch as the waste gases, which always leave the calorimeter in a saturated condition, then carry away with them a portion of the steam formed by the combustion of the gas without its undergoing condensation, and the latent heat of this portion of the steam is therefore not included. A correction should therefore be made on this account (Met. Gas Referees Notification).

The Simmance-Abady 'total-heat' calorimeter, made by A. Wright and Co., Ltd., is a modification of the original Hartley calorimeter made by the same firm, and in general method of working closely resembles the Junkers' calorimeter. It differs from it especially in that the water overflow from the upper constant level chamber of the apparatus acts as an injector, and forces through the calorimeter the necessary volume of air for the combustion of the gas. In this manner it is automatically ensured that water, air, and waste gases are all at very nearly the same temperature, and also that the air passing through the calorimeter is saturated with moisture, thus obviating any necessity for correction in the latter respect.

Recording calorimeters, such as those of Beazley and Simmance-Abady, giving a continuous record of the calorific power of gas, are also largely in use. (For details of the necessary precautions to obtain accurate results in gas calorimetry, see *J. Gas Lighting*, 1908, 104, 904; *Coste, J. Soc. Chem. Ind.* 1909, 28, 1231.)

Illuminating power. The statutory methods of determination of the illuminating power of coal gas, when burned in open flames, have been described fully in former editions, but in view of the abandonment of this test for statutory purposes, and its replacement by a calorific power test, and the small importance now attaching to such tests in practice, the description is omitted here; for information on the matter reference may be made to former editions or to the Official Notification of the Metropolitan Gas Referees for the years 1910-1918.

Photometric observations are, however, still required in connection with coal gas where it is used for illumination, such as in the determination of the illuminating power of incandescent burners, the amount of light emitted by the different burners at varying angles, and the actual illumination of indoor and outdoor surfaces. Space will not allow of the consideration here of the necessarily somewhat complicated apparatus required for these applications.

Whilst the most important property of gas is its calorific power, which is, in fact, its total potential energy, expressed in heat units, it must be remembered that this is not the only factor to be considered. The efficiency of the apparatus in which the gas is used depends, in a large number of cases, not only on the total amount of heat liberated, but also on the temperature and other properties of the flame produced. The presence of large quantities of inert incombustible gases, such as nitrogen and carbon dioxide, lowers the flame temperature at a greater rate than it does the calorific power, and although their presence in coal gas cannot be altogether avoided, it is desirable that their amount should be kept as low as possible consistently with economical working in other respects. Further, the average flame temperature in burners of the Bunsen type, by which most of the gas made is now consumed, varies greatly according to the volume of primary air drawn into the gas before combustion by the injecting action of the gas jet issuing from the burner nozzle, as the most suitable proportion depends upon the composition of the gas, and the actual amount of air drawn in varies according to both the pressure and the sp.gr. of the gas; if, therefore, an apparatus is set to give the greatest efficiency under certain conditions of pressure, composition, and sp.gr. of the gas, this efficiency will not be maintained if the gas supply undergoes considerable variations in any or all of these points. Further, the efficiency of many kinds of gas apparatus—for example, the incandescent mantle, and the columnar radiants of gas fires—depends, to a very large extent, on the exact fitting of these into the hottest part of the flame, and variations of the above conditions tend to alter the shape of the flame and often thereby very materially reduce the efficiency of the apparatus.

Whilst there is very considerable difference of opinion both within and without the gas industry with regard to the most suitable calorific power for a public supply under present conditions, having regard to the greatly varying purposes for which it is now employed, there is general agreement that, whatever the actual

calorific power fixed on may be, both this and the volume of air required for combustion of unit volume of gas, its pressure and its sp.gr. should be then maintained as regular as possible, and that, from the consumer's point of view, better results ensue from a supply of fairly uniform, although lower average, calorific power, with reasonable constancy of pressure, air requirement, and sp.gr., than with gas of considerably higher calorific power, but subject to much greater fluctuations in these respects. Whilst it is not practicable to obtain exact uniformity of calorific power, composition, and sp.gr., or of pressure throughout a large district of supply, except at a cost which would be prohibitive, it is of the greatest importance for all concerned that this end should be aimed at so far as it can be effected with reasonable economy.

Sulphuretted hydrogen. All gas supplied for public use must by law be free from sulphuretted hydrogen. According to the stipulations of the Gas Works Clauses Act, the gas, when passed for 3 minutes over bibulous paper moistened with lead acetate solution at the rate of 5 cub. ft. per hour, shall not darken the paper, owing to the formation of lead sulphide. As the formation of a brown stain in this manner is an exceedingly delicate test for sulphuretted hydrogen, this means that

for all practical purposes the gas passing the test is free from that impurity.

Determination of total sulphur. The official method for estimation of the total sulphur present in purified gas is that prescribed by the Metropolitan Gas Referees, which is illustrated in Fig. 30. The gas, if it is also to be tested for sulphuretted hydrogen and ammonia, is passed first over test papers made by soaking blotting paper in a 10 p.c. solution of lead acetate, and exposing such slips, whilst damp, to an atmosphere containing ammonia, and then over a cylinder filled with glass beads or broken glass, moistened with a known volume of standard sulphuric acid, to remove ammonia. It is then burned in a small Bunsen burner at the rate of 0.5-0.7 cub. ft. per hour until 10 cub. ft. have passed, the flame being surrounded by lumps

FIG. 30.

of commercial ammonium carbonate. The products of combustion, together with ammonia, pass by means of the trumpet tube into the glass cylinders provided with a tubulus at the bottom for connecting with the trumpet tube; the upper portion of the cylinder is filled up with glass marbles, and from the top a wide bent-glass tube is led, which acts as a chimney and final condenser. A small tube drawn out to a jet conveys the condensed products to a flask or beaker placed on a shelf below. The sulphur dioxide formed by the combustion of the sulphur condenses in presence of the moisture, excess of oxygen and ammonia forming a solution of ammonium sulphate, and when the required amount of gas has been burned, the cylinder is washed out with water, and the sulphur present in the liquor estimated as barium sulphate in the usual manner, the amount being calculated as grains of sulphur per 100 feet. This method tends to give slightly low results, as the sulphurous acid primarily formed is not always completely oxidised to sulphuric acid, and escapes precipitation with barium chloride, on which account many prefer a previous treatment of the solution with bromine, or precipitation with nitric acid and barium

nitrate. The sulphur estimation may also be made by aspirating the products of combustion through wash bottles containing sodium hypobromite solution, and subsequent precipitation of barium sulphate, or through neutral hydrogen peroxide, the sulphuric acid produced in the latter case being determined by titration with standard alkali.

Employment of coal gas. At the present time, coal gas is employed for a very great and increasing diversity of purposes. Whereas during the first 60-70 years of the existence of the industry its employment was almost entirely employed for illumination by burning it in open-flame burners of various kinds, the proportion of the gas now burned in this manner has become very small. Where gas is employed for illumination now, as is still largely the case, the light is obtained by the much more efficient incandescent burner.

In these last, the development of light is obtained by raising to incandescence a mantle composed essentially of thoria, to which about 1 p.c. of ceria has been added. The manufacture of these mantles is dealt with in a separate article (*see GAS MANTLES*). In order to raise such mantles to incandescence, the

gas is burned in a non-luminous flame of the Bunsen type, by mixing with the gas a certain proportion of primary air before it undergoes combustion, when it burns with the well-known non-luminous flame, having a definite two-coned structure.

Whilst the actual causes of the high development of light from such a mantle are still a matter of dispute, there is no question that the amount of light emitted increases greatly with the temperature to which the mantle is raised. In order, therefore, to obtain the highest practical efficiency with such burners, the gas must be burned in such a manner as to produce a flame of high temperature, and this must also have such a shape that the mantle is situated in the zone of highest temperature.

The effect of the introduction of the primary air to the gas before combustion is that in the flame the gas first undergoes combustion with the limited amount of oxygen present in it, yielding a mixture of steam, carbon dioxide, hydrogen, and carbon monoxide, together with the nitrogen of the added air, this reaction taking place in the area visible as the 'inner cone,' all hydrocarbons completely disappearing from the gas, provided the amount of oxygen in the mixed gas undergoing combustion is rather more than half that required for its complete oxidation. This mixture of 'water gas' and nitrogen forms the 'outer cone' of the flame, which has itself been raised to a very high temperature by the reactions occurring in the inner cone, and the hydrogen and carbon monoxide then burn where the air is in contact with the outer cone, further increasing the temperature at this surface, and the relative shape of flame and mantle should be so arranged that the latter occupies as nearly as possible the zone in which this final oxidation is taking place.

The higher the proportion of primary air added, the smaller is the size of the flame, and especially of the inner cone, and the higher the average temperature of the flame, the highest efficiency of an incandescent burner being obtained when the amount of primary air added is equal to that theoretically required for the complete combustion of the gas. Under ordinary conditions of gas supply, however, this condition cannot be obtained, as a mixture of gas with the full amount of air is highly explosive and the explosion wave travels back from the flame at a velocity greater than that of the advancing mixture of gases, and the burner 'fires back,' the gas then igniting at the injector nozzle. Under ordinary conditions, it is not practicable to admit as primary air more than about two-fifths to four-fifths of the total amount required for complete combustion. On the other hand, if the proportion of primary air admitted is too low, the hydrocarbons of the gas are not completely converted into water gas in the inner cone, some hydrocarbons passing to the outer cone, in which case, apart from the lower temperature of the flame produced, carbon may be deposited on the mantle, which becomes blackened, and its light emission thereby greatly reduced.

The proportion of primary air drawn in through the air holes of the burner depends, not only on the construction of the latter, but also to a very large extent on the pressure of

the gas and its specific gravity. The higher the pressure of the gas, and the lower its specific gravity, the smaller is the opening which is necessary for the passage of the required amount of gas, and the higher its velocity, and it is largely the latter factor which determines the amount of air sucked in through the air holes. On this account the pressure at which the gas must now be supplied is much higher than was necessary for flat-flame burners, and should be equal to that of a water column at least 2 inches in height; with lower pressures, especially with higher qualities of gas, it is much more difficult to get a well-aerated flame, and to avoid the deposition of carbon on the mantles.

With the upright incandescent burners, first introduced and still largely in use, the flame burns from the top of the burner. The central portion of the burner head is solid, so that the flame produced is annular, the central closed portion having a socket in which is placed the fire-clay crutch supporting the mantle, and the annular space covered with wire gauze or similar device to prevent 'flashing back.' To obtain a good efficiency, the size of the gas nozzle and air holes of the burner must be adjusted so that, under the average pressure existing at the burner, a well-aerated flame is produced, having only a small inner cone, and of such a size that the mantle, when put on, lies fully in the zone of highest temperature. When adjusted to give the best results, an efficiency of 25-30 candles per cub. ft. of gas having a calorific power of 530 B.Th.U. can be obtained, although, as the mantle ages, this tends to fall off, largely owing to alterations in shape of the mantle, which cause portions of it to occupy positions of lower temperature in the flame. Periodic cleaning of the burner is also necessary, as the dust in the air drawn in tends to settle on the gas nozzle and on the wire gauze of the burner head, and results in less air being drawn in and the production of an under-aerated flame of lower temperature.

In the inverted incandescent burner, which is now largely replacing the upright burner, the flame is directed downwards, the mouth of the burner being in this case fully open, and the mantle supported from above on a ring of fire-resisting material attached to the burner, this form possessing the great advantage that no shadows are thrown on the surfaces below, which are in most cases those which it is specially desired to illuminate. The proper adjustment of gas and air supplies, and a sufficient gas pressure, as well as the periodic cleaning of the burners from dust, is equally necessary with the inverted form, but when working under the most favourable conditions, these are more efficient than the upright burners, over 40 candles per cub. ft. of 540 B.Th.U. gas at moderate pressures.

By considerably increasing the pressure at which the gas is supplied, namely, to one equal to a column of about 55 inches of water or higher, much higher efficiencies are obtained, both with the upright and with the inverted burners. With the increased pressure, the velocity at which the gas can be made to issue from the injector nozzle is so increased, that the full amount of air necessary for its combustion can be drawn in through the air holes, and the mixture forced

with much higher velocity through the burner, so that the tendency of the flame to flash back through the highly explosive mixture can be controlled, and a flame of very high temperature produced, resulting in a much greater light emission from the mantle on which the flame acts. With such high-pressure burners, efficiencies of as high as 70 candles per cub. ft. are obtained. High-pressure installations are now very largely adopted for outside lighting of the public streets and yards, and also for interior lighting in workshops and large public buildings, special plant being usually erected for compressing the gas for each installation, or in some large towns a special high-pressure main is laid from the works or some central point for the supply of gas under such higher pressure where it is required.

Although very large quantities of coal gas are consumed for illumination purposes in incandescent burners, a still larger proportion of the gas output is now employed for other purposes, the most important uses being for heating with gas fires, cooking by gas, and for power production in gas-engines. In industrial districts especially steadily increasing quantities are employed for very diverse purposes, including gas furnaces for metal melting, annealing, gas-fired kilns, &c. For many of these purposes, as with the incandescent burner, better efficiency can frequently be obtained by the use of gas under much higher pressure than that at which it is normally supplied, and suitable compressing plant is frequently installed at individual works for this purpose, or, in some cases where high-pressure gas is required by a large number of consumers in a limited area, special high-pressure mains are laid in that district by the gas undertaking, who then carry out the compression. Previous to the outbreak of the war, rapid increase in the amount used for all purposes was taking place, especially in industrial districts, and although the abnormal conditions since then have lessened the requirements in many cases, in other districts largely engaged on war industries, the demand increased to an extent which could not be fully met at the time. It is confidently anticipated that when new post-war 'normal' conditions are reached, and it is possible to provide increased manufacturing and distribution plant, a further large development in the employment of gas for these and for fresh purposes will take place.

GAS, DOWSON, *v.* GAS, WATER.

GAS, GENERATOR, *v.* GAS, WATER.

GAS MANTLES. The discovery, by Goldsworthy Gurney, in 1826, that a piece of dense lime held in the oxy-hydrogen blowpipe flame, gave rise to intense incandescence, may be taken as the starting-point of the utilisation of this phenomenon for the generation of light, as Gurney's discovery was soon afterwards employed in practice by Drummond, who utilised the light whilst making a survey of Ireland; hence it was often known by his name, but is now more frequently called the oxy-hydrogen or lime-light.

The amount of heat necessary to raise a substance to the temperature needed for incandescence depends largely upon the size of the mass to be heated, as the larger it is the more will radiation and conduction tend to prevent

the temperature of incandescence being attained, and when, soon after the discovery of the lime light, it was attempted to utilise incandescence for public lighting in Paris, the lime cylinder was replaced by small buttons of zirconia and magnesia, which, being more resistant to atmospheric influences than the lime cylinders, and being far smaller, lasted for a longer period and could more easily be raised to the required temperature.

In this experiment, oxy-coal-gas burners were employed as the heating medium, but the expense soon led to its abandonment. In 1835 Talbot noticed that when a piece of blotting paper was dipped in a solution of a lime salt and was then incinerated in a spirit lamp, the ash which was left, consisting chiefly of lime, was so finely divided that the heat of a spirit-lamp flame was sufficient to raise it to high incandescence.

These early experiments pointed merely to the fact that if a refractory material like lime could be obtained in a sufficiently coherent and finely divided condition, a moderately hot flame would raise it to a temperature at which it would become usefully incandescent.

In 1848 Gillard, in attempting to utilise water gas for lighting as well as heating purposes, made a mantle of fine platinum wire, which, heated to incandescence in the flame, answered its purpose and emitted light for a short period, whilst in 1883 the Fahnehjelm comb (Fig. 1) was

FIG. 1.

introduced for developing light from a flat water-gas flame. It consisted of fine rods of magnesia in a metal setting, which was fixed at the requisite height above a flat-flame burner consuming water gas, and from it a light of about $4\frac{1}{2}$ candles per cub. ft. of gas consumed could be obtained.

Up to the middle of last century, the flame of water gas or of alcohol vapour were the only ones that could have been used to incandescence finely divided refractory material, owing to the deposition of carbon from any luminous flame, but the introduction by Bunsen of the atmospheric burner in the early fifties rendered coal gas available for all heating purposes, and made the mantle a practical possibility.

About 1883 Clamond introduced a form of

mantle, consisting of a conical basket of threads of calcined magnesia, which was supported with its apex downwards in a small platinum cage, a flame of coal gas and air being driven down upon it under pressure. It was not, however, until a year later that Dr. Auer von Welsbach, working in Bunsen's laboratory at Heidelberg upon the rare earths, noticed that the oxides of some of the rare metals had a wonderful power of light emissivity when incandescent, and, following up this clue, made the brilliant series of discoveries which gave the world the incandescent mantle.

These discoveries took place in three distinct stages. In his work prior to 1885 he discovered the fact that if a cotton fabric be saturated with a solution of the nitrates of the rare earths, and be then carefully incinerated, an ash is left which is an exact simulacrum of the original fabric, although the burning out of the cellulose reduces it to about one-third of its former size, so that by making a cotton sleeve about three times the size of the Bunsen flame it was intended to fit, saturating it in a solution of the nitrates of the metals of which he required the oxides, and then carefully burning it off over a blowpipe flame, he could obtain a mantle which would fit the outer zone of the Bunsen flame, and, being there heated to incandescence, would emit a useful amount of light.

His first patent, taken out in 1885, covered this part of his invention, and specifies the mixtures of oxides, which he gives as :

60 p.c. of zirconia, or oxide of zirconium.

20 p.c. of oxide of lanthanum.

20 p.c. of oxide of yttrium.

This last oxide may be omitted, and the proportions may be :

50 p.c. of oxide of zirconium.

50 p.c. of oxide of lanthanum.

In place of the oxide of yttrium, ytterite earth may be used, whilst cerite earth containing no didymium and but little cerium may be employed to replace the oxide of lanthanum.

These first mantles were a commercial failure, as they gave a light very little in excess of that yielded by the Clamond basket, and they were so fragile in character that they were unable to withstand the slightest shock.

The amount of light yielded by these mantles varied from 3 to 6 candles per cub. ft. of gas consumed, but it was exceptional to meet with the higher value. Using the purer materials now obtainable, however, mantles made according to the formulæ of the 1885 patent give the following results :—

Composition of mantle	P.c.	Gas consumed cub. ft.	Total candles	Illuminating power. Candles per cub. ft.
I.				
Zirconia	60	5.4	12.9	2.4
Lanthana	20			
Yttria	20			
II.				
Zirconia	50	5.5	9.4	1.7
Lanthana	50			

The lower candle power obtained with mantles made of the purer salts points to the fact that the impurities of the compounds at first employed endowed the older mantles with much

of the illuminating power, so that no uniformity in results could be expected, besides which the mixtures of oxides used were continually being varied in hopes of obtaining better results.

In 1886 the second Welsbach patent appeared. This covered the use of thoria either *per se* or mixed with oxides of other rare metals, and it is clear that at this period Welsbach imagined that the oxide of thorium alone had a very high power of light emissivity, but, as a fact, a mantle made of pure thoria emits practically no light, and the amount of light obtainable was due to traces of ceria, which had not been eliminated from the thorium salt in its preparation from thorite and orangite.

Later on, Welsbach discovered this fact, and also found that the addition to thoria of traces of ceria endowed it with the wonderful power of emitting light possessed by the modern mantle, and Mr. Moeller, of the Welsbach Company, took out a patent in England in 1893, in which he protected the use of thoria in combination with very small traces, not exceeding 1 or 2 p.c., of oxides of other rare metals, amongst which was cerium. It was only at this date that the incandescent mantle began to be a commercial success, and in spite of the thousands of experiments which have since been made, no mixture of oxides has been discovered which will give a light comparable with that yielded by the mixture of 99 p.c. thoria with 1 p.c. ceria, which is now universally used in mantle manufacture.

The oxides which can be used in making an incandescent mantle are limited in number, owing to the fact that they must be able to resist atmospheric influences, must be sufficiently refractory to withstand the temperature of the flame for a very long period, and must not be liable to excessive shrinkage during the burning off of the cotton fabric.

The oxides in the following table are those which most nearly fulfil such requirements, and the light given by mantles made from the commercial as well as from the carefully purified salts shows the vast differences that traces of impurity make in their power of emitting light :—

LIGHT EMITTED PER CUBIC FOOT OF GAS BY VARIOUS OXIDES.

Metallic oxides :		Pure	Commercial
Zirconia		1.5	3.1
Thoria		0.5	6.0
Earth metals :			
Cerite earths	{ Ceria	0.4	0.9
	{ Lanthana	—	6.0
Ytterite earths	{ Yttria	—	3.2
	{ Erbia	0.6	1.7
Common earths			
{ Chromium oxide		0.4	0.4
	{ Alumina	0.6	0.6
Alkaline earth metals :			
Baryta		3.3	3.3
Strontia		5.2	5.5
Magnesia		5.0	5.0

If these oxides be examined for shrinkage, duration, and strength, it is found that only three of them, zirconia, alumina, and thoria, are suitable as the basis of the mantle, and even with these three, zirconia in the hottest part of the flame is liable to considerable and rapid shrinkage, whilst with alumina there is also

slow volatilisation, so that the life of the mantle is gradually shortened by the slow wasting away of the threads of the mantle structure. The nitrate of thorium, unlike those of the other earths, has the property of adsorbing from 1 to 1.2 p.c. of thorium sulphate, and when a fabric of vegetable fibre saturated with a solution of thorium nitrate containing from 1.5 to 2 p.c. of sulphate is burned, the decomposition, towards the end of the operation, of this sulphate results in a minimum of shrinkage and gives to the oxide skeleton a spongy character, which permits of its being readily shaped and its finer particles rapidly fritted by a high-temperature blowpipe flame, leaving a mantle of regular form, comparative rigidity, and very large radiating surface. The oxide is refractory under the heat of an atmospheric burner for a much longer time than any other known.

The porous mass resulting from the incineration of the nitrate containing a small proportion of sulphate occupies more than ten times the volume of the original nitrate. This means that the resulting mass is of a spongy character, containing an enormous number of little air cells, which must render it an excellent non-conductor of heat. A mantle made of pure thoria gives practically no light, but if successive small additions of ceria be made to it, the light emitted gradually increases until a ratio of 99 p.c. thoria to 1 of ceria is reached, when the maximum illuminating effect is obtained. The light diminishes with further additions of ceria till, with 10 p.c. of ceria in the mixture, the mantle once more gives practically no illumination. No expansion takes place during the conversion of the cerium nitrate into oxide, the latter occupying about the same amount of space as the original nitrate, hence in the mantle, although the ratio of thoria to ceria is as 99 to 1 by weight, yet by volume it is as 999 to 1.

In the commercial manufacture of mantles, a cotton fabric was first employed knitted in the form of hose, the diameter of which was controlled by the number of needles on the knitting machine, which varied from 70 to 90, the size generally used being knitted by a 85-needle machine, giving to the finished fabric a diameter of $2\frac{1}{2}$ inches. The resultant hose is cut into suitable lengths, and one end turned over and sewn with thread to form the head of the mantle (which after impregnation and drying is drawn together with asbestos thread to form the top and a loop for suspension). These lengths are then saturated with the impregnating solution. This consists of a solution (approximately 30-35 p.c. by weight of solids) of the nitrate of thorium with 1 p.c. of cerium in water, there being added thorium sulphate, and from 0.7 to 1.5 p.c. of nitrates of other metals, e.g. magnesium, aluminium, calcium, glucinum, zirconium, yttrium, whose function is either to increase the porosity of or facilitate the fritting of the skeleton. One suitable formula is 1 kg. thorium nitrate, 10 grams cerium nitrate, 2 grams magnesium, 1 gram calcium, 7 grams glucinum nitrates, in 2 kilos of water. The mantles then pass through rollers, which are under pressure in order to squeeze out the excess of solution, leaving the fabric retaining the quantity that will give a satisfactory skeleton of oxides after incineration, and this quantity may be taken as 0.7

gram on the rough or 0.5 gram on the finished mantle after trimming. The soaked lengths are next stretched upon glass or papier mâché forms in a drying chamber, the temperature of which is maintained between 80° and 90°F. (27° to 32°C.). The head of the mantle is treated with a solution of magnosium, aluminium, and other nitrates, the object being to strengthen this part, which is the most liable to breakage. They are again dried, sewn with asbestos thread and 'moulded' by stretching on a wooden mould in order to give them the necessary shape for the next operation, that of 'burning off.' This is done upon suitable blowpipe burners supplied with gas or air under pressure, which gives a flame of a very high temperature, and these are mounted in such a way that either the

FIG. 2.—COTTON MANTLE BEFORE BURNING OFF.

burner or the mantle can be raised or lowered at the will of the operator, so that the flame can be made to play on every part, until the whole of the mantle has been shaped and hardened, leaving a skeleton of oxides formed by the decomposition of the nitrates of the salts employed. This skeleton is carefully dipped in a solution of collodion, an average formula for this solution being:

4 p.c. collodion	. 20.0	parts
Ether 18.3	"
Castor oil . .	. 0.96	"
Camphor 1.5	"

the two latter ingredients being added to prevent over-contraction on drying. After dipping, the mantles are dried in steam-heated air or vacuum ovens to allow the solvents to evaporate, and they are then trimmed and packed.

As soon as the incandescent mantle became a success, many attempts were made to evade the Welsbach patents, and the most successful of these consisted in impregnating a solution of nitrocellulose in ether and alcohol with the nitrates of thorium and cerium, and squirting the mixture out through minute orifices in the same way that artificial collodion silk is made. These filaments were then woven into mantle hose, and the collodion basis was denitrated by soaking in an alkaline sulphide, and after washing

and drying, the mantle was made from it by the same process as with impregnated cotton. It was found that mantles made in this way were distinctly superior to the cotton mantles, both in life and light emissivity, this being due to the difference of the structure of the thoria-ceria

in ramie fibre, which has now almost entirely replaced cotton for mantle manufacture.

The ramie fibre is produced from a plant of the nettle class, *Boehmeria tenacissima*, and when

FIG. 3.—AFTER BURNING OFF.

residue, which is shown in the photomicrographs, from which it is seen that the cotton (Figs. 2 to 5) gives a closely twisted rope of minute fibres, whilst the collodion (Figs. 6 and 7) gives a bundle of separate filaments without excessive twist or plait.

FIG. 4.—COTTON BEFORE BURNING OFF.

The advantages of the collodion mantle were, however, discounted by the cost, which was much higher than that of the cotton fabric, and attempts were made to find a substitute for cotton which would give the same results as the collodion at a cheaper price, and this was found

FIG. 5.—COTTON AFTER BURNING OFF.

freed from its glutinous coating can be woven into a beautiful silk-like material, and when the ramie thread is knitted, impregnated, and made into mantles, the structure is seen to far more

FIG. 6.—COLLODION BEFORE BURNING OFF.

nearly approach that of the collodion than of the cotton fabric (Figs. 8 and 9).

A mantle with a basis of collodion fibre is again coming into favour, particularly in connection with lighting by high-pressure gas. Artificial silk made by the Viscose process is

impregnated in a nitrate solution, the nitrate converted into hydrate by treatment with ammonia, ammonium sulphide, hydrogen peroxide, &c., and the fabric incinerated in the ordinary way.

FIG. 7.—COLLODION AFTER BURNING OFF.

Threads of this material are thin, strong, and capable of heavier impregnation than either cotton or ramie threads. Artificial fibre also

FIG. 8.—RAMIE BEFORE BURNING OFF.

possesses the advantage of uniformity of composition, diameter, and other physical properties, and gives a mantle which is more durable, is a more constant light producer, and does not undergo shrinkage.

VOL. III.—T.

Up to 1900, all the mantles used were of the upright type, supported in the atmospheric burner flame by a central rod of magnesia or an outside iron support from which the mantle was suspended, but owing to the slightly conical shape of the mantle, the maximum light was thrown at an angle a few degrees above the horizontal, whilst the shadow of the fitting was thrown on the surfaces immediately below the burner. In order to overcome this trouble, the idea was introduced by Kent, in 1897, of making an atmospheric burner with a long mixing tube, the end of which was turned downwards and the flame made to burn in an inverted mantle. It was not, however, until after 1900 that the introduction of the present forms of inverted burner and mantle popularised the idea, which has many advantages in districts where the gas is supplied at a pressure of not less than $\frac{20}{100}$ ths, i.e. 2 inches of water pressure.

FIG. 9.—RAMIE AFTER BURNING OFF.

With the inverted mantle, the maximum light is thrown downwards at an angle of 45° below the horizontal, whilst there is no shadow, and the mantle, being fixed to a fire-clay ring which is suspended from lugs on the burner tube, is far less likely to be injured by vibration than is the case with the upright mantle, which needs an anti-vibrator on the burner if used for street lighting where there is heavy traffic, whilst the slight preheating of the gas and air supply, and the fact that the flame is not hurried away from the mantle as in the case of the upright burner, bring the duty of the mantle up to 25 to 30 candles per cub. ft. of gas consumed.

In making the inverted mantle, the same methods are employed as with the upright, except that the bottom of the fabric is sewn up, after impregnating, squeezing, and drying, with a thread of the same impregnated material, and the top of the hose is bound on to the fire-clay supporting ring with asbestos thread before burning off and shaping.

The burners used with the earliest upright incandescent mantles were small Bunsens of the ordinary type, with a tube about 4 inches in length, fitted with a gallery to carry a chimney and a head stamped out of thin sheet metal. This made a very long fitting which proved an objection in many cases where flat-flame or argand burners had been employed, the result being that the burner tube was shortened, and the head carrying the gallery, which fitted over it, was made so that it but slightly increased the length.

Much ingenuity was expended in devising suitable burners for use with the upright mantle, the chief aim being to ensure a hot steady flame of the right shape with thorough admixture of the air and gas before combustion. Some of these burner heads consisted of open circular slots, others of flat gauze discs with a small baffle in the centre, whilst others were provided with gauze domes and steatite or cut metal tops. All these different varieties, however, suffered from the defect of under-aëration of the gas before combustion, so that a chimney was required in order to create an up-draught and to bring a supply of air from outside the mantle in contact with the burning gas on its surface.

If these burners were used without a chimney, the unburnt gas from the inner zone had to travel a short distance from the surface of the mantle through which it was passing before it obtained the additional air necessary for its complete combustion, with the result that the layer of highest temperature was outside the mantle, which was not in consequence raised to the highest degree of incandescence. When a chimney was used, however, the current of air created by it burnt the gas on the surface of the mantle itself, and the best results were obtained. Burners of this class still form the majority of those employed with upright mantles, and a chimney is a necessity in all burners in which less than one-half the total volume of air needed for the complete combustion of the gas is drawn in, and with a 14- or 15-candle power gas, a 6-inch chimney is generally sufficient to supply the necessary air, whilst with a rich gas a longer chimney is required.

A serious trouble with mantle lighting has been the carbonisation of the mantle, which commences with a slight sooty deposit at one spot, and then rapidly grows over the surface of the mantle, reducing the light emitted and soon destroying the mantle.

- When the flame is under-aërated and contains a ratio of less than 2·2 volumes of air to 1 of gas, some methane escapes combustion in the inner zone of the flame, and burns with the carbon monoxide and hydrogen in the outer flame, and it is this which causes the trouble.

On replacing the ordinary tube of a Bunsen burner with one made of platinum, if the ratio of gas and air be so arranged as to give a blue non-luminous flame, on heating the platinum tube the flame becomes luminous, although not to such an extent as would have been obtained from the original gas. If the tube be allowed to cool down, the flame again becomes non-luminous, showing that the luminosity is due to the restoration of heat to the flame and not to any alteration in the composition of the gas.

But with a Bunsen burning with a green inner cone, luminosity cannot be produced by heating the mixture of gas and air. On now taking an ordinary Bunsen with a brass tube, and surrounding the blue non-luminous flame with a platinum gauze cylinder so arranged that the sides of the flame heat it to a high temperature, the top of the flame will become luminous, owing to the platinum superheating the flame gases from the inner cone and causing them to decompose with separation of particles of carbon. The same result is obtained with an ordinary mantle open at the top, and it is to this cause that the deposition of carbon on the mantle is due.

Mantle burners in which regeneration has been attempted have also been tried, but the fact that the air or gas can be heated separately and then utilised to give a very hot flame, does not apply to the mixture of the two to any greater extent than is found in the inverted burner, as, when a mixture of air and gas is heated, oxidation of the gas commences, and the loss of combustible matter due to this cause outweighs the advantages of preheating.

Real improvements in the burners employed for mantle heating started in the early nineties, when Chemin and Bandsept began working at the idea of adding air to the gas in small portions so as to gain a more intimate mixture of the two before combustion, and it was the perfecting of this idea in the Kern burner which gave the best chimneyless burner in use.

In this burner, the gas issues from the usual injector into a suction tube, consisting of two cones united at their summits, which increases the proportion of air drawn in with the gas, and the mixture then passes into an enlarged head, where baffling devices ensure thorough mixing, and the burner top is so constructed that the flame of the burning gas is thrown against the mantle, yielding a higher duty than with an ordinary burner and chimney.

The sharp edge of this burner resulted, however, in the mantles having a comparatively short life, and it is being replaced very largely for public lighting by inverted systems.

The visible duty obtained from the incandescent mantle depends largely upon the pressure at which the gas is supplied, and now that its use has become universal, no gas undertaking should, in their own interest, supply gas to consumers at less than 2 inches ($\frac{24}{100}$) pressure, and when centres of high illuminating value are needed to compete with arc lighting for outside work and large buildings, the light which can be obtained from a mantle can be enormously increased by the use of high-pressure lighting, such as the Keith, Sugg, Selas, and other systems, in which either the gas or air is placed under greater pressure than the ordinary, so that by using what are practically blowpipes, a much larger volume of gas is consumed in a given space, and from 30 to 60 candles light obtained per cubic foot of gas consumed.

The quality of the gas has a certain influence on the light given by the mantle, but not as much as is generally supposed. If an ordinary burner and mantle be tested first with 16-candle gas, then with 15, and finally with 14-candle power gas, it is often found that it gives a better light with the 15 than the 16, and a further

improvement with the 14-candle gas. This, however, is dependent upon the fact that the burner is drawing in less than the necessary amount of air to give the best conditions of combustion in the inner zone, and that the right degree of aëration is being more and more nearly approached with the poorer gas. When care is taken to ensure the correct ratio of air and gas consumed in each case, it is found that for qualities of gas between 14 and 18 candle power, there is a gain of about 3 p.c. in the light emitted by the mantle for each candle-illuminating power in the gas.

Seldom in the industrial history of the world has any one invention wrought such alterations in a great manufacture as has been the case with the incandescent mantle, which, being perfected just at the time when electricity was threatening the supremacy of gas as an illuminant, entirely revolutionised the gas industry.

Before the introduction of the mantle, the usual quality of the gas supplied was what was known as 16-candle power, and the light obtained from it by the consumer was anything from 7 to 8 candles per cub. ft. with regenerative burners, down to less than 1 candle per cub. ft. with small flat-flame burners, whilst with the incandescent mantle from 14 to 60 candles per cub. ft. can be obtained.

LIGHT EMITTED PER CUBIC FOOT OF 16-CANDLE
GAS CONSUMED PER HOUR.

Burners	Candle units

It was also soon found that, in practice, a much poorer gas gave as good or better results with most incandescent mantle burners, and with the general adoption of the mantle, the candle power of the gas supply has been lowered in nearly every large town in England.

At the present time (1921), the normal annual mantle consumption of the world approximates to:

Great Britain . . .	60,000,000
America . . .	80,000,000
Germany . . .	90,000,000
France . . .	20,000,000
Italy . . .	3,000,000
Belgium . . .	5,000,000
Australia and New Zealand . . .	6,000,000
Russia ¹ . . .	3,000,000
India ¹ . . .	2,500,000
Egypt ¹ . . .	1,000,000
Scandinavia ¹ . . .	2,500,000

¹ A large proportion in conjunction with high-pressure oil lamps.

When Welsbach made the first thorium mantles, thorium salts were obtainable only in very small quantities, and from such minerals as thorite and orangite, but with the demand, new sources of supply were found in many directions, notably the immense deposits of monazite discovered in Travancore (S. India) in 1909, and during the last few years, although the amount of thorium nitrate used has more than doubled, there appears no fear of a shortage hampering the mantle industry.

Many theories have been brought forward to explain the wonderful light-giving power of the mixture of 99 p.c. thorium and 1 p.c. ceria, but none of them explains both the facts, i.e. that the maximum light is obtained only in the extreme outer layer of the Bunsen flame, where both air and combustible gases are present, and that it is only with 1 p.c. of ceria in the mixture that it is obtained, a mantle of pure thorium or pure ceria giving practically no light.

The probable explanation is that in the mantle, the thorium, being in a porous condition, is a good non-conductor, and owing to this, to its low specific heat and low power of radiating heat, it can be raised to the temperature of the flame; ceria, on the other hand, has a wonderful power of radiation, as shown by Fery, and has also a catalytic action upon mixtures of combustible gases and oxygen, but its radiation is so great that it cannot be heated in a Bunsen flame to the temperature necessary to give light.

When ceria is added to thorium, the light emitted by the mantle increases until 1 p.c. by weight, or 0.1 p.c. by volume, is present, because the ceria is so insulated by the excess of thorium that it is not only brought up to the temperature of the flame, but by its catalytic power tends to focus the combustion of the extremely attenuated flame gases upon the widely distributed ceria particles, and so raises them to a far higher temperature than the mantle, a temperature, however, which cannot be detected by the thermo-couple, which gives only the average temperature of the mass with which it is in contact, and fails to show the temperature of the 0.1 p.c. of ceria. Addition of more ceria to the mixture causes such a rapid cooling of both mantle and flame by radiation, that the light at once begins to fall; and by the time 10 p.c. of ceria is in the mixture, the mantle gives no more light than a thorium mantle, but a much increased heat radiation.

The analogy between the luminescence of thorium-ceria mixtures when heated (the maximum value being at 1 p.c. ceria, mixtures with 10 p.c. ceria and over being non-luminous), and the phosphorescence of mixtures of pairs of rare earths (say A and B), under the bombardment of cathode rays (where with pure A and more than 20 p.c. B there is no phosphorescence, which, however, reaches a maximum with 0.5 to 1 p.c. of B), is interesting (*see* Urbain, *Ann. Chim. Phys.* 1909, [viii.] 18, 222-376; Brunninghaus, *ibid.* 1910, [viii.] 20, 519-546; 21, 210-283).

The work of Le Chatelier, Nernst, Schmidt, and others, shows that the thorium-ceria mixture gives light rays rich in blue, green, and yellow, but poor in red, so that the proportion of energy radiated as light at the temperature of the mantle is high.

C. S. G.

GAS, OIL. Even before the introduction of coal gas, it had been found that oil could be decomposed at a temperature a little below 1000° with the formation of gas of high illuminating power, and when coal gas had overcome the prejudice existing against it in the early years of its inception, several attempts were made to utilise oil instead of coal for the production of illuminating gas, but with no commercial success, owing to the price of the oil.

As early as 1815 a patent was granted to John Taylor for an apparatus for the decomposition of oils, which is interesting as being of much the same type as those still employed; whilst in 1819 Gordon and Heard took out a patent for compressing oil gas, and it was in the liquid separated during compression of this gas that Faraday discovered and isolated benzene.

After this period, oil gas appears to have been but little used until in 1871, when it began to be employed for the lighting of railway carriages on the Continent in place of oil lamps, and it was from this that the firm of Julius Pintsch built up their system of railway-carriage lighting, which soon spread throughout Europe and to England and America, and at a slightly later date oil gas began to be employed for lighting country houses and small villages where the consumption of coal gas was not sufficiently great to allow the erection of coal-gas works.

It was also largely adopted, in the com-

pressed condition, for the lighting of buoys and for other purposes where the portability of cylinders containing it under compression fitted it for special uses in spite of its cost.

The oils now used for the production of gas are generally the blue or green shale oils, although slightly better results may be obtained from the Russian so-called 'solar distillate,' which is obtained by subjecting the residues of Russian oil, left after the lamp-oil fractions have been driven off, to further distillation.

Such oils begin to decompose with evolution of gas at a little under 500°, and the effect of the temperature of the retort on the products is shown in the following table 1:—

Oil used	Russian 'distillate oil'			
Specific gravity	0.864			
Flash-point	149°F. = 65°C.			
Temperature of retort	500°	700°	900°	1000°
Cubic feet of gas per gallon	12	60	72	84
Percentage of residuals	59.1	22.7	12.7	11.8
Illuminating power, candles per cub. ft. .	54.8	50.7	57.1	42.2
The gas contains, p.c. :				
Unsaturated hydrocarbons	39.13	36.56	36.55	22.04
Saturated hydrocarbons	42.41	49.45	49.45	54.83
Hydrogen	13.58	6.26	11.86	21.54
Acetylene	0.052	0.084	0.38	0.46

On decomposing the oil at 500°, the gas is small in quantity and white in colour, the hydrocarbons being present almost entirely as vapours, a large proportion of which go forward with the gas and condense in the holder, so that the 59 p.c. of residuals condensed in the receiver do not represent the total condensible hydrocarbons.

After condensation of the vapours, the gas amounts only to 12 cub. ft., and contains the saturated and unsaturated hydrocarbons in nearly equal proportion, whilst on examining the tarry residuals it is found that the flash-point is considerably lower than that of the original oil, and also that 15.5 p.c. distils over below 200°, whilst with the original oil only 3.5 comes over below that temperature.

On decomposing the oil at 700°, the yield of gas is increased to 60 cub. ft. per gallon of oil used, and is of a buff colour. In the gas the unsaturated hydrocarbons are 2.5 less in quantity than in the former case, and there are more saturated hydrocarbons. On examining the residuals, the effect of the increase in tempera-

ture is found to be most marked; they have decreased in quantity from 59.1 p.c. to 22.7 p.c. of the original oil decomposed, whilst the flash-point has fallen below the freezing-point, and 36.75 p.c. of the residuals distils below 200°. Nine p.c. of the residuals distil at 123°-125°, whilst 9.5 p.c. distils at a temperature of 140°-150°. At 900° the decomposition of the oil yields a still larger volume of gas, in which the percentage of unsaturated hydrocarbons is the same as before, but there is a large increase in the quantity of saturated hydrocarbons, and a slight increase also in the illuminating value of the gas.

The residuals, at this temperature, fall to 12.7 p.c. of the oil used, and on fractionating them more than 1 p.c. distils at 100°, and 5 p.c. at a little over 110°.

On now raising the temperature to 1000°, another increase takes place in the volume of the gas, 84 cub. ft. being obtained per gallon of oil decomposed, and the illuminating power falls from 57 to 42. On analysing the gas, it is found

¹ Lewes, J. Soc. Chem. Ind. July 30, 1892.

that the percentage of saturated hydrocarbons has slightly increased, whilst the percentage of hydrogen has risen from 11.86 to 21.54; on the other hand, the unsaturated hydrocarbons have fallen from 36.5 to 22 p.c. The gas as it leaves the retort has lost its rich chocolate-brown colour, and has become 'sooty' from separation of carbon, and this, as well as the increase in hydrogen, shows that the temperature has been forced to a point at which some of the hydrocarbons, and mainly the unsaturated hydrocarbons, have been decomposed.

The residuals collected from the gas made at this temperature are of nearly the same volume as those obtained by decomposing the oil at 300°, but differ from them in containing nothing with a lower boiling-point than 140°-150°.

From the results obtained in practical working, 900° has been generally adopted as the best retort temperature to employ, whilst the kind of oil used is generally governed by local conditions. The following table gives the results obtained with various grades of oil:—¹

Name of oil . . .	'Lustre'	Solar distillate	Shale oil	Shale oil

The form of retort and the general apparatus used vary slightly in the processes introduced by Keith, Patterson, Pintsch, and Pope, but a description of the Pintsch plant will suffice to make clear the general principles upon which they all depend.

The retorts are of iron, D-shaped and 10 inches high by 6 feet in length. They rest upon fire-brick, one above the other (Fig. 1), and are connected vertically in pairs. The lid of the upper retort is provided with a siphon pipe, fitted with a funnel at the end into which oil is allowed to flow from an overhead tank, the rate of flow being capable of adjustment by a micrometer cock. The other end of the siphon is continued inside the retort for about 12 inches, and discharges the oil on to a loose thin sheet-iron tray, about 2½ inches deep, which occupies the whole length of the retort, and which is changed and cleaned about once a week. The oil is heated and vaporised in the first retort, and the vapour passes from the further end of the retort downwards into the lower retort, which, being directly over the furnace, is considerably hotter than the upper, the temperature of the retort being a full cherry-red. Here the vapours are 'cracked' and rendered permanently gaseous, and after passage through this retort, they are led by a descension pipe to the hydraulic main. The retorts in the bench are fitted with a test cock, by which the colour

of the gas can be ascertained, as this acts as a guide to the work the retort is doing. The gas should be of a pale straw colour; if darker, it is assumed that the temperature is too high, and either the heat of the furnace is slightly reduced, or a little more oil allowed to flow in. Each pair of 10-inch retorts is capable of making 450 cub. ft. of gas per hour.

The tar from the gas-oil retorts having proved to be of little or no value, from time to time attempts were made to do away with the production of liquid residuals as far as possible in the manufacture of oil gas, so that a deposit of pitch or carbon only should be left in the retort. In 1846 Hilary tried to attain this end by placing condenser tubes above the retort, with a view to returning any liquid that condensed back to the retort, where it would be subjected to further distillation, the ultimate products being gas and carbon only. This idea was improved by W. Young, in his process for the manufacture of oil gas.

In Young's process the oil gas, which is obtained by retorting the oil at a moderate temperature, is washed by the oil which is flowing into the retort, and in this way all condensable vapours are removed, and only permanent gases allowed to pass forward to the purifier. As the oil which has served for the

¹ E. Llewellyn Price, Proc. Incorp. Instit. Gas Eng. 1892.

of railway carriages, are fixed to the under frame of the carriage. These receivers are connected with a governor, which reduces the pressure of the gas passing through it to 1 or 2 inches of water, at which pressure it is led to the lamps in the carriage roof. The gas is burnt at specially made flat-flame nipples, consuming about a foot of gas per hour, and at this rate yields a light of about 8 candles per burner.

Improvements have been made from time to time by the introduction of horizontal flat flames in place of upright flames, by the use of small regenerative burners, and also by increasing the illuminating value of the oil gas by admixture with acetylene, but the greatest advance that has been made is due to the utilisation of oil gas in the incandescent mantle, which was introduced into this country for railway lighting in 1904. Until the inception of the inverted incandescent mantle, its use for such a purpose as railway lighting was not very successful, as the vibration rapidly destroyed the mantle, and the light, being thrown in an upward direction,

FIG. 2.

necessitated the use of reflectors. With the introduction, however, of the inverted mantle, it was found that the suspension of the mantle on its frame, which merely rested on catches forming part of the nozzle of the burner, acted as a satisfactory anti-vibrator, rendering the mantle far less liable to be effected by shock, whilst in the event of an unusually violent jar breaking it, it is still held in position by a wire cage, which keeps it in contact with the flame, and ensures a light until the mantle can be replaced.

The high calorific value of oil gas, which averages 1000 B.Th.U. per cub. ft., or double that of London coal gas, enables it to be burnt in very small atmospheric burners and mantles, so that a consumption of 0.6 cub. ft. per hour gives 24 candles of illumination, thus trebling the efficiency of the lighting, whilst nearly halving the consumption.

Fig. 2 shows the arrangement of the lantern and burner as used for railway-carriage lighting, whilst Figs. 3 and 4 show the general construction of gas buoys and burners showing a flash light.

As already mentioned, when oil gas is compressed into the receivers at a pressure of about 100 lbs., about a gallon of liquid hydro-

FIG. 3.

carbons separates from 1000 cub. ft. of gas, occasioning a fall in illuminating power of about

FIG. 4.

10 candles. This is also observed, but to a smaller extent, in compressing a rich coal gas. This liquid contains as its main constituents

benzene, toluene and hydrocarbons of the ethylene (C_nH_{2n}) group up to normal heptylene, together with some naphthenes and very small quantities of other benzenoid hydrocarbons.

The tar formed during the ordinary process of manufacturing oil gas amounts to about 5 gallons for each 1009 cubic feet of gas. But little use has been found for it. It contains only very small quantities of phenols or basic constituents. In most cases, it is burnt beneath the retorts. One of the chief points in Young's process of making oil gas was that the tar is entirely got rid of, and a very dense and valuable form of carbon obtained instead. V. B. L.

GAS, PRODUCER, v. FUEL AND GAS, WATER.

GAS WARFARE. The first attempt to use poison gas in modern warfare was made by the Germans in April, 1915, when they liberated large quantities of *chlorine* from cylinders of the liquefied gas in the Ypres salient. An efficient protection against it consisted of pads of cotton wool or a flannel bag soaked in solutions of sodium thiosulphate and carbonate, contained in a helmet fitted with a mica window. Subsequently, in December, 1915, the Germans made use of *phosgene* gas, for which sodium phenate, mixed with hexamethylenetetramine, contained in a box respirator, was found to be a suitable protection. 'Activated' charcoal, or charcoal and alkaline permanganate, have also been employed. Attacks by gas clouds

were soon replaced by 'gas shells'—that is, by shells containing toxic materials which could be vapourised or 'atomised' by the explosion. The first to be used was the so-called 'tear' or 'lachrymator' shell containing xylol or benzyl bromide, afterwards replaced by the highly-poisonous *trichloromethyl chloroformate* $ClCOOCCl_3$; by the 'mustard gas,' *dichloro-diethyl sulphide* $(CH_2ClCH_2)_2S$, which has no immediate effect upon the eyes beyond a slight irritation, but produces extremely painful after-effects; the eyes swell and blister, the nose discharges freely, and coughing and vomiting occur. Direct contact with the skin also produces blistering, and the concentrated vapour penetrates clothing.

In addition to these substances, the Germans at various times made use of *phenyl carballyamine chloride*, a 'lachrymator'; *diphenyl-chloro-arsine*, a 'sneezing gas'; *allyl iso-thiocyanate*, *brominated methyl-ethyl-ketone*, *dibromo-ketone*, *chloropicrin*, *dichloro-methyl-ether*, and *sulphur trioxide*. In hand-grenades they employed *bromo-acetone*, *bromine*, *chloro-acetone*, *chloro-sulphonic acid*, *dimethyl sulphate*, and *methyl-chloro-sulphonate* (Auld, J. Wash. Acad. Sci. 1918, 8, 45; J. Soc. Chem. Ind. 1918, 127, B).

The following table, from Moureu's *La Chimie et La Guerre* (Masson et Cie, Paris), gives a list of various toxic substances used by the Germans, with their physiological properties, and the dates of their first employment.

Date when first used on the field of battle	Name of substance	Chemical formula	Physiological action
1915			
April	Chlorine (gas)	Cl_2	Suffocating
June	Bromine (liquid)	Br_2	Suffocating
June	Benzylbromide (liquid)	$C_6H_5-CH_2Br$	Lachrymatory
July	Bromoacetone (liquid)	$CH_3-CO-CH_2Br$	Suffocating, lachrymatory
August	Methyl chloro - sulphonote (liquid)	$SO_2 \begin{smallmatrix} \diagup Cl \\ \diagdown OCH_3 \end{smallmatrix}$	Suffocating
August	Chloromethyl chloroformate (liquid)	$Cl-COOCH_2Cl$	Suffocating
August	Bromomethyl ethylacetone (liquid)	$CH_3-C'O-CHBr-CH_3$	Suffocating, lachrymatory
1916			
July	Trichloromethyl chloroformate (liquid)	$Cl-COOCCl_2$	Suffocating
December	Phosgene (gas)	$COCl_2$	Suffocating
1917			
May	Chloropicrin (liquid)	CCl_3NO_2	Suffocating, lachrymatory
July	"Mustard gas" (ypérite) (liquid)	$S \begin{smallmatrix} \diagup CH_2CH_2Cl \\ \diagdown CH_2CH_2Cl \end{smallmatrix}$	Suffocating, lachrymatory, vesicant
September	Diphenylchloro-arsine (solid)	$(C_6H_5)_2AsCl$	} Suffocating, sternutatory
September	Phenyldichloro-arsine (liquid)	$(C_6H_5)_2AsCl_2$

1918			
April	Ethylarsine dichloride (liquid)	$C_2H_5AsCl_2$	Toxic, sternutatory
April	Ethylarsine dibromide (liquid)	$C_2H_5AsBr_2$	Toxic, sternutatory
June	Diphenylarsine cyanide (solid)	$(C_6H_5)_2AsCN$	Sternutatory
September	N-Ethylcarbazol (solid)	$C_6H_4-C_6H_4$ $\diagup \quad \diagdown$ NC_2H_5	Sternutatory

GAS, WATER, is the term applied to the impure gaseous mixture of hydrogen and oxides of carbon formed when steam is passed through incandescent carbon, an action which was probably discovered by Fontana in the eighteenth century, and was undoubtedly known to Lavoisier who, in 1793, noticed that when steam was passed over incandescent carbon, hydrogen and carbon monoxide were produced.

The first attempt to utilise water gas on a commercial scale dates back to 1824, when Ibbotson sought to increase the volume of gas distilled from his retorts by injecting steam into the red-hot coke remaining at the end of the period of carbonisation. This idea has been revived on many occasions, but so long as the horizontal retort remained in general use for the purpose of distilling coal, the process was found to be impracticable. With the introduction of the vertical retort, however, the system of 'steaming' was again experimented with, and has now been fairly generally adopted with a good deal of success. The original practice of admitting the steam to the retort when the greater part of the coal gas has been evolved has given way to the more effective method of admitting a restricted quantity during the whole period of distillation.

The extent of the water-gas industry in this country is shown by the statistics issued by the Board of Trade, which indicate that annually approximately 24,000 million cubic feet are generated. The number of gas works producing the gas is 148, of which 101 are companies, and 47 undertakings belonging to local authorities. The world's output of water gas is in the neighbourhood of 120 million cubic feet per annum.

When steam is passed through a mass of heated carbonaceous material, the composition of the gas formed will vary with the temperature, and, to a less extent, with other factors, such as the rate of flow and quantity of steam.

It is found by experiment that at temperatures about 600° the reaction is mainly :

the quantity of carbon monoxide being small, whilst when 1000° is passed, the reaction more nearly approaches $\text{C} + \text{H}_2\text{O} = \text{CO} + \text{H}_2$.

The products obtained vary with the temperature of the carbon in the following manner :

Temperature of carbon	Percentage composition of resulting gas		
	Hydrogen	Carbon dioxide	Carbon monoxide
600°	66	30	4
700°	65	29	6
800°	62	23	15
900°	54	7	39
1000°	50	2	48

The value of water gas as a fuel largely depends on keeping the percentage of carbon dioxide and nitrogen as low as possible, and it is clear, therefore, that the temperature of the carbon in whatever form it is used, must be kept at or above 1000°, and that a fall in temperature below 900° causes a large increase in the carbon dioxide.

It is also important, in order to keep down the percentage of carbon dioxide, to avoid any excess of steam over the quantity that can be

decomposed by the red-hot carbon, as at temperatures above 900° some of the carbon monoxide is oxidised by steam to carbon dioxide, according to the equation :

a reaction, which, being reversible, is never completed, but which causes a serious increase in the volume of carbon dioxide in the water gas if an excess of steam be present.

If, however, the temperature in the generator be maintained as high as possible throughout the gas-making 'run,' and if the volume of steam is carefully adjusted, in practice a water gas is obtained with approximately the following composition :—

Hydrogen	52.0 p.c.
Carbon monoxide	38.5 by volume
Carbon dioxide	4.5 "
Methane	1.0 "
Nitrogen	4.0 "

Theoretically, methane should be absent, but owing to the impossibility of obtaining coke entirely free from hydrocarbon bases, a small proportion is always present. It is possible, too, that catalytic action may account for a small quantity of this gas. In addition, sulphuretted hydrogen is evolved to the extent of about 120 grains per 100 cubic feet (0.02 p.c. by volume), while other gaseous sulphur compounds, chiefly carbon disulphide, are present in quantities amounting to from 10 to 15 grains per 100 cubic feet. These impurities, however, are largely dependent upon the proportion of sulphur in the original coke employed.

The systems which have been introduced for the purpose of manufacturing water gas may be classified under the following headings :—

- (1) The Continuous System.
- (2) The Intermittent System.
- (3) The Neat-Oxygen System.
- (4) Complete gasification of coal and coke in one operation, whereby a mixture of coal gas and water gas is obtained.

Early attempts to manufacture water gas by a continuous process in which steam was passed through coke contained in an externally heated generator failed for the reason that to make water gas successfully the coke must be maintained in a state of incandescence. Since the decomposition of the steam absorbs more heat than is emitted in the formation of the water gas, the coke charge cools more rapidly than the heat can be imparted to it through the fire-clay walls of the generator. Accordingly, when the temperature falls, the carbon dioxide is formed in such quantities as to render the process uneconomical.

In 1849 Gillard introduced a process in which he adopted the entirely new idea of raising the temperature of the carbonaceous fuel by blowing air on to it instead of heating it in a retort fired from without; having raised the fuel to incandescence by its own partial combustion, he then shut off the air supply and passed steam through the fuel, until the temperature was so reduced as to necessitate a fresh blowing up by air. It is this principle of 'blow and run' which has since been employed in all the water-gas processes which have had any claims to success.

After Gillard's time, numerous other attempts were made to introduce water gas, but nothing of importance was done until 1875, when Lowe and Tésié du Motay, in America, inaugurated the present carburetted water-gas systems.

A scientific, and probably a not impracticable, system is that embodying the use of neat oxygen. The process is operated on continuous lines, and results in a gas practically free from nitrogen, but containing 60-70 p.c. of carbon monoxide. Steam is admitted to the base of the generator in the ordinary manner; and along with it is passed a stream of pure oxygen. In this way, whilst steam is combining with a portion of the carbon to form water gas, the heat lost by the endothermic nature of the reactions is replaced by the exothermic combination of the oxygen with part of the carbon. If steam and oxygen are regulated in accordance with theoretical requirements the process will proceed with little trouble. R. P. Pictet has recently proposed to employ such a mixture, which is admitted through a tube of refractory material into the centre of the charge in the generator in such proportions that the temperature of the charge is maintained at about 1600°. Practically pure water gas is drawn off and is scrubbed and stored in the usual way.

The fact that water gas contains over 90 p.c. of combustible gases, whilst the ordinary producer gas contains only 30 p.c., soon attracted the attention of some European engineering firms, who required an intense heat for welding purposes, and in the early eighties several plants were installed in Europe for welding tubular boilers and other work of the same character.

From a historical point of view, it is interesting to note that the generator then employed consisted of a cupola furnace, about 20 feet in height and 7 feet in diameter, lined with fire-brick, with a constriction a short distance above the hearth, the fire-brick being protected at this point by a water-cooled ring. An air blast was admitted below the water-cooled ring, and in about 10 minutes the ignited fuel was raised to incandescence. The air blast was then cut off, steam was admitted above the top of the fuel, and passing down through it, became converted into water gas, which escaped by the same opening as that through which the air blast was admitted, this being opened and closed by means of a water-cooled slide valve of such construction that it was impossible for any explosive mixture of water gas and air to be formed. The water gas passed on to purifiers, which removed sulphuretted hydrogen and carbon dioxide, and the gas was then stored in gas holders. The fuel was fed into the generator at the top, which was closed by a cone; the whole of the steam, air, and water-gas pipes being governed by an arrangement of lever valves which rendered any explosive mixture impossible. This form of apparatus was installed at the Leeds Forge in 1887.

The impure mixture of hydrogen and carbon monoxide made by such processes burns with a blue non-luminous flame, and is technically known as 'blue water gas,' to distinguish it from the mixture of water gas and oil gas which, introduced in America in 1875, had

achieved a great success, and was largely used as a substitute for coal gas under the name of 'carburetted water gas.'

The increase in the price of cannel coal led English gas managers, in 1889, to turn their attention to the American practice of mixing carburetted water gas with the coal gas in order to raise its illuminating power. The process was adopted by the Gas Light and Coke Company, and is now used as an auxiliary to coal gas in nearly every large gas works in Great Britain.

The reasons that prevented the rapid progress of the 'blue water gas,' except for special purposes, are largely to be found in its poisonous properties and the uneconomic conditions of its manufacture at this period.

It has been shown that in the formation of water gas the perfect decomposition would be represented by the equation:

A unit weight of hydrogen in burning to water gives out 34,500 calories, and as 2 units burn to form 18 of water, the heat evolved during its production will be $34,500 \times 2 = 69,000$ calories: when the 18 units weight of water are again decomposed, this amount of heat will again be absorbed. In this case, however, the water has had to be converted into steam, and so contains an amount of heat equal to the latent heat of steam plus the heat used to raise it to the boiling-point. The latent heat of steam is 536 calories per unit weight of water, and to allow for the heat necessary to bring it up to the boiling-point, this is generally called 600. In the present case, we are dealing with 18 units of water as steam, so the heat present in it will be $600 \times 18 = 10,800$ calories, and the extra heat used up in decomposing the 18 units weight of water will be $69,000 - 10,800 = 58,200$ calories.

The water having been decomposed, its oxygen is available to burn the 12 units of carbon to carbon monoxide, and as in doing this one unit of carbon emits 2489 calories, the 12 will yield $2489 \times 12 = 29,868$ calories. If this be deducted from the previous heat deficit, the result is:

$$\begin{array}{r} -58,200 \\ +29,868 \\ \hline -28,332 \end{array}$$

or a shortage of 28,332 for the 12 units of carbon, or 2361 for one. If the units be taken as lbs., 1 lb. of carbon, in decomposing 1.5 lbs. of steam to hydrogen and carbon monoxide, uses up 2361 calories. In order to obtain this amount of heat, 1 lb. of carbon may be burnt to carbon monoxide by an air blast, so obtaining 2489 calories, so that, theoretically, it should be possible to get the required balance of heat by burning half the fuel by an air blast to producer gas, and by a steam jet converting the remaining half to water gas.

In practice, however, the loss of heat taking place from the escape of the hot producer gas, radiation, &c., necessitates the air blast being continued until a far higher proportion of the carbon in the fuel has been consumed, and by this process, instead of 50 p.c. of the carbon of the fuel being converted into water gas, the actual amount varies in practice from 25 to 30

p.c. In other words, from three to four times as much coke is consumed during the 'blow' as during the gas-making 'run.'

In making water gas by such processes as that which was employed at the Leeds Forge, fuel in the cupola is first raised to incandescence by the combustion of a portion of it under the influence of an air blast, an operation giving as a gaseous product a producer gas of the composition:

Nitrogen	. . .	64.5
Carbon monoxide	. . .	29.0
Carbon dioxide	. . .	4.0
Hydrogen	. . .	2.5

A thousand cubic feet of water gas contain, of combustible constituents:—

Hydrogen	. . .	2.75 lbs.
Carbon monoxide	. . .	30.00 „

and the thermal value will be represented by:

$$(2.75 \times 34,500) + (30 \times 2435) = 167,925 \text{ calories}$$

The thermal value of the 60 lbs. of carbon, however, used in making the water gas would be:

$$8137 \times 60 = 488,220 \text{ calories}$$

In other words, the water gas formed has only just about 30 p.c. of the heating value of the carbon from which it has been formed, and this loss of 70 p.c. of the calorific value rendered the use of water gas as made by the old European process impossible, save for special purposes.

When, however, the producer gas can be at once led away and burnt whilst hot for any purpose, another 223,328 thermal units will be produced, bringing the total calorific value of the two gases up to nearly 80 p.c. of the value of the carbon used in generating them.

If these conditions could have been satisfied in the early days there is no doubt that water gas would long ago have been highly successful, but inasmuch as the producer gas is four times greater in volume than the water gas made, and as the gases are produced intermittently and not continuously, the difficulty of utilising both was almost insurmountable, as, if storage had been provided for the producer gas, the gas holder room required would have been enormous, whilst allowing it to cool down would have rendered it hardly worth burning. In some few of the later installations, the producer gas has been successfully used in firing boilers and other work of the same character, and in this way the efficiency of the manufacture of 'blue' gas has been greatly increased.

When the manufacture of carburetted water gas was first successfully carried out by Lowe and Tessié du Motay, it became at once apparent that the producer gas, the loss of which had crippled all water-gas processes, could be utilised in raising chambers filled with chequer brickwork to the high temperature needed to decompose the oils, and so furnish the oil gas which, when mixed with the water gas, rendered the latter luminous. It was, by thus making the carburetted water-gas plant a perfect heat machine, that its greatest success was achieved, as in raising the fuel to incandescence the producer gas, with all its heat in it, was at once burnt with a fresh supply of air in the super-heating chambers, the practical loss

of heat taking place throughout the whole apparatus being reduced to a minimum.

In all attempts to make water gas prior to 1896, the incandescence of the fuel was always attained by using the air blast with so deep a bed of fuel that the carbon monoxide and residual nitrogen of the air formed the chief gaseous products. It must be remembered that when 1 lb. of carbon combines with oxygen to form carbon monoxide, as when forming producer gas, only 2489 calories are developed, whilst if air be present in sufficient quantity to burn the carbon completely to carbon dioxide, the amount of heat which is evolved is 3.27 times as great, i.e. 1 lb. of carbon gives out 8137 calories.

A process was devised by Mr. Carl Dellwik, in which this fact was utilised by adjusting the air supply, and by keeping the level of the incandescent fuel in the generator at a nearly constant height.

Under these conditions Dellwik claimed that producer gas ceased to exist as a by-product, so that the gases resulting from the 'blow' consisted merely of incombustible products, with a corresponding saving in fuel. It may be said, however, that although in practice the quantity of carbon monoxide present in the 'blow' gases was certainly reduced in Dellwik's plant, it was never possible to obtain a gas entirely free from it. The chief advantage of this type of apparatus was the proportionate increase obtained in the gas-making period owing to the reduction effected in the period of blowing.

In the old 'European' process, it was necessary to blow for nearly 10 minutes to bring the fuel bed up to the right temperature, whilst the period during which the incandescence was sufficiently great to decompose the volume of steam used, limited steaming to 4 or 5 minutes, whereas in the Dellwik process, the period of blowing rarely exceeds 2 minutes, and it is possible to steam for about 7 minutes, much depending upon the nature and condition of the fuel.

The Dellwik generator consists of a sheet-iron shell, lined with fire-brick, which contains the fuel—coke; below the grate level is the valve for the air blast, whilst steam can be admitted either at the top or bottom of the generator. The water gas is provided with two outlets, one at the top and the other at the bottom, connected by a three-way valve. A central stack valve, geared with the air-blast valve, allows the products of the 'blow' to pass away, and through it the fuel is fed into the generator. In practice, the generator is filled to the proper level with coke, which is blown up to incandescence with the air blast, the products passing off through the central stack. When the right temperature is attained, the air is cut off, the central valve being simultaneously closed, and steam is admitted at a carefully regulated rate, which, passing either up or downwards through the coke, is decomposed into water gas. The gas escapes at either of its outlets into a scrubber, where it meets with a stream of water trickling over coke; this cleanses and washes the gas, which is then stored in a holder. When the temperature of the fuel has fallen to a point at which carbon

dioxide is formed in excess, the steam is shut off, and the fuel again raised to bright incandescence by the air blast.

Another water gas process, chiefly employed for the manufacture of 'blue' gas, is that due to Kramers and Aarts. This process originated on the Continent, but several installations are now in operation in this country. The novelty in this apparatus consists in having two generators with a regenerating chamber filled with chequer brickwork behind them, so that when the coke in the generators is being raised to incandescence by the air blast, any carbon monoxide that it may contain can be burnt by an extra air supply in the regenerating chamber to heat the chequer work, so that the products escaping up the chimney consist of the products of complete combustion only, and the heat which they contain is further utilised to raise the temperature of the extra air required for the combustion in the generator. When the right temperature of the fuel in the generators has been attained, steam is blown in at the bottom of the first generator, the steam being in excess; the resulting mixture of hydrogen, carbon dioxide, carbon monoxide, and steam is then passed through the regenerator, where it is highly heated, and traverses the second generator, entering at the top and passing downwards through the coke. By this arrangement, the carbon dioxide produced by the excess of steam in the first generator becomes reduced to carbon monoxide, whilst any excess of steam is also decomposed into hydrogen. Inasmuch as in this generator the hottest portion of the fuel will be at the bottom, where the air blast has come more thoroughly in contact with it, the gases finally leave the mass of fuel at the point of highest temperature.

It is well known that when steam is forced in a contrary direction to that in which the air blast has been driven through the generator, the proportion of carbon dioxide is always less than when the steam passes in the same direction as the air blast, and this principle has been used in many forms of generator.

The alterations that have taken place during the last few years in the manufacture of water gas have practically doubled the production of gas per unit weight of fuel used in the generator. The result of several years' practical working at the Leeds Forge with the old 'European' generator, in which during the 'blow' producer gas was formed, gave as an average 34,000 cubic feet of water gas per ton of coke in the generator, but when this was replaced by the Dellwik generator, it was found that the gas coke of reasonable quality and not containing more than 8 p.c. of ash, the yields rose to over 65,000 cubic feet per ton, and under special conditions as much as 70,000 cubic feet could be made.

Gas coke is the fuel most often employed in this country in the generator, and, for effective working, attention should be paid to the size of the coke used. Small sizes can be used only in the smallest generators, and if the coke is too much crushed or contains dust, the dust chokes the air spaces between the pieces of coke and forces the blast and steam to form channels, so lessening the surface of the incandescent fuel exposed to the rapidly flowing

gases. At the same time, the coke must not be too large, as that again reduces the surface exposed per cubic foot of generator space. If it is possible to select the size of coke for any ordinary-sized generator, coke which will not pass through a 3-inch mesh, but will pass through a 5-inch, will give an exposure of about 10 square feet per cubic foot of generator space, whilst if the size be reduced so that it will not pass through a $1\frac{1}{2}$ mesh, but will pass through a $2\frac{1}{8}$, the surface of fuel exposed is nearly doubled, and a mixture of these two sizes will, with any ordinary generator, give the best results.

The consumption of steam, as found in practice, for the manufacture of water gas, usually amounts to from 27 to 30 lbs. per 1000 cubic feet of gas generated. As regards the quantity of coke used in the generator this varies in accordance with the type of plant in use. With apparatus of the Lowe type a figure of 35 lbs. of coke per 1000 cubic feet of gas is probably the most favourable, but some reduction on this may be expected in those cases where the pan coke is extracted from the generator refuse, and deducted from the total weight of coke shot into the generator. Plants designed essentially for the production of 'blue' gas are generally able to economise in the direction of fuel, and figures so low as 25 lbs. of coke per 1000 cubic feet have been obtained. These figures, as in the case of that given for the Lowe plant, are exclusive of the fuel required in the boilers for steam raising. The steam-raising plant will, with the mixture of breeze and coke usually employed on gas works, require an additional 12 to 15 lbs. of fuel per 1000 cubic feet of gas made.

The cost of manufacturing water gas must, of course, largely depend upon the prevailing value of the raw materials employed, and more especially (in the case of the carburetted gas) upon the cost of the oil utilised. The oil, in fact, in normal times, may represent from 50 to 65 p.c. of the total cost, and for this reason it will be appreciated that the manufacture of 'blue' gas is a very much less costly undertaking than is the case with a carburetted gas. The conditions brought about by the European war were responsible for drastic changes in the degree of carburisation which was possible, for whereas, just prior to the outbreak of hostilities, the oil could be obtained for little more than 2d. per gallon, it rose, after $3\frac{1}{2}$ years of war, to nearly 1s. 6d. per gallon. In fact, its scarcity, owing to the shipping position, was such that gas companies throughout the country were rationed in the way of supplies.

The cost of manufacturing carburetted water rose during the war to nearly 2s. per 1000 cubic feet, in spite of a reduction in carburisation amounting to 50 p.c. That price, however, was largely artificial, and cannot be taken as indicative of normal expenditure. For this reason the analysis of costs prevailing just prior to the war is given on p. 365.

The cost of 'blue' water gas will be practically in agreement with the above after the charges for oil have been deducted, while, so far as residuals are concerned, there will be no revenue from tar. On this basis it will be seen that 'blue' gas costs approximately 8·0d. per 1000 cubic feet. As regards capital

COST OF MANUFACTURE 14 CANDLE-POWER GAS

Oil, 2 galls. per 1000 cub. ft. at 4d.	8d. per 1000 cub. ft.	
Coke, for generators	3.5d.	„ „
„ for steam raising	1.5d.	„ „
Wages	1.5d.	„ „
Wear and tear, including labour and materials	1.0d.	„ „
Water	0.05d.	„ „
Total	15.55d.	
Less residuals :		
Tar	0.5d.	
Pan Coke	0.07d.	
Sulphur	0.03d.	0.60d.
Net cost	14.95d.	

outlay much, as is also the case with the cost of manufacture, depends upon the size of the unit, but approximately a complete plant of the Lowe type, including housing, boilers, exhausters, purifiers, relief holder, &c., entailed in pre-war times an outlay of from £20 to £30 per 1000 cubic feet capacity per day.

In the original plants employed in the manufacture of carburetted water gas it was usual to spray the oil direct on to the fuel in which it was generated. This procedure, however, proved decidedly wasteful, with the result that a separate vessel was soon introduced for the purposes of carburation. The results obtained from the carburetting medium will largely depend upon the manner in which the vessel is operated and maintained, whilst the temperature is a factor of considerable importance. The main consideration to bear in mind is that the heat must be sufficient to crack up the oil into a vapour which will, as far as possible, remain as a permanent gas, but the temperature must not be so great as to cause degradation, such as gives rise to overcracking and the deposition of free carbon. For high results in the direction of 'candles per gallon' the American oil, as now almost universally used, is preferable, decomposed at the following temperatures :

Carburettor—from 1350° to 1400° Fahr.
Superheater—from 1400° to 1450° Fahr.

The oil spray is a matter of importance, and thorough atomisation should be aimed at. For this reason it is preferable to inject the oil into the carburettor at a pressure of from 80 to 100 lbs. per square inch. The figure of 'candles per gallon' is arrived at by dividing the candle-power of the gas by the number of gallons of oil used per 1000 cubic feet of gas made. In practice the result varies between 7 and 8 candles per gallon. The amount of gas usually yielded per gallon of American gas oil varies from 70 to 90 cubic feet.

With the exception of the diluents nitrogen and carbon dioxide, 'straight or blue' gas consists almost solely of hydrogen and carbon monoxide. A small percentage of methane is usually, but not necessarily, present. The final composition of carburetted water gas depends essentially upon the proportion of oil used in its manufacture. Under any circumstances, its constituents differ materially from those of coal gas of the same lighting and

heating quality. The following table gives a comparison between the compositions of coal gas and the two types of water gas :—

	Coal Gas	Carburetted Water Gas	'Blue' Water Gas
	P.c.	P.c.	P.c.
Hydrogen	49	37.0	52.0
Carbon monoxide	9	35.0	38.0
Carbon dioxide	3.5	4.5	4.5
Methane	27.0	11.0	1.0
Unsaturated hydrocarbons	4.0	8.0	nil.
Nitrogen	7.5	4.5	4.5
Candle power	14.0	14.0	nil.
Calorific power : gross, B.Th.U. per cubic foot	550.0	535.0	300.0

The impurities in water gas consist of sulphuretted hydrogen and carbon disulphide, whereas the gas is invariably almost entirely free from ammonia. The proportions in which the impurities are present are approximately as follows :—

Sulphuretted hydrogen, 110–120 grains per 100 cubic feet of gas.

Other sulphur compounds, 10–15 grains per 100 cubic feet of gas.

The specific gravity of water gas is higher than that of coal gas, the gravity of the carburetted gas being in the neighbourhood of 0.65 as against an average figure of 0.47 for coal gas.

The average composition of the 'blow' gases issuing from the generator when the fuel bed is moderately deep is as follows :—

Carbon monoxide	17 p.c. by volume
Carbon dioxide	10 „ „
Nitrogen	73 „ „

Traces of hydrogen and methane may also be found.

Working with a fuel bed 6 feet 6 inches in depth with an ordinary Lowe type plant the following results have been found :—

'BLOW' GASES.

	CO ₂	CO
End of 1st minute	18.6 p.c.	2.9 p.c.
„ 2nd „	14.6 „	9.4 „
„ 3rd „	12.0 „	16.4 „
„ 4th „	7.6 „	19.8 „

From the above it will be seen that the quality of the producer gas is gradually undergoing improvement as the 'blow' proceeds and the fire becomes hotter. In modern plants, the blast fan driven by a reciprocating engine has been almost entirely superseded by the steam turbine, or, in a few instances, by electric motors. When a turbine is employed its speed is governed down in a ratio of about 10 to 1 so as to give a fan a speed of about 2000 revolutions per minute. The ordinary open type of fan is not a pressure-raising device, and merely propels a current of air at 20 inches water gauge through spaces which are open to it. Thus, it is customary to keep the fan running continuously, and not to shut it down during the period of steaming. As a general rule, it may be taken that the quantity of air required for the blast should not exceed from 2000 to 2500 cubic feet per 1000 cubic feet of gas made.

Thus, with a medium-sized plant, making 8000 cubic feet during a five-minutes' run, the total air passed should lie between 4000 and 5000 cubic feet per minute. Clinkering on water-gas plants must be carried out at frequent intervals, for if once the mass is permitted to accumulate it will gradually arch over in the generator until the latter is almost completely choked. With the Lowe plants it is advisable to perform the operation at intervals of 4 hours, although in cases where a good quality coke is procurable the period may be prolonged to 6 hours.

During recent years there has been some tendency towards the modification of water-gas plant, with the result that in some instances apparatus of a novel character is to be found at work. One such instance is the plant for the production of what is technically known as 'methane-hydrogen' gas, a semi-water gas enriched by means of coal gas tar. One of the most interesting plants, however, which has been erected at a number of gasworks in this country is that which is designed to gasify completely both coal and coke in a single operation. The system was originally suggested by Dr. Strache of Vienna, and has been developed in this country on lines similar to the German process. Coal is charged into the upper portion of the generator which in reality conforms to a vertical retort. This coal gradually works its way down the retort, being carbonised meanwhile by a stream of hot water gas issuing from the generator situated at the base of the vessel. The coal should be reduced to the condition of ordinary coke by the time it has passed two-thirds of the way down the retort, and it then drops into the water-gas generator. Thus, during the 'run' water gas is being evolved from the coke and coal gas from the coal, the two gases intermixing and passing out at the top of the generator. In this way, by the complete gasification of both coal and coke, about 60,000 cubic feet of gas having a gross calorific power of about 330 B.Th.U. per cubic foot may be obtained from a ton of coal.

In addition to being used as an auxiliary to coal gas, blue water gas is applied, with very satisfactory results, to the welding of plates and heating of furnaces and forges; this method has proved of great practical advantage in welding tubes for gas, water, and steam mains, for boiler work, and also for melting steel. Tests conducted by the Admiralty show the strength of a 'blue' gas weld to be equal to that of the plate. Having a very much higher calorific power than producer or suction gas, 'blue' water gas may be used for driving gas-engines, the consumption being about 35 cubic feet per B.H.P. hour. The consumption of ordinary suction gas is about 80 cubic feet per B.H.P. hour. No water gas, however, is entirely satisfactory when used for power, for the large proportion of hydrogen prevents high compression in the cylinder of the engine.

By far the most important property of blue gas is its exceedingly high flame temperature; and Dr. Roessler has found that by admixture with heated air a temperature considerably above the melting-point of platinum may be easily obtained. Under general conditions, however, the temperature of the hottest part

of the flame is about 2800°–3000°F. It is owing to this property that blue gas is applicable to such processes as welding, forging, and heating furnaces.

In all processes of the above kind, there is no necessity to purify the gas from sulphuretted hydrogen—merely an ordinary water-scrubber is used. It is, in fact, an advantage to leave the gas unpurified, for it then has a distinct smell, and any escape may be quickly perceived. Thus one of the greatest drawbacks to blue gas—its freedom from smell—is more or less overcome. It will be remembered that in Germany it has, in some cases, been thought advisable to impart a distinct odour to the gas, by passing it through a heavy hydrocarbon oil, such as mercaptan.

A process for which water gas may be employed, and one which will probably be largely developed in the future, is that of producing hydrogen. This is done by liquefying or freezing out all the other constituents—the hydrogen, which, of course, liquefies at a much lower temperature, being left behind, while a more modern method relies on catalytic reaction, by means of which the whole of the carbon monoxide is converted to carbon dioxide. The CO₂ is then readily removed by means of lime or washing with water under pressure.

Cement manufacturers make use of water gas, which is introduced into the revolving kiln for the finishing-off process, and the gas finds its way into the brick-making industry.

GASEOUS FUEL *v.* FUEL.

GASES, BLAST FURNACE, *v.* FUEL.

GASTROSAN. Trade name for bismuth bisalicylate.

GAULTHERIA OIL *v.* OILS, ESSENTIAL.

GAULTHERIASALOL. Trade name for methyl salicylosalicylate.

GAULTHERIN *v.* GLUCOSIDES.

GBLITOL. *Sodium hydrosulphite.* Used as a disinfectant.

GEDDA GUM *v.* GUMS.

GEISSOSPERMINE *v.* PEREIRO BARK.

GELATIN. Gelatin, the purest form of glue (*q.v.*), may be obtained by the action of hot water or of water in presence of dilute acids, on intercellular connective tissue such as the skin, tendons, muscles, &c. Hoofs, bones, intestines, bladders, fishbones, &c., are also made use of for preparing crude gelatin.

According to the process employed by Nelson, the parings, &c., of skins are scored on their surface, and are digested in a dilute soda lye for 10 days. They are then digested at 70°F. in an air-tight, cement-lined vat, and are washed with cold water in a revolving cylinder, and are bleached by means of sulphurous acid gas. After being freed from moisture by pressure, they are digested with water in earthen vessels enclosed in steam chests, and the resultant solution is strained at 100°–120°F. It is then solidified in a thin layer on a marble slab, and is washed free from acid, redissolved at the lowest possible temperature, and dried in thin sheets on nets. According to the process employed by Cox at Gorgie, near Edinburgh, the hides, of which the shoulders and cheeks are preferred, are washed, cut up and pulped by special machinery. The pulp is pressed

between rollers, and is mixed with water and heated from 150° to 212°F. A little cow's blood is added to the gelatin solution thus produced, at a temperature not exceeding 170°F., and the solution is further heated, the scum produced by coagulation of the blood albumen being skimmed off. The pure solution remaining is run off and solidified. As prolonged heating impairs the gelatinising power of gelatin, it is preferably dried *in vacuo*.

Several other processes, not differing widely from the above, are also employed. A mixture of vegetable and animal charcoal is sometimes used for purifying dark solutions. Gelatin may also be extracted from bones (which yield one-third of their weight) by causing water to trickle over crushed bones, through which steam is constantly passing (*cf.* GLUE).

Isinglass, the dried swimming bladder of fish, usually contains from 86 to 93 p.c. of gelatin. Russian isinglass is prepared by cutting open and washing the bladder and exposing it to the air with the delicate silvery inner membrane turned upwards. This membrane is stripped off, kneaded in damp cloths and dried. According to Martin, the bladders are first cleansed from blood in hot water, and are cut open and exposed as above, the inner membrane being finally removed by beating and rubbing.

The varieties of isinglass are known by special names dependent on the place of production and their appearance. The Russian varieties are obtained from the sturgeon; Brazilian (sometimes known as Cayenne) from the *Silurus Parkerii*; Manila and East Indian from an uncertain source. The bladders of cod, hake, and other fish are also employed. *Lump*, *pipe*, and *purse* isinglass are obtained from the unopened bladder, and *leaf* and *honeycomb* from the cut and opened bladder. Long or short *staple* and *book* and *ribbon* isinglass are respectively twisted, folded in packages, and rolled out.

Pure gelatin is an amorphous, brittle, transparent, tasteless, inodorous body, neutral to test paper, and absolutely permanent in dry air. It is heavier than water, and is insoluble in alcohol or ether.

It contains about 50.0 p.c. of carbon, 6.6 p.c. of hydrogen, 18.3 p.c. of nitrogen, and 25.1 p.c. of oxygen. According to Mulder, calcium phosphate is always present. Schlieper finds sulphur in bone and ivory gelatin to the extent of 0.12-0.14 p.c. Von Bibra has also found it in bone gelatin, and Hammersten (J. Pharm. Chim. 9, 273) has found about 0.7 p.c. of sulphur in fine commercial gelatin.

When moist or in solution, gelatin rapidly putrefies, and possesses the characteristic property of becoming acid at the commencement of the change, although ammonia is finally evolved.

When steeped in water, gelatin takes up from 5 to 10 times its weight of water, a sufficient quantity to dissolve it when warmed to 30°. When immersed in dilute HCl, the volume of liquid absorbed and the concentration of anion in the jelly depend, at a given temperature, on the ionisation and concentration of the acid (Procter, Chem. Soc. Trans. 1914, 313).

A solution containing only 1 p.c. of gelatin becomes a jelly on cooling. Prolonged or repeated heating reduces and finally destroys this property, on which the value of gelatin princi-

pally depends, so that the preparation is usually conducted at as low a temperature and as rapidly as possible.

Gelatin is soluble in concentrated acetic acid and in mineral acids, and loses its gelatinising power, but the solution forms a powerful cement for glass, &c. Dumoulin's liquid glue consists of a solution of 2 lbs. glue or gelatin in 1 quart of water and 7 ozs. nitric acid (1.355 sp.gr.). Gelatin is also soluble in alkalis, and the solution, as well as the acid solution, is laevo-rotatory.

Gelatin is precipitated from solution by tannic acid, forming tannate of gelatin, similar in composition to leather, but not capable of employment as a substitute for that material on account of its want of structure. A saturated solution of picric acid completely precipitates gelatin at 8°C. A mixture of saturated picric solution with 4 parts alcohol precipitates other proteins, but not gelatin, and this fact has been applied to a method of estimating gelatin in presence of other proteins (Berrar, Biochem. Zeitsch. 1912, 47, 189).

Gelatin is also 'tanned' by halogens; 10 grams are macerated at 0° in 500 c.c. of chlorine solution in 10 p.c. NaCl, or with 100 c.c. commercial sodium hypochlorite solution diluted to 500 c.c., and containing 2 c.c. hydrochloric acid, when an insoluble compound is formed. Corrosive sublimate also precipitates gelatin, but lead acetates and potassium ferrocyanide have not that power.

By prolonged boiling with hydrolytic agents such as sulphuric acid, gelatin yields a high percentage of glycine—leucine, proline, oxyproline, but no tryptophane, cystine, or tyrosine (Levene and Beatty, Zeitsch. physiol. Chem. 1906, 31, 165).

It gives a weak positive Millon's reaction; the xanthoproteic, biuret, and Mollisch's tests are positive; the Adamkiewicz test is negative.

The value of gelatin as a food is somewhat doubtful. Gelatin prepared from bones was largely used by the soldiers and poor of France during the first Revolution, but the idea that its large proportion of nitrogen renders it valuable as a flesh-former appears to be erroneous. It is, however, of limited value as a heat-producer instead of fat and carbohydrates.

Gelatin differs but little in appearance from *chondrin*, which is obtained from cartilaginous tissue, but has a much higher gelatinising power than that substance. Gelatin almost invariably contains *chondrin*, and, when the proportion of that substance is high, is of considerably less value, especially for the preparation of photographic emulsions, which require a maximum of tenacity.

Chondrin is precipitated from aqueous solution by acetic acid, and is not soluble in excess. Lead acetates, alum, and the sulphates of iron, aluminium, and copper also precipitate *chondrin*. A rough test for the presence of *chondrin* in gelatin, useful for photographic work, consists in adding a concentrated solution of chrome alum to a 10 p.c. solution of the gelatin in hot water. If an injurious amount of *chondrin* be present, the gelatin will set whilst hot. Most photographic gelatins, however, contain but little *chondrin*.

In judging the value of gelatin, especially for

photography, the following properties and tests will be useful: (1) The ash, according to Eder, varies from $\frac{1}{2}$ p.c. in good, to 5 p.c. in inferior, and 10 p.c. in adulterated varieties. According to Abney, however, excellent photographic gelatins sometimes contain as much as 2.5 p.c. (2) A good gelatin will take up from 5 to 10 times its weight of cold water when soaked, *i.e.* sufficient to dissolve it on warming to 30°. (3) The solubilities of gelatins vary considerably. Nelson's No. 1 will dissolve in the ordinary 'cold' water in warm weather, and scarcely sets at 75°F., whereas Coignet's gold label only melts at about 110°F., and sets rapidly. For ordinary photographic emulsions, Abney recommends a mixture of 'hard' and 'soft' gelatins in proportions dependent on the weather, a good mixture containing 1 part of the former to 3 of the latter. (4) The amount of fat in the gelatin should be estimated by precipitating the gelatin by addition of alcohol to the solution. Fatty matters are best removed by skimming the solution or by making a jelly and removing the top. (5) The colour of the solution, the tenacity of a jelly of known strength, and the presence or absence of acid, which is frequently present in sufficient quantity to be distinguished by taste, should also be noted.

Isinglass, although free from chondrin, is not available for photographic purposes on account of its great solubility and inferior tenacity.

Gelatin is largely used for culinary purposes as a vehicle for other materials, and is similarly employed in bacteriology. It is valuable for taking casts and impressions for electrotypy, &c. In photography it is employed, in addition to its use for gelatin dry plates, in the carbon process of photographic printing, which depends on the power of potassium dichromate to render gelatin insoluble when exposed to the action of light. This property is also employed in making an insoluble glue or a waterproofing material, by adding dichromate to glue or gelatin just before use.

It is also used in dyeing, for making inking rollers for printing, and as a size for paper making and painting.

For clearing beer, wine, &c., isinglass is much superior to gelatin. This property is said by some to be due to the fine, net-like structure of the former. Coarse Brazilian

isinglass is usually employed. It is 'cut' or dissolved in sulphurous or other acid before use.

GELOSE *v.* AGAR AGAR, art. GUMS.

GELOXITE *v.* EXPLOSIVES.

GELSEMINE $C_{20}H_{22}O_2N_2$, a crystalline alkaloid occurring in the root of American wild jasmine *Gelsemium sempervirens* (*Gelsemii*, Radix B.P.; *Gelsemium*, U.S.P.), (Ait.) along with gelseminine and a third alkaloid, the two latter being amorphous and yielding amorphous derivatives (Wormley, Amer. J. Pharm. 1870, 42, 1; Sonnenschein, Ber. 1876, 9, 1182; Gerrard, Pharm. J. 1882-1883, [iii.] 13, 502, 641; Thompson, *ibid.* 1886-1887, [iii.] 17, 805; Spiegel, Ber. 1893, 26, 1045; Cushny, *ibid.* 1915, 48, 1725; Goeldner, B. Ph. G. 1895, 5, 330). The roots have been re-examined by Moore (Chem. Soc. Trans. 1910, 97, 2223; 1911, 99, 1231). The third alkaloid, *sempervirine*, is little known (Stevenson and Sayre, J. Amer. Pharm. Assoc. 1915, 60).

Properties. Crystallises from acetone in glistening prisms containing 1 mol. of acetone, melts at 178°, and has $[\alpha]_D +15.9^\circ$ in chloroform. The salts crystallise well, B-HCl, m.p. 300°, small prisms; B-HNO₃, m.p. 280°, glistening prisms. Gelsemine hydrochloride is physiologically inactive to mammals, but produces strychnine-like effects in frogs. The characteristic physiological action of gelsemium roots is due to the two amorphous alkaloids, to one of which the name of 'gelseminine' has been applied. In general their physiological action resembles that of conine; they are highly toxic and also exert a mydriatic action on the eye (Cushny, *l.c.*; Moore, *l.c.*).

G. B.

GELSEMIUM ROOT. *Gelsemii Radix*, B.P. The dried rhizome and root of *Gelsemium nitidum* (Michaux).

GEMSBOK BEANS. The bean of *Bauhinia Esculenta*, Burch, used as food in India and in the South-West Protectorate of the Union of South Africa. The bean is composed of 48 p.c. of shell and 51 p.c. of kernel and is about $\frac{1}{2}$ to $\frac{3}{4}$ in. in diameter, the average weight being 2 grms., and that of the kernel 1 grm.

An examination by Bray in the laboratory of the Imperial Institute gave the following results:

	Moisture	Crude proteins	Fat	Carbo-hydrates	Fibre	Ash	Nutrient ratio	Food units
Husks alone . . .	8.5	2.5	0.2	67.2	19.8	1.8	1:27.1	74
Kernels alone . . .	4.0	32.8	41.6	17.2	1.3	3.1	1:3.4	203
Whole beans . . .	6.2	18.0	21.3	41.6	10.4	2.5	1:5.0	140

The bean is free from alkaloids and cyanogenetic glucosides. A golden yellow limpid oil with a nutty flavour and agreeable taste may be extracted from the kernels, with constants very similar to those of cottonseed oil (Bray, Analyst, 1921, 401).

GEMS *v.* PRECIOUS STONES.

GEMS, ARTIFICIAL. Almost all the mineral species that find an application in jewellery have been prepared synthetically in the laboratory. These artificial products possess

the same chemical composition and physical characters as the natural stones, from which they differ essentially only in their mode of origin. It is therefore necessary to distinguish between artificial (*i.e.* artificially produced) gems and imitation and counterfeit gems: the latter will be treated separately in the article GEMS, IMITATION AND COUNTERFEIT.

In nature, these extremely hard and intractable minerals have presumably been formed under conditions of high temperature, and

pressure during long periods of time. It is therefore not to be expected that crystals of any appreciable size could be produced in the laboratory. The high intrinsic value of the products has, however, offered an incentive to repeated experiments; and the production of corundum of gem-quality and of various colours has now been effected with a high degree of commercial success and in a most unexpected manner. Corundum and spinel are the only gem-stones that have, up to the present, been produced artificially of a size and quality suitable for jewellery.

Diamond has been produced artificially by H. Moissan and others (*v.* DIAMOND); but the many attempts made to induce the common element carbon to crystallise in this form have not resulted in the production of crystals larger than 0.4 mm. across. An interesting account of Moissan's extensive researches in this direction is given in his book *Le Four Électrique*, 1897 (English translation by A. T. de Moulpied, *The Electric Furnace*, 1904).

Corundum was produced artificially first by M. A. Gaudin in 1837, and Frémy and Fiel in 1877 succeeded in producing crystals of fair size and of a fine ruby-red colour (*E. Frémy, Synthèse du Rubis*, 1891; *v.* CORUNDUM). The largest of these crystals weighed $\frac{1}{2}$ carat (0.07 gram), and a few were faceted and mounted as gems; but owing to the extreme thinness of the small platy crystals, they were of no commercial value. About the year 1885 rubies of some size appeared mysteriously on the market, it is said from Geneva: whilst some of these were optically isotropic and softer than true ruby, being of the nature of alumina glass, others were crystalline and identical with natural ruby in their characters. These were known as 'reconstructed rubies,' and had probably been produced by fusing together small natural stones.

In 1902 A. Verneuil (*Production artificielle du rubis par fusion*, *Compt. rend.* 1902, 135, 791; *Ann. Chim.* 1904, [8] 3, 20), who had previously assisted Frémy in his experiments, described a new and eminently successful method for the artificial production of rubies of the finest gem-quality. His apparatus consists of an oxy-hydrogen blowpipe placed vertically, the inner oxygen tube of which is enlarged at its upper end to contain a fine sieve holding the alumina powder used in the process. The periodic tapping on the sieve of a small hammer, actuated by an electro-magnet or a rotating cam, causes a small continuous feed of the alumina powder to fall down the oxygen tube. Beneath the nozzle of the blowpipe is a support terminating in a small rod of fused alumina, the position of which can be adjusted by screw motions. The blowpipe nozzle and the support are enclosed in a box in order to avoid sudden changes in temperature. Hydrogen was used in the early experiments, but in the commercial process coal-gas is used. The flame, with a temperature of 1800°-2000°, must be a reducing one with an excess of hydrogen or carbon. The fine particles of alumina ejected through the nozzle of the blowpipe fall on the alumina support, and, fusing together, build up by accretion a pear-shaped mass, which continues to grow both in height and diameter as the support is gradually lowered.

These pear-shaped masses ('boules') of manufactured ruby ('*rubis scientifique*,' '*rubis synthétique*') grow at the rate of about 12 carats per hour, and they may attain a weight of 80 carats (about 16 grams). One operator can attend to ten or a dozen machines; and the total output in Paris exceeds five million carats (1000 kilos. or about 1 ton) per annum. The price of the uncut material is less than 1s. per carat. Now, the curious feature of these masses of fused alumina is that each one of them is a single individual crystal, and not, as might have been expected, an aggregate of crystals or simply an alumina glass. Although the sides of the drop are smooth with a glassy aspect, the rounded end (the last-formed and upper portion in the apparatus) is usually roughened with a fine crystalline reticulation. The narrow stem, where the drop is broken off the support, often shows a bright cleavage surface. The optic axis usually coincides with the axis of the pear-shaped mass, and a section cut perpendicular to this exhibits in the polariscope a typical uniaxial interference-figure. The sp.gr. (3.98-4.0), hardness, dichroism, refractive indices, &c., of this artificial corundum are the same as for the natural mineral. The material further possesses the same transparency, clearness, and rich colours as natural crystals of the best gem-quality. The only means of distinguishing between the two is afforded by certain minute irregularities of internal structure. With a hand-lens or under the microscope, the artificial corundum often, though not invariably, shows minute rounded cavities and curved streaks; whilst in the natural stones the cavities are angular and the streaks are straight.

When the material supplied to the Verneuil blowpipe consists of pure alumina powder (prepared by precipitation with ammonia from pure ammonium alum), the crystallised product is perfectly colourless and clear ('white sapphire'). In the early experiments, powdered natural ruby was used as the material. The best ruby-tint is given by the addition of $2\frac{1}{2}$ p.c. of chromic oxide (homogeneously mixed with the alumina by precipitating the two together from a mixed solution of ammonium alum and chromium alum). Smaller proportions of chromic oxide produce a lighter shade of red or pink, and such artificial gems have been erroneously called 'scientific topaz.' The addition of nickel oxide produces a rich yellow colour. Cobalt oxide will not produce a blue colour with alumina alone, but a fine blue is obtained when some magnesia (or lime) is

Verneuil's blowpipe for the artificial production of ruby.

present (L. Paris, Compt. rend. 1908, 147, 933; A. Verneuil, *ibid.* 1059); but now the product, instead of being corundum, is the cubic and optically isotropic mineral *spinel* (MgAl_2O_4). Attempts to produce a blue corundum (*i.e.* sapphire) had repeatedly failed until it was obtained by A. Verneuil (Compt. rend. 1910, 150, 185) by the addition of titanic oxide (TiO_2 , 0.5 p.c.) and magnetic oxide of iron (Fe_3O_4 , 1.5 p.c.). Analysis of this artificial sapphire gave: Al_2O_3 , 99.83–99.85 p.c.; TiO_2 , 0.11–0.13 p.c.; Fe_3O_4 , trace; sp.gr. 3.977–4.01 (A. J. Moses, Amer. J. Sci. 1910, 30, 271). A peculiar stone which has been sold as ‘synthetical alexandrite,’ exhibits, like the true alexandrite (a variety of chrysoberyl, BeAl_2O_4), a green colour by daylight and a red colour by lamp-light; this is in reality artificial corundum, and the change in colour may be attributed to the presence of colloidal chromic oxide (as suggested in the case of alexandrite by O. Hauser, Zeitsch. angew. Chem. 1910, 23, 1464).

GEMS, IMITATION AND COUNTERFEIT.

As pointed out in the preceding article, it is necessary to distinguish between artificial (*i.e.* artificially produced) gems and imitation and counterfeit gems. Owing to their rarity and high value, gem-stones have been imitated in various kinds of material since very early times. For instance, although a few of the ancient Egyptian scarabs were cut in genuine turquoise, the great majority of them were made of a blue pottery or faience; and amongst the Romans, coloured glass was used for the imitation of the various transparent coloured gem-stones.

The material most extensively used for the manufacture of imitation gems is a heavy lead (flint) glass known as *paste* or *strass*. This is prepared by fusing in a crucible a mixture of powdered rock-crystal (SiO_2 , 38–59 p.c.), red lead (Pb_3O_4 , 28–53 p.c.), potassium carbonate (K_2CO_3 , 8–14 p.c.), together with a small proportion of borax, white arsenic, or saltpetre. Different recipes vary widely, the amount of lead present depending on the refractive index of the gem to be imitated. A dense flint-glass of sp.gr. 3.54 (*i.e.* about the same as diamond) has $n_D=1.6118$ and dispersion $n_G-n_A=0.0315$; and an extra-dense flint-glass of sp.gr. 5.004 has $n_D=1.7784$ and dispersion $n_G-n_A=0.0568$ (the corresponding values for diamond being 2.4173 and 0.0574 respectively). Optical values still higher are obtained by replacing the potassium by thallium; the sp.gr. of a thallium-lead glass may be as high as 5.6. To obtain the best results in the manufacture of strass, the materials employed must be quite pure; and the fusion carefully conducted, in order to avoid bubbles

and streaks. Imitation diamonds (so-called ‘Parisian diamonds,’ &c.) are cut from the colourless paste. To prepare coloured pastes the colourless paste is powdered, intimately mixed with various metallic oxides or other substances, and again fused. A blue colour is obtained with cobalt oxide; green, with cupric oxide or chromic oxide; red, with cuprous oxide, gold chloride, or purple of Cassius; yellow, with silver chloride, antimony oxide or red antimony, or (in leadless glasses) with coal and a little manganese oxide; black, with tin oxide, manganese oxide, and hammer-slag. An opaque white glass, or enamel, is obtained by the addition of tin oxide, calcium phosphate, or bone-ashes; this may be suitably coloured to imitate opaque stones (*e.g.* turquoise) by the addition of metallic oxides.

These glasses often afford very clever imitations of the various precious stones, resembling them so closely, indeed, that without examination they may be readily mistaken for the genuine article. They are, however, all remarkable for their low degree of hardness, less than that of ordinary window-glass, and they can be readily scratched with a knife. In course of time, they display a dark leaden tarnish on their surface, and when worn in jewellery their edges become rubbed and chipped. When examined with a magnifying-lens, bubbles and streaks are often to be seen in them. Optically they are isotropic and lacking in dichroism.

To avoid the effects of abrasion in wear, and also no doubt as a deception in case the test of hardness is applied, these soft materials are sometimes faced with a harder material such as rock-crystal or colourless topaz. In the *doublet*, the upper portion, above the girdle, consists of this harder, colourless material, while the lower portion, protected in the setting, consists of coloured strass which imparts its fine colour and brilliancy to the whole. The *triplet* consists of an upper and a lower portion of harder material, with a layer of the coloured strass between. Such counterfeits can, of course, be readily detected when the unmounted gem is viewed sideways, but when it is mounted in its setting detection is not so easy. Doublets and triplets are also built up of genuine stones, with the object of improving the colour, and of producing a gem of larger size.

Another kind of fraud sometimes practised with precious stones is the substitution of less valuable stones for more valuable. Unfortunately, the nomenclature of gems, as adopted by jewellers, rather offers an opening in this direction. Thus stones of a red colour are often known collectively as ruby with some qualifying prefix: *e.g.* ‘spinel-ruby’ (=spinel), ‘Cape ruby’ (=pyrope garnet), and ‘Siberian ruby’ (=tourmaline), the true ruby (‘Oriental ruby’ of jewellers) being, of course, corundum; or again, ‘Oriental emerald’ (=corundum), ‘Uralian emerald’ (=demantoid garnet), ‘lithia-emerald’ (=spodumene) and ‘Brazilian emerald’ (=tourmaline), the true emerald being beryl of a grass-green colour. In the same way, yellow quartz (‘Spanish topaz’ or ‘Occidental topaz’) is often mistaken for and sold as topaz. Other deceptive terms of a like nature are ‘Marmorosch diamonds,’ ‘Cornish diamonds,’

'Bristol diamonds,' &c., for small sparkling crystals of quartz; and 'Matura diamonds' (from Matura in Ceylon) for zircon of a brilliant lustre, which has been decolourised by the application of heat. The latter, as well as colourless corundum ('white sapphire'), have occasionally been passed off as diamonds.

Other attempts have been made to produce gems of much the same chemical composition as the genuine stones. For example, green glass with the composition of emerald. Very successful imitations of turquoise have been obtained by submitting to pressure a precipitate having the same composition as the natural mineral.

The artificial colouring of natural stones is also extensively practised. Almost all cut agates have been so treated (*v. AGATE*). Chalcedony can be so cleverly coloured a delicate green with salts of nickel or chromium, as to be practically indistinguishable from the more expensive chrysoprase. A pale-coloured jasper or hornstone, quarried at Nunkirchen, near Merzig, in Rhine Province, is coloured artificially by soaking first in a solution of ferrous sulphate and afterwards in one of potassium ferrocyanide. Beads and other small ornaments of this material are cut at Oberstein and are now (1921) sold in large quantities as 'lapis-lazuli.' It is readily distinguished from true lapis-lazuli by its greater hardness and density, and by the presence of small patches of crystalline quartz, which does not take this colour. The colour of many gem-stones can be changed by heating or by exposure to the emanations of radium. A trick of the meanest kind is to smear violet ink or other bluish colouring matter on the surface of a yellowish ('off-coloured') diamond, so giving it the appearance of a colourless gem.

L. J. S.

GENESERINE, GENESEROLINE, v. ORDEAL BEAN.

GENISTA TINCTORIA v. DYER'S BROOM.

GENISTEIN v. DYER'S BROOM.

GENISTEINE $C_{16}H_{28}N_2$, a homologue of sparteine, and found associated with that alkaloid in the common broom, and may be isolated from the mother liquor from the crystallisation of sparteine sulphate; m.p. 60.5° , b.p. $177-178^\circ$ (uncorr.) at 22 mm. It forms a hydrate $C_{16}H_{28}N_2 \cdot H_2O$, which melts with loss of water at 117° ; $[\alpha]_D = -52.34$ in absolute alcohol (4 p.c. sol.). Genisteine is a saturated base, not reducing permanganate in acid solution; it does not contain a methoxyl group attached to nitrogen. It is a di-acid base (mono-acid to phenol- β -phthalein), yielding a *picrate*

m.p. 215° (decomp.), and a *platino-chloride* $C_{16}H_{28}N_2 \cdot 2HCl \cdot PtCl_4 \cdot 2.5H_2O$, which loses its water at 110° , and decomposes at 235° without melting (Valeur, J. Pharm. Chim. 1913, 8, 573).

GENTHITE v. GARNIERITE.

GENTIACAULIN, GENTIAMARIN, GENTIANOSE, GENTIN, GENTIOBIOSE, GENTIOPICRIN, GENTISIN, v. GENTIAN.

GENTIAN. *Gentianæ radix*, B. P.; *Gentiana*, U.S.P. (*Racine de Gentiane*, Fr.; *Enzianwurzel*, Ger.) The dried root of the *Gentiana lutea* (Linn.) (Bentl. a. Trim. 182) is used in medicine as a bitter tonic. Its physiological activity appears to depend upon the presence of 2 p.c. of a bitter crystalline glucoside, *gentiopicroin*, *gentianbitter*, or *gentianin*, which was first obtained in a definite form by Kromayer (Arch. Pharm. 110, 25).

To prepare gentiopicroin, the fresh gentian root is cut into small pieces and quickly dropped into boiling alcohol in order to destroy the ferment which is present in the root and would otherwise lead to loss of glucoside. Carefully dried roots may, however, be used (Bourquelot and Bridel, J. Pharm. Chim. 1910, [vii.] 1, 156). The liquid is boiled for 30 minutes, cooled, and filtered. The alcohol is then removed by evaporation, the residual liquid mixed with calcium carbonate, filtered, evaporated to a syrup, and allowed to stand for a fortnight to crystallise. The crystals obtained are purified by recrystallisation from a mixture of equal volumes of chloroform and 95 p.c. alcohol (Bourquelot and Hérissé, Compt. rend. 131, 113). Gentiopicroin has the composition

It melts at 122° , or, when anhydrous, at 191° (Tanret, *ibid.* 1905, 141, 207). By the action of dilute acids or emulsin, gentiopicroin breaks up into dextrose, and of *gentiogenin*, $C_{10}H_{10}O_4$ needles, m.p. 185° , which is soluble in alcohol, but almost insoluble in water, and not bitter (Tanret).

The mother liquors resulting from the purification of gentiopicroin contain a glucoside, *gentiin* $C_{25}H_{28}O_{14}$, which forms microscopic slightly yellow needles, m.p. 274° (decomp.). It is slowly hydrolysed by dilute sulphuric acid at 100° , forming dextrose (1 mol.), xylose (1 mol.), and *gentienin* $C_{14}H_{10}O_5$ (1 mol.).

The last-named compound, on heating, begins to sublime at 195° and melts at 225° . It is isomeric with gentisin, another constituent of gentian to be described presently, but melts at a lower temperature, and gives a yellow coloration with nitric acid. Gentisin, under these circumstances, gives a green colour (Tanret, Compt. rend. 141, 263). The alcoholic extract of gentian root, from which gentiopicroin separates, also contains a third, amorphous, glucoside, *gentiamarin*, which has the composition $C_{16}H_{22}O_{10}$ or $C_{16}H_{20}O_{10}$. On hydrolysis with acids, gentiamarin yields an amorphous brown substance; with emulsin, dextrose and an amorphous maroon-coloured substance distinct from gentiogenin (Tanret, Bull. Soc. chim. 1905, [iii.] 33, 1071).

Gentian also contains, in very small proportion, another compound which, though physiologically inactive, is much better known. It is a yellow crystalline acid, *gentianic acid*, *gentisin*, or *gentianin* $C_{14}H_{10}O_5$, and by the earlier investigators (Gm. 16, 178) was confused with gentian-bitter or gentiopicroin, and to both these compounds the name 'gentianin' has been

applied (Henry and Caventou, J. Pharm. Chim. 7, 173; Trommsdorff, Annalen, 21, 134; Leconte, *ibid.* 25, 202; Baumert, *ibid.* 62, 106; Hlasiwetz and Habermann, *ibid.* 175, 63; 180, 348).

Gentisin crystallises in large pale-yellow silky needles. Heated to 200°, it darkens in colour, and sublimes with decomposition at 300°–400°. It is nearly insoluble in water, at 16°, 1 part requiring 3630 parts of water for solution, but in alkaline solutions and in hot alcohol it dissolves readily. Melted with potash, acetic acid, phloroglucin and gentisic acid

(1 : 2 : 5) are formed (H. and H.).

Gentisin has been obtained synthetically by Kostanecki and Tambor (Monatsh. 15, 1), and is the methyl ether of gentisein, 1 : 3 : 7-tri-hydroxyxanthone $\text{OH}\cdot\text{C}_6\text{H}_3\text{<O>C}_6\text{H}_2(\text{OH})_2$.

Pectin is present in gentian root in large proportion. This yields mucic acid on oxidation by dilute nitric acid and arabinose on hydrolysis with dilute sulphuric acid (Bourquelot and Hérissay, J. Pharm. Chim. [vi.] 8, 49). Fermentable sugar is present in so large a proportion that it has led to the root being employed in Switzerland and Bavaria in the manufacture of spirit (*see below*). Investigations carried out by Bourquelot and his co-workers (Bourquelot and Nardin, Compt. rend. 126, 280; Bourquelot and Hérissay, *ibid.* 131, 750; 135, 290) show that fresh gentian root contains *gentianose*, a hexotriose, $\text{C}_{15}\text{H}_{32}\text{O}_{16}$, which melts at 207°–209°, and is dextro-rotatory. It does not reduce Barreswil's (Fehling's) solution, but, if boiled with dilute sulphuric acid or acted upon by invertase, it becomes laevo-rotatory, and acquires considerable reducing power, having become hydrolysed into lævulose and a new hexobiose, *gentiobiose*, which, by more vigorous treatment, can be hydrolysed into 2 molecules of dextrose. For derivatives *v.* Hudson and Johnson, J. Amer. Chem. Soc. 1917, 39, 1272.

For the detection of gentian-bitter in beer, *v.* Dragendorff (Chem. Zentr. 1881, 285 and 299); Allen (Analyst, 12, 107; 13, 43).

Various other species of gentian contain gentiopicroin and gentianose (Bridel, J. Pharm. Chim. 1913; [vii.] 7, 289, 392, 486; 1914, [vii.] 10, 62; Compt. rend. 1912, 155, 1164; 1913, 156, 627); but *G. acaulis* roots contain no gentiopicroin but *gentiacaaulin*, $\text{C}_{47}\text{H}_{60}\text{O}_{29}$, m.p. 145°–160°, $[\alpha]_D -63.84^\circ$ (Bridel, J. Pharm. Chim. 1913, [vii.] 8, 241; 1914, [vii.] 10, 329). For seasonal variations of constituents in *G. lutea*, *v.* Bridel (J. Pharm. Chim. 1911, [vii.] 3, 294). Gentiopicroin, 2 p.c., slightly increased in June and July; gentianose, 3–5 p.c., maximum in September; in May and June it is replaced by gentiobiose. G. B.

GENTIAN BLUE 6 B. *Spirit Soluble Blue*, *Spirit Blue O*, *Opal Blue v.* TRIPHENYLMETHANE COLOURING MATTERS.

GENTIAN ROOT. The *Gentiana lutea* (Linn.), from which the gentian root is derived, chiefly occurs in mountainous districts, especially in Switzerland and the Tyrol. There is present in the root of this and other species of *gentiana* a

bitter principle which is said to possess valuable tonic virtues, and on this account some quantity of the material is imported into this country for medicinal purposes.

Gentisin, the colouring matter of gentian root, was first isolated by Henry and Caventou (J. Pharm. Chim. 1821, 178), and was shown by Baumert (Annalen, 62, 106) to possess the formula $\text{C}_{14}\text{H}_{10}\text{O}_5$. Hlasiwetz and Habermann (*ibid.* 175, 63; 180, 343), somewhat later, found that gentisin contains two hydroxyl groups, and when fused with potassium hydroxide, *phloroglucinol* and *gentisic acid* (hydroquinone carboxylic acid) are produced from it. By the action of hydrochloric acid on fused gentisin, methyl chloride was evolved, a probable indication of the presence of a methoxy-group. To prepare gentisin (Baumert, *l.c.*), the root is well washed with water, then extracted with alcohol, and the extract evaporated to a small bulk. The residue is washed with water to remove the bitter principle, and then with ether to extract plant wax. For purification, the crude colouring matter is repeatedly crystallised from alcohol: 10 kilos. of the root yield about 4 grams of the substance. Gentisin crystallises in yellow needles, is sparingly soluble in alcohol, and dissolved in alkaline solutions with a yellow colour.

Gentisein $\text{C}_{13}\text{H}_8\text{O}_5 \cdot 2\text{H}_2\text{O}$. When gentisin is digested with boiling hydriodic acid, it is converted into gentisein with evolution of 1 molecule of methyl iodide. Gentisein consists of straw-yellow needles, melting at 315°, and gives with sodium amalgam a blood-red coloration, whereas gentisin, by a similar method, yields a deep green-coloured liquid (*v.* Kostanecki, Monatsh. 12, 205). By the action of acetic anhydride, gentisein is converted into a *triacetyl* derivative, $\text{C}_{13}\text{H}_5\text{O}_5(\text{C}_2\text{H}_3\text{O})_3$, needles, m.p. 226° (*v.* Kostanecki, *l.c.*); but on methylation with methyl iodide, a *dimethyl ether*

yellow needles, m.p. 167°, is produced (*v.* Kostanecki and Schmidt, Monatsh. 12, 318).

Partial methylation converts gentisein into gentisin, and it is thus certain that the latter consists of *gentisein monomethyl ether*. V. Kostanecki and Tambor (Monatsh. 15, 1) obtained gentisein by distilling a mixture of phloroglucinol and hydroquinone carboxylic acid with acetic anhydride

and its constitution is therefore represented as 1 : 3 : 7-trihydroxy-xanthone. By a study of *dis-azobenzene-gentisin*: $\text{C}_{14}\text{H}_8\text{O}_5(\text{C}_6\text{H}_5\text{N}_2)_2$, scarlet-red needles, m.p. 251°–252° (Perkin, Chem. Soc. Trans. 73, 1028), which gives the diacetyl derivative, $\text{C}_{14}\text{H}_8\text{O}_5(\text{C}_2\text{H}_3\text{O})_2(\text{C}_6\text{H}_5\text{N}_2)_2$, orange-red

needles, m.p. 218°–220°, it has been shown that gentisin itself possesses the constitution I.

As gentisin yields by means of methyl iodide only a monomethyl ether, the original methoxy-group cannot be in the position (I). On the other hand, if gentisin is represented by the formula II, the azobenzene groups would enter the positions 4 and 2, and from such a compound an acetyl-derivative cannot be obtained (compare *dis-azobenzene phloroglucinol*).

Gentisin is a feeble dyestuff, and gives on wool mordanted with chromium, aluminium, and tin respectively, pale-green yellow, pale bright yellow, and very pale cream-coloured shades (Perkin and Hummel, Chem. Soc. Trans. 1896, 69, 1290). A. G. P.

GERANINE *v.* AZO-COLOURING MATTERS and PRIMULINE.

GERANIUM OIL *v.* OILS, ESSENTIAL.

GERMANIUM, Ge. At. wt. 72.5 (Winkler), is the *ekasilicon* predicted by Mendeleëff. It was discovered by Winkler in 1866 in *argyrodite* $\text{GeS}_2 \cdot 4\text{Ag}_2\text{S}$, in which it is present to the extent of about 6–7 p.c. (Kolbeck, Centr. Min. 1908, 331). It is also present in *canfieldite*, *franchetteite*, and *brongniardite* (Prior and Spencer, Min. Mag. 1898, 12, 5; Shroutschoff, J. Russ. Phys. Chem. Soc. 1892, 130), but its presence in *euxenite* and *samaraskite* has been denied by Lincio (Centr. Min. 1904, 142). According to Buchanan (J. Ind. Eng. Chem. 1917, 9, 661), small quantities of germanium are present in Wisconsin and Missouri zinc ores and tend to become concentrated in the residues remaining in the retorts. The metal is obtained by the reduction of the dioxide with carbon at a red heat. It is a greyish-white, brittle, readily powdered lustrous metal of sp.gr. 5.469; which melts at $958 \pm 5^\circ$, and does not volatilise at 1350° . It oxidises in air at high temperatures, combines directly with the halogens, is insoluble in hydrochloric acid, and dissolves in *aqua regia*, forming the dioxide.

Compounds.—The metal is tetravalent, and its compounds resemble those of the silicon group.

Germanium dioxide GeO_2 is obtained from *argyrodite* by treatment with nitre and potassium carbonate at a red heat, then with acid, after which it is purified by being converted into the sulphide, which is roasted and treated with nitric acid. The oxide forms a white powder having acid properties, but

soluble in acids, and is readily reduced by carbon, sodium or magnesium. A colloidal solution of germanium hydroxide is obtained by decomposing an alkaline solution of the dioxide with carbon dioxide.

Germanous oxide GeO is a greyish-black powder, and the corresponding hydroxide $\text{Ge}(\text{OH})_2$ is a yellow powder obtained by the action of alkalis on germanium chloroform or chloride. According to Hantzsch (Zeitsch. anorg. Chem. 1902, 30, 289), in aqueous solution it is a weak monobasic acid, and has the constitution $\text{HGeO} \cdot \text{OH}$, being analogous to formic acid.

Germanium chloroform GeHCl_3 is obtained when germanium is heated in a current of hydrogen chloride, a colourless liquid being thus formed, which separates into two layers, of which the heavier is germanium chloroform; it is a colourless fuming liquid, b.p. 75° . The lighter liquid is *germanium oxychloride* GeOCl_2 ; it is similar in properties to the chloroform, but is less mobile, and boils above 100° . *Germanium dichloride* GeCl_2 , the *tetrachloride* GeCl_4 , and the corresponding tetrabromide, -iodide, and -ethide GeEt_4 , are also known.

Germanium tetrafluoride $\text{GeF}_4 \cdot 3\text{H}_2\text{O}$ combines with hydrofluoric acid, forming *germano-fluoric acid*, of which the potassium salt K_2GeF_6 forms hexagonal crystals isomorphous with those of ammonium silicofluoride.

Germanium disulphide GeS_2 is the most characteristic of the germanium derivatives, and is prepared by passing sulphuretted hydrogen in a solution of germanium dioxide; it is a white powder, soluble in water to some extent and in ammonium sulphide (Vogelen, Zeitsch. anorg. Chem. 1902, 30, 329). The monosulphide GeS and thiogermanates are also known (J. pr. Chem. 1887, [2] 36, 177; Ber. 1888, 21, 131).

Germanium hydride GeH_4 is formed when germanium chloride is reduced with sodium amalgam. It is also formed as a mirror in the Marsh apparatus, as in the arsenic test. The mirror is red by transmitted and green by reflected light, is soluble in sodium hypochlorite, but with difficulty in hot hydrochloric acid. With sulphuretted hydrogen it forms the sulphide; heated in air it gives the dioxide, whilst with silver nitrate it forms a black silver germanium compound, probably GeAg_4 (Vogelen, l.c. 325).

GERMAN SILVER *v.* NICKEL.

GERMOL. A disinfectant consisting of crude cresols.

GERSDORFFITE. Sulph-arsenide of nickel, NiAsS , crystallised in the cubic system. The nickel (35.4 p.c. according to the formula) is usually partly replaced isomorphously by iron, and less often by cobalt. Analyses show Ni 16.24–35.97 p.c., with Fe nil–16.64 and Co nil–14.12 p.c. Crystals are usually octahedral in habit, and they show good cleavages parallel to the faces of the cube. The colour is steel-grey with metallic lustre, but usually the material is tarnished and dull black; the streak is greyish-black. Sp.gr. 5.6–6.2; H. 5: The mineral occurs in metalliferous veins, and has been recorded from several localities in Central Europe; also from Lech Fyne in Scotland, Sudbury in Ontario, &c. L. J. S.

GESILIT *v.* EXPLOSIVES.

GETAH WAX *v.* **WAXES.****GETALIN, GITONIN, v. DIGITALIS.**

GEYSERITE or **SILICEOUS SINTER.** (Ger. *Kieselsinter*.) An opaline form of hydrated silica deposited by the hot springs (geysers) of volcanic regions. It is white or greyish in colour and porous in texture. On the exterior it usually assumes fantastic shapes—stalactitic, filiform, and cauliflower-like masses—and it is sometimes found encrusting plants. Compact-massive and pulverulent forms also occur. Sp.gr. 1.8–2.0. The material consists of nearly pure silica, SiO_2 82–97 p.c. with H_2O 3–10 p.c., and small amounts of aluminium, iron, calcium, magnesium, and alkalis. Immense deposits occur in Iceland, New Zealand, Luzon in the Philippine Islands, Azores, and Yellowstone National Park in Wyoming. Its use has been suggested for the manufacture of porcelain, glass, silica-glass, &c., and as an inert filling material. L. J. S.

GHATTI *v.* **GUMS.**

GHEDDA or **EAST INDIAN WAX.** Differs from ordinary beeswax in containing only one alcohol, ceryl alcohol, present in the form of esters. M.p. 62°–63°, solidifies at 59°–58°, acid value 5.7–5, ester value 86–92.

The wax contains approximately 48 p.c. of ceryl alcohol, 5 p.c. of heptacosane, $\text{C}_{27}\text{H}_{56}$, 2 p.c. of hentriacontane, $\text{C}_{31}\text{H}_{64}$, 24–25 p.c. of hydroxymargaric acid, $\text{C}_{17}\text{H}_{34}\text{O}_2$, m.p. 55°–56°, 1.5–2 p.c. of an isomeric hydroxymargaric acid, m.p. 71°–72°, 9–10 p.c. of margaric acid, 8–9 p.c. of palmitic acid, 2 p.c. of “Ghedda” acid, and 1 p.c. of cerotic acid, with traces of formic, acetic and butyric acids and tarry matter.

“Ghedda” acid ($\text{C}_{34}\text{H}_{68}\text{O}_2$?), m.p. 94°–95°, forms mossy aggregates of white needles; sparingly soluble in ether. (Lipp and collaborators, J. pr. Chem., 1912, [ii.] 86, 184; *idem*. 1919, [ii.] 99, 243, 99, 256.)

GHEE. A clarified butter used in the East mainly for cooking.

GIALLOLINO or **NAPLES YELLOW** *v.* **PIGMENTS.****GIANT POWDER** *v.* **EXPLOSIVES.**

GIBBSITE or **HYDRARGILLITE.** Hydrated alumina, $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$ (Al_2O_3 65.4 p.c.), crystallised in the monoclinic system. It usually forms white or greyish, stalactitic or mamillated, encrusting masses. Crystals, to which the name hydrargillite is more particularly applied, have the form of thin six-sided plates with a pearly lustre on the perfect basal cleavage; these are found in a magnetite-bearing schist at Shishimsk, near Zlatoust in the Urals, and in nepheline-syenite in the Langesund-fjord, Norway. Sp.gr. 2.3–2.4; H. 2½–3½. A bed, about a foot in thickness, of nodular plates of amorphous material is found beneath the soil overlying igneous rocks over a wide area in the Palni Hills in Madras. As a constituent of bauxite and laterite it is of wide distribution, and it has also been identified in some highly aluminous fire-clays. If found in sufficient quantity it would be of value as an aluminium ore.

L. J. S.

GILO, GOLANCHA, and GULOH. Indian names for *Tinospora cordifolia* (Miers). This plant flourishes in India, the drug being sold extensively in the bazaars as a tonic and antiperiodic, in the form of cylindrical pieces, 2 to

5 cm. long and 1 to 5 cm. in diameter. It is a perennial creeper, climbing to the summit of the highest trees, its branches putting forth roots which, reaching to the ground, initiate a fresh growth. Roots, stem, and leaves are equally in demand as a drug. The Indian pharmacopœia commends its use as a tincture (4 to 8 c.c. *in die*); as an extract (0.6 gram to 1 gram *per diem* in the form of pills); and as an infusion (1 : 10), of which 60 c.c. to 90 c.c. are to be taken thrice a day. The stems contain verberin, an uncrystallisable bitter substance, changed by dilute sulphuric acid into a glucoside, and a bitter kind of starch meal known as ‘palo’ (J. Soc. Chem. Ind. 6, 49).

GILSONITE. A mineral hydrocarbon occurring in Utah, the Philippines, and elsewhere, used in the paving industry, and in the manufacture of electrical insulators, roofing materials, for waterproofing pipes and aqueducts, preventing corrosion of iron plates of ship’s bottoms, coating wire fencing, sea-walls, poles, &c., lining tanks for chemicals, paints, lubricants for heavy machinery, rubber substitute, binder for briquettes, &c.

GIN or **GENEVA** is a spirituous liquor made from spirit derived from grain and distilled with juniper berries and other flavouring substances. The term is a corruption of the word ‘*genièvre*’ or ‘*jenever*’, the French and Dutch equivalents respectively for *juniper*, which is the essential flavouring ingredient.

The principal varieties are the English, known as ‘gin,’ and the Dutch, described as ‘Geneva,’ ‘Hollands,’ and ‘Schnapps.’ The difference between them is chiefly one of flavour, and each manufacturer has his own special recipe, which is carefully preserved as a trade secret. The principal flavouring ingredients used besides juniper are angelica root, almond cake, calamus root, cardamom seeds, cassia buds, coriander seeds, creosote, liquorice powder, orris root, sweet fennel, and turpentine.

The grain used is almost invariably a mixture of maize, malt, and rye, the proportions being usually about 75 p.c. maize, 15 p.c. malt, and 10 p.c. rye for English gin, and about equal parts of each for the Dutch varieties, although sometimes maize is absent.

During the Napoleonic wars at the beginning of the last century, the use of corn, owing to its scarcity, was prohibited in the United Kingdom for the manufacture of spirit, and the manufacturers had recourse to molasses or low-grade sugar. This, however, produces a very inferior quality of gin, which is essentially a grain spirit, but it is still made, chiefly for exportation, by the addition of juniper oil or similar flavouring agent to the crude spirit.

In England, patent-still spirit is generally employed as a basis, but it is preferably not rectified so highly as to deprive it of the characteristic flavour of grain spirit. The flavouring ingredients are in some cases added directly or they are separately distilled and the distillate added to the spirit to be flavoured. Another and probably the best method is to redistil the spirit, after the addition of the flavouring ingredients, in a kind of pot-still with a long head or other simple rectifying arrangement.

In Holland, the manufacture is carried on mainly at Schiedam, where pot-stills are chiefly

employed. The spirit is subjected to three or four rectifications, when it is known as 'mout-wijn' or 'maltwine.' This is sold to the manufacturers of Geneva or Hollands who flavour it by methods similar to those above described for English gin.

The best 'Hollands' is said to be prepared as follows: A mixture of two measures of ground rye with one measure of ground barley malt is mashed with about 24 gallons of water for each cwt. of the mixed meal. The mashing being completed, the sp.gr. of the wort is reduced by cold water to between 1033 and 1038. It is then fermented, after which the whole is thrown into a still. To the first product of distillation, called *low wines*, a varying proportion of juniper berries with a little salt is added, and it is re-distilled. The spirit which now passes over is flavoured with essential oils or resins derived from the juniper as well as from the rye and barley used in brewing.

Sweetened gin (e.g. 'Old Tom' and 'Old Geneva') is made by the addition of sugar syrup to plain gin. The syrup is prepared by dissolving refined sugar in its own weight of pure water. Sometimes it is flavoured with orange-flower water, and is known as 'capillaire.' The clear solution is added in the proportion of about 6 gallons of syrup to 100 gallons of gin.

Plymouth gin is a special variety of gin made in Plymouth, and used extensively in the West of England. It has a characteristic flavour, said to be due to ether resulting from the addition of a little sulphuric acid to the spirit to be rectified.

The adulteration of gin, except by dilution with water, is not common. Alkaline carbonates, and sometimes alum and salts of zinc and lead, have been found. Juniper wood oil and turpentine oil are occasionally used as substitutes for or admixed with the oil from the juniper berry.

By the Sale of Food and Drugs Amendment Act, 42 & 43 Vict. c. 30, s. 6, gin may not be sold at a strength below 35 under proof, unless declared to be diluted. The percentage of water added may be found by multiplying the excess of degrees under proof beyond 35 by the factor 1.54. For example, a gin of strength 45 u.p. contains 10×1.54 , or 15.4 p.c. of added water over and above that present in gin at the minimum statutory strength of 35 u.p.

J. C.

GINGELLY or GINGILI OIL v. SESAMÉ OIL. GINGER.

Description.—Ginger is the dried rhizome, either whole or ground to a powder, of *Zingiber officinale* (Roscoe), a plant 3 to 4 feet in height, which grows wild in India and China and is

cultivated extensively in most tropical countries. At the present time, the chief kinds which find their way into the English market are Jamaica, Calicut, Cochin, African, Japanese, and in less quantity, Bombay. Japanese ginger is not derived from *Z. officinale* and is therefore not official for medicinal purposes.

Preparation and properties.—The rhizomes are dug up when the plant is about a year old, washed, and dried in the sun. In some cases the epidermis is removed by scraping or cutting, in others the root is dried intact.

To meet the popular prejudice in favour of a white product various methods of treating the root are adopted. The commonest consists in immersion in milk of lime, when the coating of lime left after drying is of advantage in preventing the attacks of insects, fungi, &c. Gypsum and chalk are also used with a similar object. Ginger is also said to be bleached with sulphurous acid or bleaching powder, but most of the so-called bleached ginger has probably only been 'limed.'

The unscraped root has a yellow-brown wrinkled surface, while the scraped variety is smooth and nearly white. The pieces are, as a rule, from 2 to 4 inches in length, knotted and bent, flattened in section and with a short fracture.

On being cut with a knife, the best ginger presents a soft floury surface, inferior qualities appear hard, resinous, and shiny.

The chief structures observed when ground ginger is examined under the microscope are the starch grains, the vessels, reticulated, spiral, and scalariform, the sclerenchymatous cells, broad bast fibres with somewhat thin walls and occasionally thin-walled polygonal parenchymatous cells and oleoresin cells, which have escaped destruction during the grinding. The starch grains are, for the most part, elongated, simple (except in Japan ginger where aggregates of small granules occur), sack-shaped or oval, and vary in length from 12 to 50 μ , the majority being between 20 and 30 μ . The hilum is placed close to the narrow end and the striations are visible in the larger granules if properly illuminated.

Ginger is used as a condiment and flavouring agent and in medicine as an aromatic stimulant and carminative.

Composition.—Its chief characteristic constituents are a volatile oil to which the aroma is due; a fixed oil, gingerol, which gives the pungent flavour; starch and resin. The following figures (Richardson, from Leach, Food Inspection and Analysis, 446) will afford some idea of its composition:—

TABLE I.

	Water	Ash	Volatile oil	Fixed oil and resin	Starch	Crude fibre	Albuminoids	Undetermined	Nitrogen
Calcutta	9.60	7.02	2.27	4.58	49.3	7.45	6.30	13.4	1.01
Cochin	9.41	3.39	1.84	4.07	53.3	2.05	7.00	18.9	1.12
Unbleached Jamaica	10.49	3.44	2.03	2.29	50.6	4.74	10.85	15.6	1.74
Bleached Jamaica (London)	11.00	4.54	1.89	3.04	49.3	1.70	9.28	10.2	1.48
" " (America)	10.11	5.58	2.54	2.69	50.7	7.65	9.10	11.7	1.46

Determinations by Garnet and Grier (Pharm. J. 1909, 83, 159-160) give the gingerol as from 1.1 to 2.2 p.c.

The composition of gingerol has been further investigated by Lapworth, Pearson, and Royle (Chem. Soc. Trans. 1907, 111, 777), who found the pungent principle of ginger to be a mixture of saturated phenolic compounds derived from a residue of zingerone (*v. below*) in association with a molecular proportion of the residue of a saturated aliphatic aldehyde. The gingerol was obtained by extracting the residue from an alcoholic extract of ginger with 35 p.c. alcohol, evaporating *in vacuo* at minimum temperature, removing water as far as possible and re-extracting with 50 p.c. alcohol. To the solution milk of lime was then added, and after standing the clear liquid was neutralised with hydrochloric acid, and the alcohol again removed under reduced pressure. The resulting oil was separated from water, dissolved in chloroform, the solution dried and evaporated. After fractional extraction with hot petroleum and removing the latter, a viscous yellow oil was obtained which was further purified by distillation in a cathode ray vacuum. The best samples of the faintly yellow oil probably contained about 25 p.c. of impurities.

From it was prepared methyl-gingerol, which crystallises in slender needles, m.p. 64°C., optically active in 2 p.c. chloroform, $\alpha_D^{21} = -27.3^\circ$.

Zingerone. Nomura (Chem. Soc. Trans. 1917, 111, 769) has prepared from ginger, also Lapworth and Dykes from gingerol (*ibid.* 783), a ketonic body, *Zingerone*, the yield amounting to about 0.04 p.c. of the ginger, to which they agree in assigning the formula $C_{11}H_{14}O_3$, the constitution of the metone being

From ginger it was prepared by shaking the ethereal extract, previously evaporated to a syrup, with 2 p.c. sodium hydroxide, passing carbon dioxide through the alkaline liquid and extracting with ether.

The ethereal solution, washed first with 2N. sodium carbonate and then with water, until no longer alkaline, was evaporated, distilled under a pressure of 13-23 mm. and afterwards under 0.5 to 1 mm. until the temperature of the water-bath reached 320°. From the distillate the bisulphite compound of the ketone was prepared. This was washed with ether, decomposed with sodium carbonate, and the resulting oil extracted with ether, the solution washed with water, dried over anhydrous sodium sulphate, and evaporated.

The oil, when shaken with a crystal of the solid ketone, solidified, and was recrystallised from light petroleum. It forms colourless needles, rhombohedra, or lustrous plates, m.p. 40°-41° (Nomura), 31°-34° (Lapworth, Pearson, and Royle), and has the odour of salicylaldehyde, and the pungent taste of ginger. It dissolves easily in most organic solvents, except light petroleum, but sparingly in water, and is only slightly volatile in steam. Warmed with concentrated mineral acids the mixture shows a striking series of colour changing from faint

yellow to brown, and then deep purple; on adding alkali it becomes blue, green, and finally colourless. The mixture gives a red colour with Millon's reagent, dissolves to a green solution with alcoholic ferric chloride, and reduces ammoniacal silver nitrate.

From it were prepared a *monobenzoyl* derivative, colourless crystals, melting at 126°-127°; a crystalline *monoacetyl* derivative, m.p. 40°-42°; also *Methyl Zingerone*, m.p. 55°-56°; *Methyl Zingerone-oxime*, m.p. 93°-93.5°; and *Ethyl Zingerone*, m.p. 66°.

In addition to zingerone, Nomura finds in Japanese ginger a pungent principle *Shogaol*, $C_{17}H_{24}O_3$, b.p. 231°-238°/15.5 mm.; sp.gr. 1.0448/25°, containing a methoxyl radicle and a hydroxyl and ketonic group. Nomura and Nozawa have sought to establish to what constitutional factors the pungency of the principles in ginger is due (J. Soc. Chem. Ind. 1918, 606, A.).

Brooks and Humphrey (J. Amer. Chem. Soc. 1916, [38] 430) prepared from ginger oil freed from terpenes and sesqui-terpenes a tertiary alcohol distilling between 154° and 157° at 14.5 mm. pressure, having the formula $C_{15}H_{26}O$, which possessed the peculiarly fragrant odour of ginger. From it the hydrocarbon in zingiberene $C_{15}H_{24}$, boiling from between 254° to 257°, was obtained.

Adulteration.—The only form of adulteration to which whole ginger is subject is the addition of or substitution by ginger from which more or less of the strength has been removed by extraction with dilute alcohol or water, in the manufacture of ginger beer, &c.; or with strong alcohol for the preparation of the essence or tincture. Ground ginger may be adulterated by the addition of foreign starches—wheat, maize, rice, turmeric; and in the past at all events, cayenne pepper and turmeric have been employed to restore the pungency and colour where these have been reduced by the practices already referred to.

Mineral matter, especially calcium carbonate and calcium sulphate, may also be present in excess, owing either to their deliberate addition or to the too liberal employment in the preparation of the article.

Detection of adulteration.—The detection of exhausted ginger in small proportion is at present impossible, and even when the amount is substantial, the problem is by no means an easy one, because the constituents which are removed by extraction with alcohol and water occur in widely varying proportions, even in different samples of the same kind of ginger, while, in the case of different kinds, the variations are still more marked. The tables on p. 377 show this and also the changes in composition brought about by the processes of extraction as commercially carried out.

The most useful determinations for the detection and estimation of exhausted ginger are the ash soluble in water, the alcoholic extract after extraction with ether, and the cold water extract, and these may with advantage be supplemented by the light petroleum extract or the methyl alcohol extract and a determination of the potash. Microscopical examination is of no assistance but the taste and smell of the sample are of limited utility on account of the

TABLE II.—RESULTS OF ANALYSIS OF 87 SAMPLES OF GINGER.

great variations in strength of the different kinds of ginger.

No legitimate manufacturing operation affects the analytical results sufficiently to cause any trouble (Clayton, *l.c.*), but it must be borne in mind that the method by which the sample has been extracted, of which the analyst is usually ignorant, considerably affects the analytical results. (For the effect of exhaustion with alcohol of different strengths, see *Liversedge*, Pharm. J. 1896, ii, 112, and for information as to methods of extraction actually employed by ginger beer manufacturers, &c., see *Analyst*, 1893, 8, 200.)

The starchy substances likely to be added to ginger may be detected by the microscope. The unsymmetrical cross observed when ginger starch is viewed under polarised light distinguishes it at once from wheat.

Capsicum may be detected by the test suggested by Garnett and Grier (Pharm. J. 1909, 441), based on the fact that the pungent flavour of gingerol is destroyed by heating with alkalis whereas that of capsicum is not.

Standards.—The United States Department of Agriculture has fixed the following standard for ginger: the starch (by diastase method) shall not be less than 42 p.c., the crude fibre not over 8 p.c., the total ash not over 8 p.c., the lime not over 1 p.c., and the ash insoluble in HCl not over 3 p.c. *British Pharmacopœia*: Alcoholic extract (90 p.c. alcohol) not less than 5 p.c., and cold water extract not less than 8.5 p.c., ash not to exceed 6 p.c., insoluble ash under 1.5 p.c. The Pharmaceutical Codex provides that the volatile oil shall be between

1 and 3 p.c., the ash between 3 and 5 p.c., and the aqueous extract not under 10 p.c.

GLASS. **History.** Despite Pliny's pretty story of the accidental discovery by the Phœnicians of the mode of making glass, all evidence points to Egypt as having been the home of the art. Flinders Petrie in *Arts and Crafts of Ancient Egypt*, says that glassmaking, apart from pottery, does not go back further than 1600 B.C. and that blown glass was not developed until many centuries later, the glass object being fashioned round a core of sand. The Phœnicians most probably acquired the art from the Egyptians, and they carried their glassware, beads, and vases, as well as Egyptian glassware, into many countries bordering upon the Mediterranean. In the 1st century B.C. the Roman market for Egyptian glassware developed at a rapid rate, resulting in the attraction of a number of Egyptian workmen to Rome and the setting up there during the last half-century B.C. of a number of factories. Glassmaking under the Romans reached a very high standard, and in respect of some productions their manipulative skill has scarcely been surpassed. Many new shades of colour in glass were developed whilst glass engraving and the production of cameos were well advanced.

The Venetian glassmaking period dates back to the beginning of the 13th century, and reached its culminating period in the 16th and 17th centuries. The fame which the art brought to the Republic of Venice was marked by the privileged position accorded by the State to the Corporation of Glassmakers, as instanced by the enactment which permitted nobles without loss of rank to marry daughters of glassmakers, and by other laws which inflicted heavy penalties on Venetians who went abroad and taught the art of glassmaking. Elegance of form characterised the Venetian productions which were made of a lime glass, either plain or ornamented by a variety of methods including filigree work, lattice pattern and gilding.

Glassmaking was undoubtedly carried on in England, France, and Germany under Roman occupation. In later times, the earliest reference to the existence of glass manufacture in this country was in 1439 when the Countess of Warwick stipulated that no English glass should be used in the windows of the Beauchamp Chapel at Warwick. Elizabeth endeavoured to build up a native industry, but it was not until the later half of the 17th century—and especially during the 18th—that it acquired importance. London was the chief centre in the development, whilst Newcastle probably followed in order. The chief contribution of England to the glass industry was the discovery in the 17th century of lead glass, and the brilliant effect produced by the decoration of this glass by the cutting process contributed to the decline in the demand for the Venetian wares.

The intensive scientific study of glass was the outstanding feature of Germany's efforts in the last quarter of the 19th century. Already in England in 1834, Rev. V. Harcourt began a long series of investigations of the relation between the physical properties and the composition of glass, and showed that borate and phosphate glasses had valuable optical properties. This work was pursued, in later years in conjunction with Stokes, until 1864, when Harcourt died. Schott's experiments, beginning with the lithium glasses, described in 1879, were more successful in that they culminated in commercial manufacture. Early on associated with the physicist Abbe, considerable improvement was soon effected in optical glass, and, uniting with the firm of Zeiss, the first works at Jena were founded in 1884. Many new varieties of optical glass were made, whilst the information obtained in this field not only by Schott, but also by Winkelmann, Weber, and others attached to the Jena school of workers, led to great improvement in chemical glassware, thermometer glasses, and heat-resisting glass.

No glassmaking of any real note took place in America before 1800. The last twenty-five years there have been noteworthy for remarkable mechanical inventions for the manipulation of glass. In this field the Americans stand supreme.

As the result of the war, glassmaking has developed in a number of new centres. In both Great Britain and America chemical glassware superior to the best German has been produced, whilst remarkable progress has been made in England in optical glass of high quality. Japan has undertaken extensive glass manufactures.

whilst India is cultivating the industry. Glass-making is likewise being encouraged as new, or comparatively new, industries in Australia, South Africa, Brazil, and the Argentine.

GLASS.

Definition. Owing to its complexity and to the large number of possible varieties, glass cannot be brought adequately within the scope of a single or simple definition. It may be defined as an amorphous, hard, brittle substance, usually transparent, but sometimes translucent or even opaque, breaking with a conchoidal fracture and consisting of a material obtained by the fusion of one or more of the oxides, silica, boric oxide, phosphoric oxide, and the metallic oxides, followed by sufficiently rapid cooling of the fused mass as to prevent crystallisation of the components. The glass may be colourless or may be coloured either by one or more of the constituent oxides or from the effect of neutral bodies such as carbon, sulphur, and selenium. According to the definition, glass, being amorphous, will be isotropic. There are some substances, however, which, in certain optical instruments, serve as glasses but are anisotropic in character, and have properties differing in the directions of their crystallographic axes. Such crystalline substances in common use are quartz, fluorspar, and calc spar, or Iceland spar.

Properties of Glass. From their mode of preparation, ordinary glasses must be considered as mixtures of compounds, usually of silicates, but also of borates and, in rarer cases, of phosphates and arsenates. A study of the freezing point curves or equilibrium diagrams of binary and ternary mixtures of silica with other basic oxides has been the most fruitful source hitherto of our knowledge of these compounds probably present in silicate glasses (*see*, for example, Hilpert and Weiler, *Ber.* 1909, 42, 2969; 1910, 43, 2565. Day and Shepherd, *Amer. J. Soc.* 1906, 22, 265. Rankin and Wright, *ibid.* 1916, 39, 1. Shepherd and Rankin, *ibid.* 1909, 28, 301; 1915, 39, 9. Rankin and Wright, *ibid.* 1915, 39, 68); whilst the investigations of Wallace (*Trans. Cer. Soc.*, 1909-10, 9, 172) and others have shown that some of these silicates, such as sodium and barium metasilicates, lithium and sodium metasilicates, and sodium aluminium trisilicate and calcium aluminium trisilicate (albite and anorthite) form continuous series of solid solutions; and certain others, such as lithium and calcium metasilicates, are soluble only to a limited extent in the solid state.

On rapid cooling, the viscosity of the mass increases greatly and the mixture at length sets, not at any definite temperature, but over an interval which it is not easy to define with precision. On reheating, it also softens gradually, and has no melting-point. Accordingly, the commonly prevailing view is that glass is to be regarded as a super-cooled liquid of extremely high viscosity. It is the high viscosity which is the most important factor in preventing the separation out in the crystalline form of the compounds present, although it has been suggested that even in apparently transparent

glasses, incipient crystallisation may exist, thus explaining, for example, the phosphorescence of fused zinc silicate and bringing glass into line with the behaviour of certain other amorphous substances, such as sulphur, which tend to revert to the stable crystalline state (see Jackson, J. Roy. Soc. Arts, 1919; S. C. Bradford, J. Soc. Glass Tech. 1919, 3, 282).

The general statement made above in regard to the setting and the softening of glass, is not intended to imply that these processes are absolutely continuous. Tool and Valasek (Bureau of Standards Papers, 1920, No. 358), indeed, have shown that there is distinct discontinuity in the heating curve of a glass when softening begins, due to slight heat absorption, and a corresponding heat evolution on cooling.

Although ordinary glasses consist of mixtures of compounds, the properties of glasses can, with a considerable degree of success, be referred to the influence of the constituent oxides or added substances; indeed, in some properties there appears to be an additive relationship, as in the case of the density and the coefficient of expansion of sodium-calcium silicate glasses of similar molecular type. The following important properties are largely discussed on the basis of the effect of the constituent oxides.

Durability. Resistance to disintegrating agents such as water, aqueous solutions of salts, acids, or alkalis, atmospheric moisture, and dust must be possessed by a glass if it is to be capable of service. Borate glasses and phosphate glasses, whilst possessing valuable optical properties, have hitherto been little used owing to instability in the presence of weathering agents.

Methods of testing the durability of a glass are numerous (Cauwood, English, and Turner, J. Soc. Glass Tech. 1917, 1, 153). Mylius employed a test in which iodo eosin was precipitated from an alcohol-ether solution by the alkali set free from the glass surface to which it was applied. The amount of iodo eosin precipitated per unit area of a fractured glass surface after the latter had been exposed initially to an enclosed damp space for seven days before being dipped in the iodo eosin solution for one minute at 18°C. was called the weathering alkalinity. According to the weathering alkalinity, the durability of the glasses examined was classified as h_1 , h_2 , h_3 , h_4 , h_5 . Thus:

Class	Types of glass	m.gm. iodo eosin per-sq. metre		Alkalinity by solution from	
		Weathering alkalinity	Durability*	hollow ware at 18°	at 80°*
1	Water resistant	0-5	h_1	0-5	0-20
2	Resistant glasses	5-10	h_2	5-16	20-61
3	Hard apparatus	10-20	h_3	16-49	61-202
4	Soft	20-40	h_4	49-202	202-809
5	Unsatisfactory glasses	>40	h_5	>202	>809

Peddle (J. Soc. Tech. 1920, 4, 39) found that the amount of alkali extracted from powdered glass (160 mesh) by treatment with water at 80° for 1 hour was a ready measure of durability. With five optical glasses previously classified by Schott as h_1 , h_2 , h_3 , h_4 , h_5 respectively, he found:

Type of glass	Schott No.	classification	m.gm. H_2SO_4 required to neutralise 100 grs. glass
Light barium flint	0463	h_1	159
Borosilicate crown	0144	h_2	362
Silicate crown	0337	h_3	580
"	0203	h_4	729
"	0381	h_5	899

The reagents tending to corrode chemical glassware may be (1) water or salt solutions, (2) acids or acid solutions, (3) alkalis or alkaline solutions. Usually the corrosive action of alkaline solutions, such as sodium or potassium hydroxides and carbonates, is much more severe than that of acids or water. Concentrated acids, sulphuric and nitric, appear to act on lime-soda glassware to a less extent than pure water. A flask of first-class chemical glassware should not lose more than about 1 m.gm. per 100 sq. cm. when pure water is placed in a 500 c.c. flask and evaporated from 300 c.c. to 100 c.c. in two hours; hydrochloric acid solution of 20-24 p.c. strength should not extract more than 3.4 m.gm. per 100 sq. cm. when evaporated from 250 c.c. to 100 c.c. in 1½ hours in a 500 c.c. flask; 2N.-caustic soda should not extract at 100° for three hours more than about 100 mg., and 2N.-sodium carbonate not more than 35 mg. per 100 sq. cm. (Cauwood, English, and Turner, l.c.).

In the case of water, the amount of corrosion may more accurately be determined by the extraction of alkali; for the nature of the action, namely, first absorption of the water, followed by hydration, is such, that the net loss in weight of the glass may be less than the actual extent of corrosion. With HCl, the corrosion may be determined by evaporation of the acid extract in platinum, gentle ignition to avoid loss of the alkaline chlorides, and calculation of the weight of residue in terms of Na_2O or K_2O .

Oxides which bestow (1) resistance to water are SiO_2 , B_2O_3 , Al_2O_3 , ZnO , PbO ; (2) resistance to acids, SiO_2 , Al_2O_3 , CaO , B_2O_3 , ZnO ; (3) resistance to alkali, Al_2O_3 . Acidic oxides naturally do not offer great resistance to alkaline solutions.

The weathering of optical glass has also been measured by exposing it to moist air for definite periods and also to dust. The latter may be organic and serve to condense moisture or to produce acid matter. Blobs or hair-like markings, or both, may in consequence be developed. The weathering power of optical glass can be determined most speedily by the determination of its chemical resistance to water (see W. E. S. Turner and collaborators, J. Soc. Glass Tech. 1917, 1, 145, 153, 213; 1918, 2, 219, 235; 1919, 3, 129, 228; E. Zschimmer, Chem. Zeit. 1901, 25, 780. C. J. Peddle, J. Soc. Glass Tech. 1920, 4, 39).

Thermal expansion appears to be a linear function of the composition in a simple series of glasses (English and Turner, J. Soc. Glass Tech. 1919, 3, 238; 1920, 4, 115; 1921, 5, 183).

In the tri-silicate series of glasses $3SiO_2 \cdot xCaO$ (or MgO) yNa_2O where $x+y=1$, the calcium glasses have linear expansion ranging from 115.3×10^{-7} when CaO is 0.0 p.c. to 76.9×10^{-7} for CaO 11.63 p.c. For MgO 1.10 p.c. it is 111.1×10^{-7} , and for 9.30 p.c. 59.4×10^{-7} .

* Seven days' treatment at 18°, three hours at 80°.

Glasses of comparatively small expansibility can therefore be obtained by suitably modifying the composition. Pyrex glass has a linear coefficient of 32×10^{-7} ; Jena 59¹¹¹ of 42×10^{-7} ; Jena 16¹¹¹ of 76.9×10^{-7} . Glasses rich in alkali have high expansibility. SiO_2 , B_2O_3 , MgO , and ZnO reduce the expansibility.

Winkelmann and Schott found empirically that the cubical expansion (3α) of a glass could be represented by the formula $3\alpha = xa + yb + zc$ where x , y , and z are the percentages of each oxide and a , b , and c the contribution to the total cubical expansion which each 1 p.c. of the oxide makes.

The factors a , b , c , &c. calculated by Winkelmann and Schott have been shown by English and Turner not to be correct in some cases. The recalculated values of 3α for four oxides are SiO_2 , 0.15; CaO , 4.9; Na_2O , 13.0; and MgO , 1.35, multiplied by 10^{-7} in each case.

The rate of expansion increases with temperature. Up to near the softening-point, the temperature coefficient appears to be linear. Over the softening range (about 40°C .) the rate of expansion increases notably, being from two to seven times the rate prior to softening (*see* Peters and Cragoe, *J. Amer. Opt. Soc.* 1920, 4, 105).

Apart from the desirability of using low expansion glass for chemical apparatus (beakers and flasks) and heat-resisting illuminating ware, the magnitude of the coefficient of expansion is of importance when two glasses have to be united, as in the 'flashing' process, or when metallic wires have to be sealed into glass. In both cases it is desirable for the two objects to be sealed to have rates of expansion not very far different. The expansion rate of a glass can be modified by its composition be varied over a considerable range so as to provide for the sealing in of metals such as copper and tungsten. This variation of linear thermal expansion may range, approximately, from 30×10^{-7} to 130×10^{-7} (E. C. Sullivan, *J. Soc. Chem. Ind.* 1916, 35, 51). Lead glasses have been largely used not only for casing or depositing one on the other in layers, but also for sealing in platinum wires. The coefficient of expansion of a normal lead glass containing 20–30 p.c. of lead oxide is not very far removed from that of platinum. There is no doubt, however, that successful casing or sealing-in depends also on the softness or plasticity of the materials to be united, and lead glass possesses this property in a marked degree.

Resistance to Sudden Change of Temperature depends not only on the thermal expansion but also on the specific heat, the conductivity, the density, the tensile and compression strength, and elasticity. The so-called *thermal endurance* can be measured comparatively by heating to a definite temperature glass rods of similar length and diameter within a vertical electric tube furnace and then allowing them to fall into cold water at a definite temperature. Flasks may be compared by charging them with paraffin wax, heating them to a definite temperature and plunging into water at 20°C . Well-annealed Jena flasks have been found to withstand sudden chilling from 250° to 20° , although the range usually observed is not

quite so wide. Both the actual thickness and the uniformity of distribution of the glass in a piece of glassware influence the cracking temperature. Common beer bottles containing hot water and immersed in a hot water bath will rarely withstand removal and quenching from 80°C . to 20°C . in cold water.

The thermal conductivity of glasses has been investigated by Winkelmann, by Paalhorn, and by Fochs, but it cannot yet be said that the relationship between composition and thermal conductivity has yet been worked out satisfactorily. Apparently, increasing the amount of the oxides Al_2O_3 , SiO_2 , B_2O_3 , MgO , and CaO tends to increase the conductivity of the glass, whilst the oxides PbO , ZnO , BaO , and K_2O , on the other hand, most effectively diminish it.

The specific heat of glasses at temperatures 0° – 100° can be calculated approximately from the values for the oxides by use of the formula

$$C = \frac{p_1}{100} c_1 + \frac{p_2}{100} c_2 + \frac{p_3}{100} c_3 + \dots$$

where p_1 , p_2 , p_3 , &c. are the percentage amounts of each oxide, and c_1 , c_2 , c_3 , &c. the specific heats of the oxides, C being the specific heat of the glass. The values for some oxides are SiO_2 , 0.191; B_2O_3 , 0.227; Na_2O , 0.267; K_2O , 0.186; CaO , 0.190; BaO , 0.067; MgO , 0.244; PbO , 0.051; ZnO , 0.125. Knowledge of the specific heat of glasses at high temperatures is almost entirely lacking (*see also* W. P. White, *Amer. J. Sci.* 1919, 47, 1).

The density, in the case of glasses of similar constitution, varies in an approximately linear manner with the composition (Larsen, *Amer. J. Sci.* 1909, 28, 263; Tillotson, *J. Ind. Chem.* 1911, 3, 897; English and Turner, *J. Soc. Glass Tech.* 1920, 4, 78, 153). This applies, for example, to the sodium-calcium and sodium-magnesium trisilicate glasses.

In general, the densest commercial glasses are those containing lead, although thallium glasses are still specifically heavier. Lead silicate glass, containing approximately 80 p.c. PbO , has a density of about 6.3. Winkelmann believed the density and composition were so related that $100/D = p_1/d_1 + p_2/d_2 + p_3/d_3 + \dots$ where D is the density of the glass, p_1 , p_2 , p_3 , &c. the percentages of the several oxides, and d_1 , d_2 , d_3 , &c. the density factors by which the density was increased for each 1 p.c. of oxide. These density factors were, for SiO_2 , 2.3; B_2O_3 , 1.9; CaO , 3.3; Na_2O , 2.6; PbO , 9.6 (*see, however, English and Turner, l.c.; Baillie, J. Soc. Glass Ind.* 1921, 40, 141.)

Young's modulus of elasticity was shown by Winkelmann and Schott to be related to the composition in such a way that if E is the elasticity, $E = a_1Z_1 + a_2Z_2 + a_3Z_3 + \dots$ where a_1 , a_2 , a_3 , &c. are the percentage amounts of each constituent oxide, and z_1 , z_2 , z_3 , &c. factors which represent the increase of elasticity due to each 1 p.c. of the oxide. These factors were calculated by Winkelmann and Schott, but there is reason to doubt their accuracy; for example, the effect of CaO when replacing Na_2O in a series of trisilicate glasses is to increase greatly the elasticity (J. R. Clarke and W. E. S. Turner, *J. Soc. Glass Tech.* 1920, 4, 260) whereas Winkelmann and Schott ascribe equal effects to them. For the glass 6SiO_2 , $1.9\text{Na}_2\text{O}$, 0.1CaO , $E = 5930 \text{ kg./mm.}^2$ and for 6SiO_2 , $1.1\text{Na}_2\text{O}$,

0.9CaO, $E=7249$ kg./mm.². Zschimmer gives limiting values hitherto found for different glasses as 4800–7970 kg./mm.². A glass with SiO₂, 66.6 p.c.; CaO, 18.06 p.c., and Na₂O, 12.7 p.c., however, had a value 8343 kg./mm.² (Clarke and Turner, *l.c.*).

Tensile strength has proved in the past not easy to measure with accuracy. Zschimmer quotes limits found for glasses as 3.3–8.1 kg./mm.². Winkelmann and Schott concluded that an additive relationship existed between composition and tensile strength. Glasses containing CaO and ZnO had highest, and those with Na₂O and K₂O least, tensile strength.

The compression strength is much greater than the tensile strength. The limits quoted by Zschimmer from the observations of various workers are 60.5–126.4 kg./mm.². According to Winkelmann and Schott, SiO₂, Al₂O₃, MgO, and B₂O₃ effectively increase resistance to compression, whilst the alkalis Na₂O and K₂O as well as BaO reduce it most.

On the viscosity of glass and especially on the change of viscosity with temperature depends its working in practice. Unfortunately, few systematic data have been recorded. Lead glasses are noteworthy as having a long working range, that is, the viscosity changes slowly over the range from 550° to 850°. On the other hand, high CaO content gives fluidity above 1200°, but the glass very rapidly sets when cooled below 1100°. Such glass is therefore advantageous in producing hand-made, thick-walled bottles of considerable size. Magnesia glasses have much higher viscosity than lime glasses at high temperatures. Silica and alumina increase the viscosity. Glasses containing both Na₂O and K₂O work more easily than those with one alkaline oxide only (see K. Arndt, *Zeitsch. Chem. Apparatkunde*, 1911, 44, 457; A. L. Feild, *Trans. Faraday Soc.* 1917, 13, 3; E. W. Washburn, *Trans. Amer. Cer. Soc.* 1920, 3, 735).

The afterworking of glass is the phenomenon of slow shrinking observed in glass after being reheated. For this reason, a thermometer bulb may show a slight rise of zero with age whilst, if heated, and then cooled fairly quickly, the zero is depressed. The depression constant of a thermometer is the depression observed when heated to 100°C. and cooled fairly quickly to normal air temperature. Weber, in 1883, showed that large depression constants were due to the presence of both Na₂O and K₂O. For thermometer purposes only one alkaline oxide should be present in the glass, and the glass also should not be too soft. Much effort was made by the Jena workers to eliminate or reduce afterworking; two successful glasses, 16 (111) and 59 (111) were made having depression constants of only 0.05° and 0.02° respectively. The French glass *verre dur*, resembling window glass in composition, also has a very low depression constant.

Devitrification is the phenomenon of loss of the glassy or vitreous state. Whilst several changes in glass are sometimes associated with devitrification, the term would perhaps be best confined to the separation out in the crystalline state of some constituent present in excess of

the solubility limit. The constituent may be silica or may be a silicate, the former frequently being deposited both from lead and from calcium glasses containing a high proportion of silica. This silica may be, according to the temperature, cristobalite or tridymite, and may give the glass either a mere opalescence or smokiness, or may produce a dense white deposit. Of the silicates, CaSiO₃ or wollastonite, is the best known cause of devitrification of soda-lime glasses. BaSi₂O₅ from barium crown glasses has also been observed. PbSiO₃ is only deposited from glasses containing a very high proportion of PbO. Devitrification depends on the maintenance of the soft glass at a suitable deposition temperature for a sufficient length of time. The viscosity is therefore a most important factor. In this connection, lithium glasses are most readily devitrified, sodium less easily and potassium least of the three alkalis, the viscosity increasing rapidly also in this order, the potassium glasses being most viscous. The addition of certain oxides, as Al₂O₃ and B₂O₃, hinders devitrification, and for this reason the first-named oxide is a constituent of lamp-working (bench glass blowing) glasses, and is a useful addition to sodium calcium glasses which have to be maintained for any considerable time in a fairly plastic state.

The specific electrical resistance is influenced by the state of annealing, well-annealed glass having the higher resistance. The best insulating glasses are usually those most resistant to weathering and chemical attack. Increase of lead in potassium lead silicate glasses increases the electrical resistance. The glass containing SiO₂, 33; Al₂O₃, 6.0; BaO, 48.0; and B₂O₃, 12.0 p.c. is a most efficient insulator. Gray and Dobbie observed that the electrical conductivity of glasses was doubled for each 9°C. rise in temperature (*Proc. Roy. Soc.* 1898, 63, 38; 1900, 67, 197).

The dielectric constant or specific inductive capacity of glass has been found from observation to be between the limits 5.4–8.5 at ordinary temperature. The effect of composition remains yet to be satisfactorily worked out.

Refractive index is related to density, and the two properties increase or diminish in a parallel manner in similar glasses. Although the composition of glass may vary very widely, the refractive index does not change in so marked a degree as other physical properties. For n_D , the limits for practically all known glasses lie approximately between 1.50 and 1.96. Lead glasses, the densest in general use, have highest refractive index, the glass of density 6.3 (*see p. 380*) having value for n_D of 1.96. The barium glasses come next in order. The optical constants of a glass most frequently used are n_C , n_D , n_F , n_G , the refractive indices for the C, D, F, and G lines of the hydrogen spectrum; the total dispersion defined as $(n_F - n_C)$ and the ratio $\frac{n_D - 1}{n_F - n_C}$, designated by the symbol ν .

The lead glasses are characterised by high refractive index and dispersion, and consequently low value of ν . Sodium-calcium and potassium-calcium glasses have low refractive index and dispersion, and fairly high ν value. Barium

glasses possess high refractive index, low dispersion, and high values of ν . Increase in the content of SiO_2 , B_2O_3 , Na_2O , or K_2O diminishes the refractive index.

In a series of similarly constituted glasses, such as the sodium-calcium trisilicates, the relationship between composition and refractive index is linear (Larsen, Amer. J. Sci. 1909, 28, 263; Clarke and Turner, J. Soc. Glass Tech. 1920, 4, 111; see also C. J. Peddle, J. Soc. Glass Tech. 1920, 4, 1, 299; 1921, 5, 72).

The absorption of light is dependent partly on the thickness, but mainly on the composition of the glass, especially in respect of its content of oxides which exercise selective absorption. The best optical glass should transmit 98-99 p.c. of the incident light. On the other hand, unpolished mirror glass, 8 mm. thick, may only transmit about 87 p.c., whilst for glass strengthened by wire mesh, the transmitted light may be only 55-60 p.c. The foregoing refers to general transmission of ordinary white light. In the case of selective absorption, the different coloured oxides vary in the strength of their effect, cobalt oxide being one of the most powerful. The absorption curves for several glasses containing CoO , Cr_2O_3 , NiO , Fe_2O_3 , and Mn_2O_3 have been measured by Zsigmondy (Ann. Physik. 1901, 4, 60).

The selective absorption varies both with the concentration of the oxide and with the temperature. The general effect of rise of temperature is to shift the absorption towards the red end whilst the amount of absorption may simultaneously be increased. This is illustrated by the following relative transmission factors at different temperatures:

Colouring agent	Colour		Relative transmission factor		
	(1) Cold	(2) Hot	30°	200°	350°
Cu . Medium red	—	—	100	92	84
Co . Light blue	—	—	100	104	108
Co . Deep violet	Deep blue	Deep blue	No appreciable change		
Au . Pink	Violet	—	100	96	93
Cu . Bluish-green	Yellowish-green	—	100	94	82
Mn . Purple	Bluish-violet	—	100	94	90
Cu . Deep red	—	—	100	67	42
Cr . Yellowish-green	Yellow	—	100	84	67

In regard to ultra-violet radiation, fused quartz and fused B_2O_3 are transparent, whilst a mixture of B_2O_3 , CaF_2 , and Al_2O_3 shows only weak absorption. Heavy lead glasses and glasses coloured slightly with Cr_2O_3 absorb ultra-violet light.

Glasses which absorb heat radiations may be obtained by the use of the oxides or other compounds of chromium, cerium, and iron, and certain other elements. The mineral biotite and the oxide Fe_3O_4 dissolved in soda-lime glass absorb a high proportion of incident heat rays, whilst Crookes prepared a soda-lime glass from a batch containing 10 p.c. of ferrous oxalate which absorbed 98 p.c. of the heat radiations (Crookes, Phil. Trans. 1914, 214, 1).

CLASSIFICATION OF GLASSES.

As almost all glasses contain silica, and as, moreover, certain metallic oxides such as

calcium oxide and sodium oxide, are present in many different types of glass, a simple classification based on composition is not available. Perhaps a better method, by no means a definite system, may be to classify glasses according to their use. In this way, we have the following varieties:

1. Lime-soda glasses for common use.

This type of glass is far and away the most important, since bottles of all kinds, window glass, and plate glass are made from it, as well as many articles for domestic use such as the cheaper forms of tumblers and pressed table glassware.

A. Common bottles and glass containers.

Analyses of actual samples show that considerable diversity of composition exists.

	1	2	3	4	5	6
SiO_2	75.34	73.06	69.73	73.26	69.11	61.90
Na_2O	13.78	15.26	11.22	17.88	11.07	6.16
K_2O	3.41	0.98	—	—	—	1.13
CaO	6.83	8.70	17.38	7.24	11.83	17.95
MgO	0.21	0.17	0.55	0.17	1.58	6.38
Al_2O_3	0.45	1.30	0.50	1.31	3.46	4.44
Fe_2O_3	0.30	0.30	0.25	0.11	1.82	1.66
MnO	—	—	—	—	1.13	—
Sb_2O_3	trace	trace	—	—	—	—
As_2O_3	—	—	0.47	trace	—	—
Se	—	—	—	trace	—	—
CoO	—	—	—	trace	—	—

1. Continental-made soda-water syphon.
2. Meat jar.
3. British glass for hand-made bottles.
4. Automatic machine-made bottle of colourless glass.
5. Dark green bottle machine-made by O'Neill machine.
6. Champagne hand-made wine bottle.

B. Pressed glassware of the cheaper types frequently has a composition somewhat similar to the bottle glass A4.

A considerable improvement in the appearance of pressed table-ware may be obtained by replacing the calcium partly by barium oxide, and the latter is accordingly frequently used.

C. Window and plate glass from different sources do not vary greatly in composition, as illustrated by the following figures:

	Window glass		Plate glass		
	French	German	American	German	French
SiO ₂	72.1	72.68	71.5	72.5	71.3
Na ₂ O	12.2	13.24	13.7	13.8	10.4
K ₂ O	—	—	—	0.2	0.4
CaO	15.7	12.76	12.4	11.5	14.7
MgO	—	0.26	—	—	—
Al ₂ O ₃	}traces	1.06	0.1	0.1	0.4
Fe ₂ O ₃					
As ₂ O ₃	—	—	0.1	—	—
Sb ₂ O ₃	—	—	—	0.5	—

D. Illuminating glassware. A good deal of the common illuminating ware such as lamp chimneys and globes and shades is made from a calcium-sodium or calcium-sodium-potassium glass, with or without other oxides. Calcium-sodium glass containing magnesium has come into extended use for the manufacture of electric light bulbs, replacing the more expensive lead glass. Common machine-made globes

have a composition not much different from that given under A (4). Other calcium-containing glasses for illuminating purposes are included for convenience in the section on illuminating glassware.

2. Lead-containing glasses. The best British glass for table-ware, known as English crystal, or heavy crystal glass, contains silica, lead oxide, and potash, the proportion of lead oxide in the finished glass exceeding 30 p.c.

Lead oxide has, until recently, been an important oxide in the composition of glass for electric light bulbs, the amount present varying from 18 to 30 p.c. Other illuminating ware, especially in opal glass, usually has a lead oxide base. Glass rod and tubing intended for use in the manufacture of electric light bulbs has also hitherto contained lead oxide.

As examples of lead-containing glasses, the following analytical compositions of commercial bulbs may be given:

	Electric bulbs and rod			
	Tumbler	British (1)	British (2)	Swedish
SiO ₂	54.25	62.85	56.80	63.56
B ₂ O ₃	—	—	—	0.67
PbO	33.38	21.48	30.10	17.29
Al ₂ O ₃	0.14	0.35	0.50	0.48
Fe ₂ O ₃	—	0.10	0.16	0.09
CaO	0.08	0.40	1.30	1.55
MgO	0.16	0.10	trace	0.57
ZnO	—	0.93	—	—
MnO	trace	—	—	trace
Se	—	—	trace	—
Na ₂ O	1.76	9.00	10.62	11.56
K ₂ O	10.30	4.60	0.98	1.60
Sb ₂ O ₃	—	—	—	1.79
SO ₃	—	—	—	0.96

3. Chemical, general scientific and heat-resisting glassware may be of very widely different composition, which may be simple, such as in the case of Pyrex glass, the chief constituents of which are silica and boric oxide, or may be complex like the British chemical resistant glasses, containing silica, boric oxide, calcium, magnesium, aluminium, and sodium oxides with zinc oxide in most cases also.

A. Chemical glassware. The following table states the percentage composition of some different types:

	German		British		American	
	Jena	Greiner & Friedrich	I.	II.	I.	II.
					(Pyrex)	(Nonsol)
SiO ₂	64.58	66.62	66.51	66.38	80.62	68.03
B ₂ O ₃	10.03	3.74	4.57	6.92	11.90	5.81
Al ₂ O ₃	6.28	3.11	6.74	6.60	2.00	2.62
Fe ₂ O ₃	0.10	0.14	0.08	0.12	0.14	0.20
ZnO	11.78	8.20	3.62	8.66	—	7.39
CaO	0.08	0.20	4.35	0.49	0.22	0.80
MgO	0.12	3.29	0.33	0.12	0.29	3.41
Na ₂ O	7.38	11.76	11.52	10.02	3.83	11.18
K ₂ O	trace	1.40	2.58	1.09	0.61	0.30
MnO	trace	0.13	0.10	trace	trace	trace
Sb ₂ O ₃	—	1.80	—	—	—	0.45
As ₂ O ₃	—	—	—	—	0.66	—

B. Lampworking glass, from which light blown articles of glassware (condensers, absorption bulbs, pipettes, &c.) are made, may also vary considerably in percentage composition as indicated in table next column:

	Thermometer Glasses			
	I.		II.	
			Jena 59 (III.)	Jena 16 (III.)
SiO ₂	69.30	69.10	72.86	66.58
As ₂ O ₃	trace	0.10	—	—
Sb ₂ O ₃	—	—	—	—
Al ₂ O ₃	4.05	3.10	6.24	3.84
Fe ₂ O ₃	0.18	—	—	—
CaO	8.28	6.89	0.35	7.18
MgO	0.07	0.20	0.20	0.17
K ₂ O	4.96	6.38	0.10	trace
Na ₂ O	12.80	14.50	9.82	14.80
MnO	0.20	0.10	trace	trace
B ₂ O ₃	—	—	10.43	0.91
ZnO	—	—	—	6.24
	99.84	100.37	100.00	99.72

Some very soft glasses serving as seals on intermediate joints in lampworking operations are made either from lead oxide or with a considerable proportion of boric oxide. Others contain zinc oxide and boric oxide, these being fused with common soft soda-lime glass to form a soft sealing-in glass.

C. Heat-resisting glass. Glass made for the purpose of resisting chemical action is also heat resisting. Thus, Jena heat-resisting lamp chimneys had a composition similar to the Jena chemical glassware, whilst Pyrex glass is made not only into flasks and beakers, but is also pressed into dishes for cooking-ware.

Under heat-resisting glassware, we include articles which not only have a high softening-point but will also withstand sudden changes of temperature—combustion tubing, and tubing for high temperature thermometers, chemical ware, lamp and gas chimneys, globes, and cooking ware.

	Kavalier combustion tubing	Jena Miner's lamp	Jena incandescent gas chimney	Austrian "Sun Brand" chimney
SiO ₂	79.57	73.08	73.88	76.78
B ₂ O ₃	—	17.22	16.48	—

As ₂ O ₃	—	—	0.73	—
MnO	—	—	trace	—

4. Optical glass. If colour screens are included, glass for optical purposes embraces practically all the other types. There are no particular constituents peculiar to optical glass, and the properties of refractive index, dispersion, and absorption required, are so varied in range as to lead to the employment of many and varied constituents.

The simpler types of optical glass are the 'crowns' and the 'flints.' The former are glasses containing calcium, the latter lead. When the glasses contain barium, or zinc, or boric oxide, or phosphoric oxide, the crown glasses are barium crowns, zinc crowns, borosilicate crowns, or phosphate crowns. In the case of flint glasses, we have such types as barium flints and boro-silicate flints. Each type is also classified according to the density, so that we have light flints, medium flints,

dense flints, extra dense flints, light barium flints, and so on.

The percentage composition of some types is stated in the following table :

	Light flint	Medium flint	Dense flint	Very dense flint	Barium flint
SiO ₂ .	53.9	44.1	39.0	20.0	53.69
PbO .	36.7	44.7	49.0	79.9	16.71

5. Coloured glass. The range of colours which it is possible to impart to glass is very great. If we include white or opal, it is possible to divide the coloured glasses into groups according to the origin of the colour.

(a) *Coloured silicates.* A number of oxides produce coloured silicates. Cobalt oxide produces a silicate which is blue. From a similar cause probably arise the following colours—Green: ferrous oxide, uranium oxide (fluorescent), chromium oxide, and (at high temperature) manganese oxide. Blue: cobalt oxide and copper oxide (the latter under oxidising conditions). Pink or purple: manganese oxide, nickel oxide.

(b) *Colour due to colloidal solution or suspension.* The ruby colours due to gold, copper, or selenium, are good examples. Each reagent is added to the batch mixture as a salt, accompanied by a reducing agent (although the selenium may be added as such or may be reduced by the furnace flame alone). When first made, the glasses are either colourless or have a light straw colour, but, on reheating, the ultra-microscopic particles of gold, copper, or selenium, grow larger by segregation leading to

the production of the ruby colour. If the last treatment is continued, the colour will ultimately become brown and finally visible particles of gold appear, resulting in the production of *aventurine glass*.

Amber colours, due to colloidal carbon and possibly also producible by colloidal sulphur; and yellow, due to silver, are further examples.

(c) *Opals produced by separation of an emulsion.* The calcium phosphate (bone-ash) opals, appear to be due to this cause, the phosphate dissolving initially at high temperature and being precipitated from solution at a lower.

(d) *Opals produced by inclusion of air or gas bubbles.*

(e) *Opals produced by devitrification.* The devitrification may be due to deposition of silica, when the effect may vary from a mere cloudiness or smokiness to actual opalescence. Opal may also be formed by the separation of masses of CaSiO₃ or other silicates in very small crystals.

THE RAW MATERIALS FOR GLASSMAKING.

The raw materials for glassmaking may be classified as—

I. Fundamental materials, or those which yield the acid and basic oxides comprising the main substance of the glass: SiO₂, B₂O₃, P₂O₅, Al₂O₃, Na₂O, K₂O, Li₂O, CaO, MgO, PbO, BaO, ZnO, FeO, and Fe₂O₃.

II. Fluxes: As₂O₃, Sb₂O₃, B₂O₃, Na₂B₄O₇, CaF₂, K₂SiF₆, NaNO₃, KNO₃.

III. (a) Colouring agents: CuO, FeO, CaO, MnO, Se, C, S, AuCl₃.

(b) Decolorisers: MnO₂, Se, As₂O₃, Sb₂O₃, NiO.

(c) Opacifiers: SnO₂, Ca₃(PO₄)₂, Na₃AlF₆, ZrO₂, As₂O₅.

IV. Oxidising agents: NaNO₃, KNO₃, BaO₂, Pb₃O₄, MnO₂.

V. Reducing agents: C (as coal, coke, or other form of carbon), Zn, Rochelle Salt, SnO.

It is to be understood that the basic oxides referred to above are generally used in the form of their salts. Only the more important materials are commented on in the section which follows.

ACID OXIDES AND THEIR SOURCES.

Silica. Sand constitutes the only really important source of the silica which is present, in the majority of lead glasses, to at least 55 p.c., and in calcium and other glasses to not less than 66 p.c. The degree of purity demanded in a sand varies with the type of glass to be made. Iron oxide is the impurity least desired by the glass manufacturer. It may be present as hydrated oxide, limonite (Fe₂O₃.H₂O) or may be associated with clay material, in both of which cases it may be reduced by washing; or again, a definite iron-containing mineral, such as ilmenite, in which case separation is difficult.

For optical glass, the amount of iron oxide (as Fe₂O₃) should not exceed 0.03 p.c.; for the best table-ware, not exceeding 0.05 p.c.; for second grade table-ware and chemical glassware up to 0.08 or even 0.1 p.c.; window glass 0.15 to 0.25 p.c.; for dark-green bottle glass, as much as 2-3 p.c. or even more. For practical purposes, there are no workable deposits of sand in the United Kingdom capable of satisfactory

use for good optical or the best table-ware glass. Excellent sands are found in France at Fontainebleau; in Germany at Hohenbockaer and Nivelstein; in the United States at Berkeley Springs, West Virginia, and at Ottawa, Illinois, with good sands also at various locations in

Pennsylvania, New Jersey, and Massachusetts. Belgium has excellent sand. The best British sands, at present, come from King's Lynn, Aylesbury, and Leighton Buzzard.

The following table states the composition of samples examined:—

Sand	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	TiO ₂	CaO	MgO	Na ₂ O	K ₂ O	Loss on ignition	Remarks

* White variety.

For optical glass, and, generally speaking, for the finest table-ware glass, impurities should be absent as far as possible, and the percentage of silica reach 99.5 p.c. Except for iron oxide, the other impurities may even be an advantage in the glass when optical glass is not in preparation, whilst the iron oxide is a useful constituent when dark bottle glass is to be made.

The size of the sand grain is also of importance. No particles should be incapable of passing a 20-mesh sieve, and a good sand is one which consists mainly (more than 90 p.c.) of particles between 30 and 70-mesh. The coarse particles are difficult to melt; the very fine material contains a great proportion of impurity and may entrap fine air bubbles.

Boric oxide is added variously as borax, boric acid H_3BO_3 , and as oxide, B_2O_3 , the first-named being usable only when the glass contains sufficient sodium oxide to permit part of it to be introduced as borax. The oxide is usually too expensive. Boric oxide bestows great resistance to corrosion by water, and a small amount (1 p.c.) greatly improves lead table-ware glass in this respect, whilst the best glass for water gauges and chemical ware also contains it as an essential constituent. It serves as a valuable flux and is a good solvent for colouring materials. Accordingly, some colours which are due probably to colloidal solution are not readily developed in presence of boric oxide.

Phosphoric oxide in any considerable amount is rarely met with. It is employed in special optical glasses (e.g. phosphate crowns) intended for use in protected portions of optical apparatus. Most phosphate glasses are readily attacked by atmospheric moisture and weathering agencies.

It is also used in small amounts in glass for table-ware as it bestows on it a bright appearance. For such a purpose it has sometimes been added as bone ash but may better be added as sodium phosphate (Na_2HPO_4). For optical glass, meta-phosphoric acid is the form employed.

Phosphate glasses, in which the chief acid oxide is silica, are the opal glasses produced by the addition of bone ash or calcium phosphate (p. 388).

Arsenious oxide (As_2O_3) (technically 'arsenic') and antimony oxide (Sb_2O_3) may be classified under the acidic oxides. Alumina probably also exercises an acidic function, but it is dealt with below under basic oxides.

BASIC OXIDES.

Calcium compounds. Calcium may be added as carbonate, oxide, or hydrated oxide. Precipitated carbonate and powdered calcite (limespar) are used where impurities must be excluded, whilst chemical lime and soap waste (both industrial by-products) as well as limestone, are used for common bottle glass. Burnt lime is largely used in American glass practice; slaked lime is used occasionally in Great Britain.

Unless for common bottle glass, the impurity to be avoided is iron oxide. Precipitated calcium carbonate usually has negligible quantities of iron oxide, alumina, and silica; limespar may have larger amounts of each of these impurities, and the iron may to some extent be introduced during the grinding of the limespar. When used for ordinary white glass, the iron oxide content should not exceed 0.1 p.c. In the limestones, organic matter and some phosphate may be present. Magnesia may or may not be considered as an impurity. In some cases it is deliberately added as dolomite limestone, in America as burnt dolomite.

Calcium carbonate in one of its various forms has the advantage of evolving gas during the glass-melting operations, thus assisting to stir up the molten material. Burnt lime must be used quickly owing to its absorption of moisture and carbon dioxide; to a smaller degree slaked lime deteriorates also. On the other hand, burnt lime appears to dissolve more quickly than limestone in sodium carbonate and it is also free from organic matter.

Sodium compounds are introduced as sodium carbonate (technically soda ash), sodium sulphate ('Saltecake'), sodium nitrate (technically 'soda nitre' and 'Chili nitre') and borax. All of these serve as a source of sodium oxide for the glass, and the remainder of the salt escapes as a gaseous product except in the case of borax which also serves as a source of boric oxide.

For all practical purposes, the soda ash employed is manufactured by the ammonia-soda process. It may be 'dense alkali' or 'light alkali' dependent on its specific gravity. The former is preferable.

The impurities are sodium chloride and small amounts of iron oxide and sodium sulphate. Soda ash is one of the most trustworthy products a glass manufacturer has to deal with.

Sodium sulphate or saltecake has had a great vogue in making bottle glass in Great Britain until recently, whilst both in this country and abroad it is largely used for making window glass. It is the custom to add powdered coal or coke, about 5 p.c. of the weight of the saltecake, in order to assist in the reduction of the latter. Some manufacturers, however, work the furnace at a high temperature and rely on the reducing action of the furnace flame entirely. Whilst this is possible in a tank furnace and, to some extent with open pots, a reducing agent must certainly be used if saltecake is in whole or part employed in closed pot operations.

Ordinary samples of saltecake are much less pure than sodium carbonate, and may contain sodium chloride, sodium bisulphate, iron oxide, calcium sulphate, insoluble matter, and moisture as the chief impurities. A good average sample should contain 94-95 p.c. of actual sodium sulphate. Samples yielding only 85 p.c. have not infrequently been met with.

Saltecake was, prior to 1915, much cheaper than soda ash and was used for this main reason. Generally speaking, glass takes longer to prepare when made from saltecake than from soda ash, whilst saltecake is more corrosive of furnace blocks than soda ash.

Sodium nitrate melts easily and therefore serves as a flux, whilst as an oxidising agent it prevents lead oxide in lead batches from being reduced to metallic lead and also hinders the development of the green ferrous silicate. It is added only in conjunction with sodium carbonate; that is, it provides only the minor proportion of the total sodium oxide content.

Borax, as $\text{Na}_2\text{B}_4\text{O}_7$, is a very useful flux, whilst it serves also as a source of boric oxide. It seldom provides more than a small proportion of the total sodium oxide.

Potassium compounds. Potassium carbonate is the chief. It may be added as K_2CO_3 or (to a much smaller extent nowadays) as the hydrated form $\text{K}_2\text{CO}_3\cdot\text{H}_2\text{O}$. The usual impurities are small amounts of potassium chloride and sulphate. Russian potash often contains several per cent. of chloride and sulphate, leading to the production of opalescence in lead glasses. Potassium nitrate is used for similar reasons to sodium nitrate and in like proportions. For chemical glassware, where the presence of alumina is also desired, potassium may conveniently be added in the form of potash feldspar (orthoclase) $\text{K}_2\text{O}\cdot\text{Al}_2\text{O}_3\cdot 6\text{SiO}_2$.

Lead is generally introduced as red lead,

Pb_3O_4 , but sometimes as litharge. Lead sulphate has been used to a smaller extent. The darker variety of red lead, containing an appreciable amount of PbO_2 , is preferred by some glass manufacturers.

Barium compounds. Barium carbonate is the only one in extensive use.

Zinc is added in the form of carbonate.

Aluminium is added in various forms. It is generally present in smaller or larger amounts in the sand used and in the other raw materials. It is also absorbed in small amounts from the fireclay material of which the glass pots or the tank furnace blocks are made. For good colourless glass, aluminium may be added as hydrated oxide, $\text{Al}_2\text{O}_3\cdot\text{H}_2\text{O}$, or as calcined oxide, Al_2O_3 , felspar, lepidolite, and china clay of low iron oxide content. China clay has the disadvantage of being less easy to incorporate in the batch than the other forms mentioned.

For common bottle glass, ground bricks or tiles, or even dried raw clay, have been used as sources of alumina.

Opal glass is frequently made by the addition of cryolite, Na_3AlF_6 .

Alumina bestows mechanical strength and resistance to chemical corrosion on glass. The addition of small amounts (1 p.c. of the total batch) may make melting easier, but beyond 5 p.c., fusion needs a hot furnace, and with 10 p.c. the glass is not easy to work.

COLOURING AGENTS.

These have already been enumerated. Cobalt is added either as the pure oxide, or, since its colouring power is great, in a diluted form, such as by powdered blue, zaffre (an impure basic cobalt arsenate), or smalt (a glass made from powdered quartz, potassium carbonate, and cobalt oxide, containing about 2-7 p.c. of cobalt oxide. This glass is ground fine for use). Used alone, the oxide imparts a blue colour; with manganese dioxide a violet colour; and added in small quantities to copper and gold glasses, a bluish cast is given to the red colour. Cobalt oxide produces a faint blue colour when present to the extent only of 1 in 100,000 of glass. One part per 1000 produces a deep blue.

Copper for the production of blue glasses may be added as oxide CuO or nitrate. When added as sulphate (copper vitriol) a greenish-blue colour is obtained. For copper ruby glasses, either the red oxide Cu_2O or black oxide CuO is used, in the presence of some reducing agent. In conjunction with chromium compounds, various shades of green may be obtained.

Chromium is employed most frequently in the form of oxide Cr_2O_3 , and potassium chromate or dichromate. Care has to be taken, especially with the oxide, to mix thoroughly with the batch owing to limited solubility. In lead glasses a lemon-yellow, and in calcium glasses a greenish-yellow colour is obtained. Barium chromate and copper chromate have also been used.

Uranium, producing a greenish-yellow colour in lead glasses and a fluorescent greenish-yellow in calcium glasses, is used in the form of sodium uranate $\text{Na}_2\text{U}_2\text{O}_7\cdot 2\text{H}_2\text{O}$.

Manganese dioxide is the only manganese compound employed, usually in the form of the

mineral pyrolusite. Under oxidising conditions, it produces a purple colour with sodium and a violet with potassium glasses. Used in conjunction with ferric oxide, varying shades of red, brown, and purple may be obtained, dependent on the relative amount and total amount of the two oxides, and, on the presence of oxidising or reducing conditions.

Nickel oxide produces a violet colour in potassium and red-brown in sodium glasses.

Selenium, used either in the form of the element or as the selenite in conjunction with a reducing agent, for example, arsenious oxide, gives rise to various shades of red varying from pink to ruby.

Decolorisers and the decolorising of glass. Within narrow limits of iron oxide content, the greenish colour produced by ferrous oxide can be removed by decolorisers. Oxidising agents such as sodium and potassium nitrates tend to retain or to produce the higher ferric state of oxidation which has but slight colour, namely, straw or yellow. Arsenious oxide, which is readily reduced, assists in the oxidation of carbonaceous matter which would otherwise reduce the iron to the ferrous condition.

The usual decolorising agents, however, are those which when present alone are colouring agents, namely, manganese dioxide, nickel oxide, and selenium. Potassium glass containing the first-named oxide shows most marked absorption in the yellow and green part of the spectrum, the red and violet being transmitted. A glass with iron oxide, on the other hand, transmits green and yellow to the greatest extent, whilst the red and blue show absorption. When the two oxides are present in small amounts simultaneously, they each absorb what the other transmits, resulting in a slight general absorption only. Although the resulting glass may appear colourless, the reduction in the light transmitted tends to create a dull or greyish appearance. For optical glass, raw materials with very low iron oxide content are used so as to avoid the necessity of adding a decoloriser. Manganese dioxide does not perfectly decolorise sodium glasses, a brownish tinge being left, which is removed when a minute amount of cobalt oxide is added with the manganese dioxide.

Manganese dioxide needs to be used under oxidising conditions, and is therefore suitable for closed pot operations. Nickel oxide is not affected by the furnace atmosphere. It is frequently used with 5-7 p.c. of its weight of cobalt oxide in sodium glasses. Selenium needs a reducing atmosphere, making it very suitable for tank furnace practice. It is usually employed in conjunction with 10-50 times its own weight of arsenious oxide.

THE GLASS BATCH.

General composition. A number of attempts have been made to establish a definite relationship between the basic and acidic oxides of a stable glass. The simple, two component glasses composed of the sodium silicates (*Water glasses*, see later) are not sufficiently stable for the manufacture of glassware. The introduction of a di- or trivalent oxide, such as CaO, PbO, or Al₂O₃, brings about a large increase in stability. Most commercially successful glasses contain at least three components. Benrath came to

the conclusion from the examination of a number of good glasses on the one hand and faulty on the other, that, with the special exception of certain optical glasses, the normal composition of satisfactory alkali-lime-lead oxide glasses should vary between the limits

Tscheuschner about ten years later (1885) deduced the following formula for a good glass containing the alkalis and alkaline earths,

namely $x\text{A} + y\text{E} + 3\left(\frac{x}{y} + 1\right)\text{SiO}_2$, where $x\text{A}$ repre-

sents the number of equivalents of the total alkalis Na₂O and K₂O, $y\text{E}$ of the alkaline earth oxides.

More recently still, Koerner (1915) has arrived at the conclusion that in lime-containing glasses, the proportion of silica should be greater when potash is present than is required for soda. Thus, when one equivalent of lime is present (*i.e.* $y=1$), the proportion of SiO₂ needed is $4(x^2+1)$. If both soda and potash are present, x representing the total equivalent of the alkaline oxides, and $x\text{K}$ represents that of K₂O, the amount of SiO₂ needed is $\left(3 + \frac{x\text{K}}{x}\right)(x^2+1)$.

Certainly it is true that a calcium glass of the composition 6SiO₂, CaO, Na₂O shows great stability, and many of the commercial calcium-containing glasses, may, very approximately, be represented by the so-called trisilicate formula, in which, for each 3SiO₂, the CaO does not fall below 0.3 molecule.

Whilst experience in the past appears to have led to this adoption of a trisilicate formula, it does not follow that for modern methods of treatment, it gives the most suitable glass. Peddle recommends a sodium-calcium-containing glass of composition 5SiO₂, CaO, Na₂O for many types of hollow ware. Pyrex glass, on the other hand, even contains 92 p.c. of acidic oxides.

Preparation of the batch. In modern plants specialising in the production of a limited variety of articles, such as bottles, the various raw materials are stored in large, cylindrical concrete tanks, arranged in a row, and at an elevation from the ground sufficient to permit of a truck or waggon to run beneath and collect from each bin the required quantity of material for the mixture or batch. In one system, a weighing machine mounted on a motor-driven truck propelled along a track below the storage tanks, carries a cylindrical drum. By means of a series of indicators set by the management, several materials may be weighed separately into the drum, and when the required amounts have been obtained the drum is rotated by a second motor and the batch thoroughly mixed. It is then emptied down a grating on to a conveyor belt which carries it to hoppers suspended over the feeding end of the furnace. It is possible, by such a system, for one man to mix sufficient batch to maintain six large tank furnaces in continuous operation.

In other, simpler systems, the materials are weighed out into a truck and emptied into a mixing machine such as the Smith mixer,

specially made for the purpose, consisting of a short cylinder with truncated conical ends, like some types of concrete mixer.

Where the number of types of glassware made in a factory is so large that many different batches have to be made up, as in certain pot-furnace works, a correspondingly small mixing plant is used, and may consist merely of a rectangular box rotating on an axis passing through one diagonal, or even of a simple barrel. Hand mixing is often still employed, the materials being weighed out into a wooden vat and mixed by a wooden scoop or shovel.

Batches for different types of glass. The following batches will serve to indicate the general proportions of the various constituents used in making different glasses, especially illustrating the amounts of colouring, opacifying, or decolorising materials required. Whilst they have actually been employed in practice, it does not follow that the batches represent the best possible for any particular type of operation.

The terms soda ash and potash, used below, correspond to anhydrous sodium carbonate (58 p.c. alkali) and potassium carbonate respectively.

I. Lime-containing glasses.

A. Bottles.

1. *Quick-setting glass for large hand-made beverage bottles.* Sand 1000, limestone 500, soda ash 300, saltcake 100.

2. *For Owens' machine.* Sand 1000, soda ash 375, limestone 175.

3. O'Neill's and similar machines.

(a) *Colourless.* First-grade sand 1000, soda ash 375, limespar 170, borax 1, arsenious oxide 1, powdered blue 0.06, selenium 0.03.

(b) *Amber-coloured glass.* Sand 1000, soda ash 380, limestone 180, saltcake 8, carbon (as coal or coke) 10, graphite 1.

B. Cheap glass for common pressed tumblers.

1. White sand 1000, soda ash 400, limespar 180, arsenious oxide 1, selenium 0.03.

2. *Medium quality glass tumblers.* Sand 1000, soda ash 300, potash 50, limespar 100, baryta 100, potassium nitrate 50, manganese dioxide 2.

C. Window glass.

1. Sand 1000, soda ash 260, saltcake 60, limestone 370.

2. Sand 1000, saltcake 420, limestone 300, powdered anthracite 17.5.

II. Lead-containing glasses.

A. *Best crystal glass for table-ware (English crystal).*

1. Fontainebleau (or equal grade) sand 1000, potash 330, borax 30, potassium nitrate 40, red lead 660, arsenious oxide 2.5, manganese dioxide 2.

2. *Semi-crystal.* Fontainebleau (or equal grade) sand 1000, potash 350, limespar 140, red lead 100, nickel oxide 0.02.

B. Electric light bulbs.

1. Fontainebleau sand 1000, soda ash 330, red lead 480, borax 90, felspar 70, sodium nitrate 50, manganese dioxide 2.

2. Fontainebleau sand 1000, soda ash 140, potash 200, red lead 160, limespar 120, manganese dioxide 0.5, nickel oxide 0.02.

III. Chemical, general scientific, and illuminating glassware.

A. *Glass tubing for general chemical purposes.* Lynn double-washed sand 1000, felspar 367, limespar 220, soda ash 448, potash 151, magnesia 4, manganese dioxide 2.75.

B. Beakers, flasks, &c.

Lynn double-washed sand 1000, hydrated alumina 182, limespar 182, magnesia 15, potassium nitrate 30, soda ash 150, calcined borax 185.

IV. Optical glass.

Such glasses are designed to meet certain specific requirements of refractive index and dispersion, and the batches for these must be arranged accordingly. Thus, an ordinary crown glass of approximate refractive index $n_D = 1.517$, and ν value 60.0 may be obtained from the following batch: Sand (high grade) 1000, potash 420, limespar 265, arsenious oxide 5; whilst a medium flint of $n_D = 1.605$ and $\nu = 37.6$ may be prepared from: Sand (high grade) 1000, potash 103, potassium nitrate 78, soda ash 154, lead oxide (PbO) 884, arsenious oxide 6. The variety of batches for optical glass is very great.

V. Coloured glass.

A. White, alabaster, or opal.

1. *Alabaster.* Sand 1000, red lead 560, soda ash 490, sodium nitrate 50, sodium chloride 50, sodium fluoride 75, alumina calcined 225, felspar 1200, antimony oxide 5.

2. *Cryolite opal.* Sand 1000, soda ash 230, potash 40, cryolite 100, felspar 100, fluorspar 100, arsenious oxide 5.

3. *Bone-ash opal.* Sand 1000, potash 300, soda ash 70, bone ash 300, limespar 100.

4. *Milk white glass for lamp shades.* Sand 1000, soda ash 150, felspar 180, fluorspar 90, cryolite 80, tin oxide (SnO_2) 40.

B. Black glass.

Sand 1000, potash 100, soda ash 250, limespar 150, manganese dioxide 100, copper oxide 80, cobalt oxide 40, hammer scale (Fe_3O_4) 40.

C. Red glass.

1. *Gold ruby.* Sand 1000, red lead 440, potash 290, borax 200, gold chloride 0.36.

2. *Copper ruby.* Sand 1000, potash 200, red lead 300, cupric oxide 3, stannous oxide 1.

In both these cases the ruby colour is only developed on reheating the glass at the mouth of the furnace.

D. Yellow glass.

1. *Amber yellow.* Sand 1000, soda ash 250, potash 100, limespar 160, sulphur 15, arsenious oxide 5.

2. *Orange yellow.* Sand 1000, potash 120, soda ash 190, limespar 145, potassium nitrate 5, uranium oxide 3, selenium 0.6, arsenious oxide 2.5.

3. *Canary yellow (opal).* Sand 1000, potash 300, red lead 150, limespar 90, potassium nitrate 50, calcium phosphate 30, borax 15, sodium sulphide 7.5, Rochelle salt 7.5, cadmium sulphide 30.

E. Green.

1. *Vegetable green.* Sand 1000, soda ash 320, limespar 180, potassium chromate 6.5, hammer scale 4, arsenious oxide 4.

2. *Golden green.* Sand 1000, potash 100, soda ash 200, burnt lime 140, red lead 3, cupric oxide 5, uranium oxide 12.5, arsenious oxide 5.

3. *Aventurine green.* Sand 1000, soda ash

350, felspar 220, fluorspar 100, barium carbonate 180, potassium dichromate 120, manganese dioxide 60.

F. Blue.

1. *Dark blue.* Sand 1600, soda ash 350, limespar 160, cobalt oxide 2.

2. *Aquamarine blue.* Sand 1000, potash 50, soda ash 250, limespar 16, copper vitriol 20.

3. *Azure blue.* Sand 1000, potash 200, limespar 120, cryolite 120, copper vitriol 45, smalt 5.

Sand of high grade is desirable in most cases or producing coloured glasses.

Any batch taken from a list such as the above may require adjustment to suit the article for which it is to be worked and the normal temperature of the furnace. The colour also depends on: (1) the freedom of the sand or other raw materials from iron oxide; (2) the presence of oxidising or reducing conditions; (3) the nature of the other constituents present. Thus, as previously indicated, the same colouring agent frequently yields somewhat different colours according as the glass contains lead or calcium, or according as the alkaline element is sodium or potassium.

In general, closed pots are most suitable for coloured glasses, although cobalt blue, iron oxide green, vegetable green, and certain shades of amber can be made successfully in tank furnaces.

In addition to the raw materials stated above, it is usual to add a proportion of previously melted glass or cullet. The amount may vary between 20 and 35 p.c. of the weight of the raw batch. Whatever amount is used it should be kept constant.

THE MELTING OF GLASS.

Glass is melted in clay pots or crucibles, in a pot furnace or in a tank furnace.

Pot furnaces. Pot furnaces are employed for the manufacture of table-ware glass, plain and coloured, and optical glass, and generally in factories where a number of different types of glass are made simultaneously. They are used for making glass of the highest quality.

A pot furnace may hold any number of pots from two to eighteen, and these may contain from about 4 to 30 cwts. of glass. The floor or 'siege' consists of thick fireclay blocks, and its shape may be circular, oval, or rectangular. Rising from the floor are arches, the pillars of which are of fireclay or silica bricks, and the arch is of such dimensions as to accommodate a pot of definite size. A curved roof of silica bricks called the 'crown' completes the enclosure. The understructure depends on the mode of firing adopted. In the old direct-fired, and the semi-gas-fired system, a circular firebox is built below the furnace opening into a circular hole in the siege called the 'eye' through which flame passes from a coal fire, or round which combustion of gas should begin to reach an advanced stage.

Modern furnaces are of two types, recuperative and regenerative, both fired by producer gas.

Figs. 1 and 2 show two vertical sections of the Hermansen type of recuperative furnace. The firing is by means of producer gas generated in the producer P, which forms part of the understructure of the furnace. The gas rises to the eye E, and is mixed with the secondary

preheated air which enters the shaft just below the eye at B. The preheating of the air is accomplished in a series of rectangular fireclay tubes, the ends of which are seen in Fig. 2. These tubes are made and put together in such a way as to constitute one set, the ends of which are seen, giving exit to waste hot gases,

FIG. 1.

and a second series at right angles for the air. The waste gases from the furnace are divided into two streams which pass, one into each recuperator, through the tubes and downwards into the main channel leading to the chimney. The air enters at the base of the recuperator, and following a course at right angles to the

FIG. 2.

spent gas, rises, and becomes hotter and hotter. It finds its way out at B.

The pots. These are made in various sizes and shapes, and may be covered or open. Fig 3 shows different types: (a) a closed or covered pot is used generally for the highest grades of glassmaking. In one type, the 'oval' or 'dog-house' pot, the distance from the mouth to the

back is considerably greater than between the side walls; (b) an open pot, used for medium quality glass, including plate glass and also, in America, for optical glass; (c) a skittle pot, used in the furnace in an inclined position so that the workman can readily gather the glass; (d) a potette, used occasionally in tank furnaces where the charging has to be done at the sides and not at the end of the tank, and also where the temperature at the working end makes the

FIG. 3.

glass too fluid. The glass from the tank flows into the potette through an opening near the bottom. The pots are made of fireclay which has been carefully picked and weathered. Three fireclay constituents go to form the tempered mixture from which the pot is built, namely, a plastic clay called a bind clay, a base clay which should be as refractory as possible, and grog, or mixed fireclay which has been previously burnt to a high temperature. Analyses of fireclays which have found considerable use for glass pots are as follows:—

	PERCENTAGE COMPOSITION OF CLAYS AFTER IGNITION.			
	1	2	3	4
SiO_2 .	68.58	57.35	75.60	71.90
Al_2O_3 .	25.21	37.27	19.26	22.54
Fe_2O_3 .	2.52	2.19	2.30	2.59
TiO_2 .	1.75	1.20	1.27	1.17
CaO .	0.33	0.48	0.13	0.17
MgO .	0.28	0.45	0.40	0.49
K_2O .	0.96	0.42	0.89	0.72
Na_2O .	0.37	0.67	0.16	0.42

1 and 2, Stourbridge clays; 3, Halifax, Yorks; 4, Huddersfield.

The chemical composition, however, is by no means a sure guide to the properties of the clay.

The relative proportions of clay and grog for a pot mixture vary. The following are some which have been employed: (1) Stourbridge

base clay, 5; Stourbridge bind clay, 4; burnt mixed clay, 2; potsherds, $1\frac{1}{2}$. (2) Mixed Stourbridge clay, 9; burnt Stourbridge clay, 5; potsherds, 5.

The proportions are always measured by volume. The first formula is typical of British practice, the second is one used in Germany. Potsherds are obtained from old pots by chipping off all glass and crushing to a regular grain size.

From the moist and plastic, tempered clay, the pot is usually built up by hand in stages, allowing intervals for the uniform drying of the mass, the base being considerably thicker than the upper portions. Pots are built quicker by using a wooden mould or shape, in which the clay is built and hammered to remove air bubbles. More recently, the casting process has come into use. The clay mixture is made fluid or converted into 'slip' by the addition of a small amount of a weak solution of sodium carbonate and silicate. This slip is poured into a plaster mould containing a core, and the plaster absorbs the moisture producing a firm structure. The crown or cover is usually cast separately, and united while both it and the body are still moist though firm.

The pot is now allowed to dry slowly, devices being employed in modern plants to control the degree of humidity. Subsequently, the pot is stored for months in a dry room at about 65°F. prior to use and kept free from vibration. In preparation for the glass furnace it is first heated in a special furnace called a pot arch, in which the temperature can slowly be raised to about 1100°C. or 1200°C., and the moisture, combined water and carbonaceous matter, driven off. In America, the following rate of heating is considered good practice: in 1 day, 75°C.; 2 days, 120°C.; 3 days, 371°C.; 4 days, 596°C.; 5 days, 816°C.; 6 days, 1025°C.; and 7 days, 1160°C. At the last-mentioned temperature the pot should be maintained for 30 hours.

The process of 'pot setting' next follows. The pot is removed from the pot arch on a heavy iron carriage and placed carefully in position in one of the arches of the furnace, and the front of the arch closed as rapidly as possible, preferably by fireclay blocks made to fit the arch. The only part exposed is the neck or mouth of the closed pot, and into this neck or mouth a flat slab or stopper is placed. An open pot stands entirely behind the furnace wall, being worked through an opening in the latter. When in position the pot should be allowed to remain empty for a day at as high a temperature as possible, short of incipient softening, before being glazed and filled.

Tank furnaces. These are of much later introduction than the pot furnace. Essentially they consist of a tank, the bottom and sides of which are composed of suitable refractory blocks, usually pot clay, a silica brick crown, and means of introducing batch and flame, and of removing glass. In size they may vary from a dead weight capacity of about 2 tons to 1250 tons, the latter being the approximate capacity of one window glass tank in America. Furnaces of from 100 to 350 tons deadweight capacity are quite usual.

Fig. 4 represents the cross-section of a glass tank furnace. It will be seen to be similar, generally, to an open hearth steel furnace.

The bottom (A) consists of clay blocks supported on girders, resting on piers so that air has direct access to keep the bottom cool. The sides below the port mouth usually consist of three courses of fireclay blocks (B), in modern furnaces 9 inches thick. Round the mouth of the port (P) the blocks are of silica, and the crown (C) is of silica brick. The tank furnace shown is heated by producer gas and is of the regenerative type, the outer and larger chamber for pre-heating the air, the other the gas. In the furnace shown, the tongue in the port is air-cooled by two flues which run through it. The gas and air mix before entering the tank itself. A glass tank furnace always consists of a melting end and of a working end, and almost always

there is a division between them. This often consists of a double wall of fireclay blocks with a square or a circular channel called the 'dog hole' communicating between the two portions. In other cases a floating fireclay bridge or dam consisting of two or three portions is used. In both cases the object is to prevent unmelted batch or other floating impurities from passing into the working end, where clear, bubble-free glass is required. The small rectangle (D) in the middle of the figure is the 'dog hole.' The larger rectangle in broken outline (E) corresponds to the end of the dog house, that is, a well which is merely an extension of the melting end of the furnace into which the batch mixture is charged.

FIG. 4.

In modern furnaces the melting end only has gas ports, and these may be from two to seven or more in number, depending on the size of the furnace. Reversal of the direction of the flame takes place at least each half-hour.

The fusion process. In a pot furnace, supposing the pot to have been set and maintained for some time at the temperature of the furnace, a small quantity of cullet is usually added so as to furnish a glaze for the sides and bottom. Batch is then filled in by hand (except in some plate glass factories where a changing machine is used) and melting begins. Gas is given off from the batch materials, mainly carbon dioxide and moisture, and helps to stir up the molten mass. When all batch material has disappeared, bubbles of gas usually remain, and to eliminate them the temperature is allowed to rise, thereby reducing the viscosity of the glass and enabling them to escape. Assistance is sometimes necessary in this 'fining' or 'plaining' process, as it is called, and is given by pushing small pellets of ammonium nitrate or white arsenic as far below the surface as possible, or by water, pushed to the bottom in a blowpipe. These materials produce large bubbles on volatilisation and sweep out the small ones. When free from bubbles the glass is ready for working after it has been sufficiently cooled as to attain the workable consistency, and after skimming the surface from impurities.

In a tank furnace the charging in of batch and the working of the 'fined' glass are continuous, as previously explained, and the temperature is maintained constantly higher at the melting than at the working end.

THE MANUFACTURE OF DIFFERENT TYPES OF GLASSWARE.

The manipulation of glass and its formation into articles of glassware can be carried out entirely by hand, in many cases now also by machine. Machinery is now rapidly displacing hand labour for the common types of glassware capable of being produced in bulk to a standard pattern. In practically all cases, the molten glass in the furnace is taken and shaped straightway into the articles required. Two exceptional cases are: (1) in the manufacture of better-class optical glass lenses and prisms, where the pot of glass is allowed to cool down slowly and the cold pieces of glass form the basis of further working; (2) in the lampworking or bench-glass blowing industry, the raw material for which consists of glass tubing or rod previously made at the furnace.

Manipulation by hand. The processes involved and tools used are numerous; two or three of them are common to almost every operation, some others are also of very general use. Thus, gathering glass on a blowpipe and marvering it or shaping it in a shaping block

are the usual initial stages in making any glass object.

Fig. 5 depicts several of the more essential tools. The blowpipe (*a*) has a rounded end for mouth-piece and a 'nose,' usually slightly trumpet-shaped on the end of which glass is gathered by dipping into and rotating in the molten glass. The marver is a polished iron plate on which the gathered mass is rolled on the end of the marver until it attains a cylindrical form, called the *parison*, either hollow or solid, the hollow form being obtained by blowing down the pipe. The glassmaker's chair

glass is frequently blown in a mould and the stem and foot added at the chair.

The following diagrams (Fig. 6) will serve to illustrate the operation of producing the hand-made tumbler, that is, an example of turned work. A very small quantity of glass is gathered on the end of the blowpipe and blown out into a small bulb (*a*). This in turn serves as the centre round which a further gathering (*b*) is made, sufficient for the size of tumbler to be made. By blowing down the pipe and also rotating the mass of glass in a shaping block, the shape (*c*) is obtained, the constriction being

made so that eventually the fully blown vessels can be detached readily. By swinging the iron slightly, and by the further use of the shaping block, the parison is given a slightly conical shape (*d*), after which, by blowing and swinging, shape (*e*) is obtained, and finally (*f*), after the somewhat thicker bottom has been flattened out by contact with a flat and perfectly smooth iron plate. The pipe is detached by drawing a tool across the constricted part of the shoulder while

the vessel is still hot and then giving the pipe a slight tap at its extreme end. The tumbler, with adhering shoulder, is now given its final form in one of two ways. This may be done at the chair by placing the bottom of the tumbler in a holder, reheating the shoulder in the mouth of the furnace, and cutting it away

FIG. 5.

(*b*) has projecting arms on which the blowpipe is rolled backwards and forwards in order that the spinning or rotating shall preserve the rounded outline of the vessel. At this chair sits the master workman, or glassmaker, who finishes the article by means of various tools, such as the tongs, shears, callipers, and flattening boards shown in Fig. 5, in conjunction with rotation of the pipe.

The various types of hand operation may be classified as (1) free hand work, involving gathering, marvering, blowing, and drawing as in making glass tubing; (2) turned work, or chair work, involving, may be, all the preceding processes together with the use of tools; (3) mould blown work, in which the marvered gathering is blown out in a mould—bottles, electric lamp bulbs, beakers, and flasks; (4) combined mould and turned work. This last is now common. Nowadays the bowl of a wine

FIG. 6.

by means of shears. The glassmaker then finally rotates the cylinder on the arms of the chair, and by means of tongs rounds off the lip. The second process of finishing consists of making a scratch horizontally on the tumbler, at the required shoulder height, and then causing a crack to follow this scratch by rotating the tumbler at the top of the flame from several fine-pointed gas jets. Cracking off machines

are constructed in which these processes can be readily carried out. The edges are rounded off by gas flames, applied either in another portion of the cracking off machine, or, by placing the tumbler in a holder and rotating the mouth in a gas flame.

In the case of mould-blown glassware, the gathering of glass after being marvered and formed into the parison, is blown out into a mould corresponding to the external size of the article required. The moulds may be of wood, carbon, brass, or iron. Moulds of special alloys have also been tried. The moulds of wood and carbon produce the best finish, whilst the iron moulds are less satisfactory from this point of view, although their durability causes them to be used in the majority of cases. Metal moulds may be used dry or may be covered with some form of lubrication, usually a paste, in which case the moulds are referred to as paste moulds. The paste is frequently a mixture of finely-divided carbon, such as lamp black, red lead, and linseed oil, but other forms of paste are in use. The paste must be thinly and uniformly spread, and the moulds after each blowing operation are dipped into water to cool them and prevent the paste being burned away too rapidly. Electric lamp bulbs, chimneys, blown tumblers, beakers, and flasks are blown in paste moulds.

Hand-made bottles are almost invariably blown in dry moulds. The process involves gathering at the end of the pipe, marvering into the parison, which usually has a somewhat smaller diameter at the end adjacent to the pipe than at the free end, swinging slightly to cause elongation, and then blowing out into the mould. Two methods of finishing the bottle are used according to the thickness of the neck. In heavy bottles with a thickened neck the latter is made at the furnace by the bottle maker, who adds an additional ribbon to the neck where it has been broken off from the pipe, and then by rotating the bottle at the chair and inserting a neck-forming tool the neck is given its final shape. In lighter made bottles, such as those used for medicines, the end which has been burst off from the blowing iron, is softened in a small subsidiary furnace known as a glory hole, usually heated by town gas or oil, and the neck is formed by pressing back the softened portion of the glass by means of the neck-forming tool.

GLASSMAKING MACHINES.

These are of various types. Six main types may be distinguished according to the process involved.

1. *Pressing machines*, as used for thick and heavy dishes, glass reflectors, jars, &c.

The machine may be hand operated, as in the case of large glass dishes. The mould consists essentially of two parts, namely, the mould proper into which any design may be cut so as to produce the design on the exterior of the glass article, and the plunger, corresponding to the interior of the vessel. The mould is fed with the requisite quantity of glass, and the plunger brought vertically down into the middle of the mass of glass, pressing it out so that it occupies the mould completely.

2. *Blowing machines*, either semi-automatic

or fully automatic, in which the gathering of glass is blown out into a mould. Such machines are used for making glass chimneys, blown tumblers, electric light bulbs, &c. The manufacture of the latter is referred to later.

3. *Pressing and blowing machines*. In such machines there are two sets of moulds. The first into which the requisite quantity of glass is charged is called the 'parison mould.' This gives the initial shape to the neck of the vessel, the neck being formed by a plunger under pressure, in some cases by suction. The second set of moulds, known as 'finishing moulds,' have the glass from the parison mould transferred to them and the article then blown up to its complete shape and size.

4. *Drawing machines* such as those in which sheet glass and also glass rod are drawn out continuously.

5. *Blowing and drawing machines*, such as for the continuous manufacture of glass tubing and cylinders for window glass.

6. *Casting and rolling machines*, as in the manufacture of plate glass with its various varieties of rolled, ribbed, and wired glass.

A few illustrations will now be given of the production of different types of articles in glass.

Considering these types in the order of the classification given previously, common forms of glass were made from sodium-calcium glass come first.

Bottles. The hand process has already been referred to. It is now largely confined to small bottles such as are used for medicines and perfumes, and especially the small bottles which are to be provided with a ground-in stopper. Most bottles and jars are now made by machine.

Fig. 7 illustrates one modern type of bottle machine, namely, the O'Neill. The machine consists of two circular tables each carrying six moulds, the one table carrying the parison or neck-shaping moulds (P), and the other the finishing moulds (F), seen in various positions in the figure, one of them being open. Glass is fed into one of the parison moulds from the furnace, and after insertion the operator touches the trigger (T) by means of his blowpipe, when the machine is set into operation and the mould moves forward to its second station. At the second station a blowing head (H) descends on to the top of the parison moulds, and the plunger is forced up from below to form the neck. At the fourth station the parison is transferred to the second table into the open blow mould, which then closes round it, and a blowing head at the second station on this table comes down and blows out the bottle. A further automatic device removes the bottle from the mould. When fed by hand such machines make from 10 to 15 bottles per minute according to size.

Machines of this type are also adapted, by using suitable moulds, for producing jars and lamp-shades.

The machines may be made fully automatic by feeding them either by means of what is known as a flowing device or by a glass feeding device. In very recent years these devices have come into extensive operation. In all cases the device is attached to a glass tank furnace; pots are unsuitable. Usually it consists of a

short trough, constituting an extension of the tank furnace, and from the trough glass either flows by gravity or is propelled mechanically through an orifice, below which a pair of shears severs the glass into pieces of uniform weight. In the Hartford-Fairmont feeder, the temperature of the glass in the trough or fore-hearth is controlled by gas burners, and the glass is scooped over a spout at the end of the trough by means of a paddle. The operation of the feeding device is timed so as to correspond precisely with the motion of the glassmaking machine, so that a mould stands ready below

the feeder at the moment when a piece of glass is severed by the shears.

Machines similar to the O'Neill are the W. J. Miller, the Lynch, the Edward Miller, the Teeple, the Cox, and the Hartford-Fairmont, all of them of American design.

Fig. 8 illustrates the 15-arm Owens machine, which is completely automatic. Each of the arms is provided with a parison mould and a finishing mould. In operation, the parison moulds as they are carried round the machine are, by a special movement, lowered into a revolving circular trough of glass fed from the

FIG. 7.

main melting tank furnace. Glass is sucked up into the parison mould and the neck is formed by suction, and not by pressure in this case. As the parison mould leaves the trough a knife severs the excess glass from the bottom of the mould. The parison is next transferred to the finishing mould and blown out completely.

Such machines have actually been adapted for making bottles and jars of all sizes, from about $\frac{1}{8}$ oz. up to a carboy holding 15 gallons. In the case of very tiny bottles as many as 160-200 per minute are produced. This quantity is obtained by making each mould double or triple, so that at each rotation either 30 or 45 bottles are produced.

Window glass. Window glass is made by hand and by various types of machines. In

the hand process the figures (Fig. 9, p. 396) illustrate the several stages of the operation. Glass is gathered and marvered, and shaped into the ball (a). By rotation and blowing in a shaping block, the pear shape (b) is attained, and subsequently (c) and (d). The glass is then swung, pendulum fashion, at the end of the blowpipe in a rectangular pit, the operator standing on a platform. The end of the cylinder may have to be reheated several times in the mouth of the furnace before the full length is attained. The end of the cylinder is cut open with the shears, and by rapid rotation the mouth so formed expands until of the same diameter as the main portion (g). The shoulder is then cracked off (h). The size of the cylinder made varies in different countries. A length of

about 5 feet 6 inches and diameter about 12 inches is frequent in this country.

Much larger cylinders are made by machine. In one process a charge of about 550 lbs. of glass is removed from the tank furnace in a ladle, transferred to a shallow circular fireclay trough, and after its temperature has been adjusted by gas flames, a blowing head is lowered into the glass, kept there until the glass adheres, and is then drawn out slowly, air under low pressure (1-2-inch water pressure) passing down the stem and blowing out the glass which assumes and retains the cylindrical form as the head is raised. Heavy cylinders between 300-400 inches long and 26 inches or more in diameter can be drawn.

The cylinder is cut into lengths by an electrically heated wire, and each portion split longitudinally by a red-hot iron rod (*k*). In some cases the cylinder is split into two parts. The split lengths (*l*) are placed in a flattening furnace on a smooth stone table and flattened by use of a wooden block.

When flat, it is passed forward, after slight cooling, into the annealing kiln.

Two processes of window glass making by machinery produce the flattened sheet straightway. These are the Fourcault and the Colburn processes respectively, the latter being better known as the Libbey-Owens process. In the former, a bait which may be of metal, or a strip of glass, is let down into a well which forms the

FIG. 8.

extension of a tank furnace. The adhering glass is then drawn vertically upwards, and at a short space above the well passes between rollers which not only assist the upward movement, but keep the sheet flat. The long chamber up which the sheet is drawn also serves as the annealing chamber. In the Colburn or Libbey-Owens process glass flows from a tank furnace into a shallow trough into which a metal bait is lowered. The bait with the adhering glass is then drawn upwards, vertically, for a distance of about 3 feet, and then is passed over a metal roller into the horizontal position, and on to a travelling belt. The glass sheet is thus conveyed horizontally through an annealing oven a distance of about 200 feet. The drawing operation is carried on at a rate varying from about 26 to 72 inches per minute, according to the thickness of the glass required.

Plate glass is made on a long iron table which can be traversed by a heavy iron roller. The table is spread with a layer of sand to

prevent the glass sticking, and for the same purpose the roller is scored in such a way that it has a somewhat roughened surface. The glass is melted in open pots and poured evenly before the roller, which is then moved forward along the table. Immediately after being rolled the piece of plate is transferred to a very long lehr, or annealing oven, which may exceed 300 feet in length, where it is cooled down. It is then cut up into suitable pieces and fixed, in plaster of Paris, on a circular grinding table and ground down with water and several gradings of sand, commencing with the coarse and ending with the finer gradings. Emery may subsequently also be used. After the grinding of both sides, the pieces are re-embedded in the table and polished by means of water and rouge.

Strengthened sheet glass, for constructional work, is made in several different ways. Wire glass is one important form of such glass. In the latest method it is formed by crimping the wire mesh, placing it on the casting table, pouring

glass over it and rolling out the sheet in the ordinary manner.

A more recent type of strengthened glass has been produced by rolling a sheet of celluloid as a layer between two sheets of plate glass of half the usual thickness, and in another type both wire and celluloid are embedded.

Triplex glass, which rendered very great service during the war in motor cars, aeroplanes, and submarines owing to its non-shattering properties when fractured, is produced by cementing together three sheets of glass so closely as to appear one. On being struck by a missile such as a bullet, cracks radiate in star form from the point of contact, but no splintering occurs.

Lead-containing glasses are used very largely for table-ware and general artistic glass. The manipulative process is almost always that of hand operation along the lines previously indicated.

Electric lamp bulbs are made by hand and by machinery, in both cases by blowing into paste moulds.

Two types of machines have recently come into use, the one known as the Empire machine, being semi-automatic, the other, the Westlake, being fully automatic. In the former, the glass

FIG. 9.

is gathered by the workman at the end of a blowing iron, and the blowing iron then inserted in the machine where the glass is marvered and finally blown out into the mould. The machine has four arms. The Westlake machine is fully automatic, and may have 12 or 24 arms. Glass is gathered by an arm which is projected into the glass furnace and transfers the glass obtained into a cup, and thence to the end of a blowpipe, which is, initially, in the vertical position with its nose upwards. The arms carry out the various operations similarly to the human blower, but the productive capacity is very much

greater, a 12-arm machine producing at least 1000 bulbs per hour.

Chemical, scientific, and heat-resisting glass-ware. Almost all types of this particular class

FIG. 10.

FIG. 11.

are made by hand. Flasks and beakers are blown in paste moulds. Fig. 10 shows a mould for a flask, and Fig. 11 the initial form of a beaker. The shoulder is then cut off by the second process described in connection with the tumbler (p. 392), and the edges are heated and flanged and a lip added where desired.

Glass tubing is drawn by first marvering a thick hollow cylinder of glass, built up by several gatherings, and then lowering this cylinder in a vertical position until its base unites with a disc of hot and soft glass, attached to a holder held by another operator. When the union is firm, the assistant with the holder walks backwards along a wooden track crossed by strips of wood, pulling out the glass tubing as he walks, the chief glass blower at the same time turning his blowpipe round and round and occasionally blowing down it to prevent the walls of the glass from collapsing. The tubing is laid on the wooden strips and after cooling cut into lengths.

The Libbey-Owens machine, invented by Danner, improves the uniformity and enormously increases the production of glass tubing. Glass from a furnace flows in a stream on to an inclined rotating clay tube slightly cone-shaped, and runs down to the end (Fig. 12). It is prevented from forming a solid mass by a current of air transmitted by an iron water-cooled tube enclosed by the clay tube. The glass pulled from the end of the latter is hollow and cylindrical. The pulling is done by a machine, attached to which is a wheel which cuts the tubing into lengths. Glass tubing can by this machine be made at more than 120 feet per minute. When glass rod is required, the air current is shut off.

Optical glass. Since the use of decolorisers in glass results in a loss of transmission of light, it is essential that practically iron-free materials be used, and that the pot be as little subject to corrosion as possible.

After the batch has been melted, a water-cooled fireclay stirrer is inserted in the pot and the glass stirred thoroughly so as to remove both bubbles and layers of different density. In one works, stirring is actually begun during

the melting. After the glass is 'plain' the stirring is continued while the temperature is being reduced, until the glass is too stiff for further movement.

The pot is then allowed to cool very slowly, either by bricking up the furnace, if the latter is of the unit type, or transferring to a heated pot arch, where the temperature is slowly

FIG. 12.

reduced, or again, by removing the pot and covering with a non-conducting cover.

When cold, the glass is found to be broken up into angular portions. Usually most of the glass must be rejected because of the contamination derived from the pot. Often, only about 20 p.c. is recovered as slabs of good glass.

For use, the angular portions are re-heated in a muffle furnace to softening point, then pressed into rectangular slabs and subsequently annealed. Fine annealing, for the removal of all strain, may take from two to three weeks.

The slabs are cut across, and opposite ends polished and examined in the polariscope for striae and strain, as also for bubble.

THE ANNEALING OF GLASS.

All articles of glassware, as also slabs of optical glass after being made into regular block form, need to be annealed in order to remove strain set up in them during the cooling process. Glass, being a very viscous material, and having only poor conductivity, sets hard on the exterior, while the mass in the interior is at a distinctly higher temperature and is more fluid. Consequently, stresses are set up on the exterior and strain on the inner layers, so that these inner layers tend to contract on to the outer ones. Where the exterior is chilled rapidly, as in the production of Rupert's drops, by allowing small blobs of molten glass to fall into water, the interior layers contract on to the exterior to such an extent as to leave an apparent bubble. The stress and strain in glass can be removed as soon as the glass is

sufficiently soft. If the glass is quite soft then the strain is relieved rapidly; or, in other words, annealing takes place quickly. If, on the other hand, the glass is only slightly removed from the rigid state, then annealing requires a considerable period of time. In practice, speed is an important factor in the production of most articles of glassware. In such case the articles are heated up to a temperature as high as possible, just short of deformation, so that the strain is rapidly removed. The annealing temperature employed under these conditions has been defined as the upper critical annealing temperature. The glass must subsequently be cooled down at a fairly slow and definite rate, until it has become so rigid that movement of different layers is practically impossible, so that no strain can be reintroduced. The temperature of sufficient rigidity has been described as the lower critical annealing temperature. In the case of optical glass it may be advisable to anneal at a temperature only slightly exceeding the lower critical annealing temperature. A slight reduction of temperature, which can be made very readily, is then sufficient to remove the glass from the region of possible recurring strain.

The actual upper annealing temperature and also the length of range between that and the lower value, obviously depend on the viscosity of the glass and on the rate of change of viscosity. These in turn depend on the composition of the glass.

The oxide constituents which tend to reduce the annealing temperature are sodium oxide, potassium oxide, and lead oxide. Lead-containing glasses can be readily annealed. English crystal glassware has an upper annealing temperature in the neighbourhood of 450°C., and most commercial types of lead glass are readily annealed at temperatures of 450°C. to 500°C. Window glass, and, generally speaking, sodium-calcium glasses, have an annealing temperature round about 550°-560°, although, according to the composition and the percentage of calcium oxide, the value may range from 540° to 610°. Miner's lamp glass which contains high silica and boric oxide content requires a temperature of approximately 590°, whilst resistance glass for chemical apparatus may need a temperature as high as 630° (English and Turner, *J. Soc. Glass Tech.* 1918, 2, 90; 1919, 3, 125 and 278; 1920, 4, 387).

In commercial practice two main types of furnace are used for annealing, namely, the kiln and the continuous annealing oven, called the 'lehr.'

The use of kilns is now almost entirely confined to heavy glassware for table use, and similar articles on which work such as cutting and engraving has subsequently to be done. In America gas-fired muffle kilns are used for thick glass jugs, tumblers, &c., with much advantage.

The continuous annealing oven, or lehr, consists essentially of a brickwork combustion chamber extending about 10 or 12 feet from front to back, and leading into a continuous tunnel, so that the total length from the front of the combustion chamber to the end of the lehr may be from 40 to 70 feet long, and in the case of window and plate glass very much longer, even exceeding 300 feet. The combustion

chamber is usually heated by gas, although oil and coke heating are still used, and in this section of the lehr the object aimed at is to maintain the articles at the required annealing temperature so that all strain is removed. The heated air and, except where the combustion chamber takes the form of a muffle, as in the modern "muffle-lehrs," the products of combustion may pass down the tunnel for a certain distance which can be controlled by flues and dampers. The width of the lehr is frequently about 6 feet, but may be as much as 12. The articles of glass-ware may be placed in pans which are linked on to one another and drawn through the lehr gradually, on pulleys attached to a fixed track. In a few cases the articles are placed in wagons which run on a track. In modern lehrs for mass production an endless belt carries a moving platform on which the articles are placed, and the speed of this platform is controlled mechanically according to the character of the glass and the time required for annealing.

The best test of satisfactory annealing is to examine the articles of glassware between crossed Nicols. A well-annealed specimen permits practically no light to pass through it, whilst a strained sample will transmit an amount of light dependent on the degree of strain.

Hardening of glass. This may be carried out either by the process of De la Bastie or by that of Siemens. In the former, discovered in 1873, the glass article, while still red hot, is quenched in a bath of oil or fat, the actual temperature of both glass and the bath, that is, the quenching range, depending both on the composition and thickness of the glass. Sodium-calcium glasses can withstand a greater quenching range than the lead glasses. The process results in the sudden chilling of the outer before the inner layers, so that the surface layers undergo greater shrinkage, causing them to be subjected to compression, whilst the inner layers, on the other hand, are in tension. Glass in this condition becomes less brittle, is more elastic, and capable of withstanding mechanical shock and sudden change of temperature, but if the surface is once broken the whole mass becomes shattered.

In Siemens' process, the temperature of pressed glass articles is rapidly but uniformly reduced in special moulds, or between metallic or clay plates maintained at a suitable temperature. Pavement lights treated in this manner resist cutting by a diamond.

Compound glass, the basis of the durax water-gauge tubes, was developed by Schott to give the same resistance to shock and change of temperature as hardened glass. A gathering of glass 16 (III) is made over 59 (III) and the cylinder drawn into tubing. The former has the larger thermal expansion (and contraction), so that on cooling the outer layer is under compression and the inner under tension. When the tubing is heated up both compression and tension become relaxed. Glass 59 (III) which forms the inner layer is also very resistant to the action of water and steam.

THE DECORATION AND AFTER-TREATMENT OF GLASS.

The processes by which glass may be ornamented or marked are numerous. They may

be divided into two classes, namely: (1) those carried out at the furnace during the formation of the article; (2) those dependent on the treatment of the surface. To the former belong such processes as casing, spinning, filigree, and mosaic working. The second class is divisible into two groups, according as the surface is treated by mechanical means, such as those involved in decoration by grinding, cutting, bevelling, polishing, engraving, sand-blasting, and frosting; or by the action of chemical reagents, such as in etching, silvering, iridising, and in glass painting. In rather a different category is the art of treating glass tubing or rod by lampworking or bench glass blowing.

Casing consists usually in spreading a uniform, thin layer of colour over an article of colourless glass. The coloured glasses most commonly used are ruby, blue, and opal. The essential conditions for casing are that the glasses shall have approximately equal coefficients of expansion and be soft or plastic. Glasses of fairly high lead content are very suitable for such treatment. One method of carrying out the operation is to make a gathering of the colourless glass, to blow it up slightly, and then dip into a pot of the coloured glass in such a way that a uniform outer layer is obtained. The combined gathering is then worked up by turning or blowing in the usual manner.

Banded glass, feather glass, filigree glass, and the insertion of an enamel backing in thermometer and other tubing are all special examples of casing. The enamel backing of tubing is a simple example. One method of making it consists in preparing a rod of opal glass and inserting a length of it in a vertical recess in a mould. The parison of colourless glass is introduced into the mould so as to come into contact with, and pick up the opal rod, after which the parison is marvered further to complete the union. A further gathering of colourless glass to cover the opal is then made and the whole mass drawn into tubing in the ordinary way.

For details of manipulative methods of decorating glassware at the furnace the reader should consult Hohlbaum's *Herstellung, Bearbeitung, und Verzierung des feineren Hohlglases*, 1911; Apsley Pellatt's *Curiosities of Glassmaking* contains a good account, but is unfortunately long out of print.

Cutting for decorative processes, largely employed for thick table-ware, is carried out in several stages. The pattern to be followed is marked out in chalk and then cut over by an edged iron wheel working in a vertical plane, the edge being constantly fed with sand and water. This first, or roughing process, leaves the cut portions with a roughened surface which is then gone over by a similar stone wheel, Craighleith stone being in common use, and finally by a wooden wheel using putty powder or other soft polishing material; or again, the final polishing stage may be carried out by immersion in an etching bath for a short period.

In some classes of pressed glassware the roughing process, or use of the iron wheel, is abolished by cutting the pattern in the mould so that the article receives the main impression at the furnace. Immediately after being pressed, the interior of such articles, usually

dishes and bowls, is 'fire polished' by the action of a hot gas flame which removes all roughness caused by the plunger of the press. The article may be sold without further treatment, or the pattern on it may be considerably improved by the use of the stone wheel and the subsequent polishing process.

Engraving is carried out by sharp-edged or bevelled copper wheels varying in size from that of a pin's head to 2 inches or more in diameter, the spindle carrying the wheel being fixed in the chuck of a lathe. The glass article is held in the engraver's hands against the rotating wheel.

Very pleasing effects are obtained by cutting or engraving designs on cased glass, especially where the cutting penetrates the outer coloured layer to the inner colourless one.

Glass grinding is carried out not only for decorative purposes, as described under 'cutting,' but also in the production of lenses and prisms, glass stoppers, both solid and hollow, all-glass syringes, and in the smoothing off of various articles whose ends would otherwise have sharp edges through being cracked off in a flame, articles such as blown tumblers, chimneys, and miners' lamp glasses. Lenses for grinding are embedded, a large number simultaneously, in pitch. The 'block' so produced may be flat if plane lenses are required or may have a curved surface corresponding to the lens curvature required. The grinding is done by a tool or head of iron with its surface shaped to the required curvature. In the grinding process this tool moves over the block of lenses in a path which is continuously varying. Fine carborundum or emery powder are the usual grinding media with water, and rouge follows in the polishing stage.

For the bottoms and edges of glass articles large carborundum wheels, revolving in the horizontal plane or carborundum cylinders with the flat-end set vertically, are used. In the former case, the articles to be ground are held vertically, in the latter, horizontally. In modern machines, a large number of articles, such as tumblers, can be treated in a very short time. Following such edge grinding, tumblers and similar articles are transferred to an 'edge melting' machine consisting of a continuous belt or track, by means of which the articles are carried through a zone of flame obtained from a double row of impinging gas jets where the edges are rounded off. Solid glass stoppers are ground by fixing in a chuck on a lathe and grinding with sand and water to the required degree and taper.

The grinding of hollow stoppers and internal grinding generally is done by soft steel or iron drills, suitably tapered and fixed in the chuck of the lathe. The rotating drill is inserted in the article and fed with water and one of the various grinding powders, which include diamond dust.

Sandblasting, employing the cutting action of wind-driven sand grains, was introduced by Tilghmann in America. The matt surface so produced can be controlled in extent and design by covering part of the glass surface. For this purpose a metal stencil may be employed, or a transfer comprising some definite design done in oil or fat or other soft material which prevents

the cutting action of the sand, and can subsequently readily be removed, leaving a pattern or design in clear glass.

Frosted glass, in which the surface is marked in fern-like patterns, is based on the discovery of Cailletet (Compt. rend. 1902, 134, 400), who found that a coating of glue or of gelatine, containing some neutral salt, when applied to glass exerted so powerful a disruptive action during its drying and shrinkage as to produce frost-like patterns when the dried coating was removed. The process is applied to window glass. One mixture employed consists of gum sandarac 18 parts, gum mastic 4, benzene 40, ether 200 and the mixture is poured uniformly over the previously cleaned surface. The sheets of glass after treatment remain in a drying room until the gelatine is set, and afterwards in a warm room to speed up the contraction of the coating.

Etching, by means of hydrofluoric acid or fluoride solutions, is commonly employed both for decorative purposes and for marking graduated glass instruments. The reaction may be expressed by the equation:

The effect produced depends on the type of glass, and on the nature and strength of the etching solution. The glasses of high lead content, as used largely for table-ware, are best suited for etching. Hard potash glasses and chemical resistance glass are only very slowly attacked. Dependent on the solution, one may obtain matt etching, clear etching, or may even get a polished surface. A good matt etching is obtained by immersion at ordinary temperature in a solution of 10 parts HF in 100 water, the solution being neutralised by potassium carbonate and 2 additional parts of HF then added. Aqueous solutions of ammonium fluoride, usually made as required by neutralising the acid with ammonium carbonate, act rather slowly. A mixture of ammonium fluoride 5 parts, hydrofluoric acid 2, and water 5, will produce at ordinary temperature a very rough matt etch. A satin etch is obtained by a solution of potassium fluoride 10, hydrochloric acid 1, water 100, the temperature of the solution being 40°–60°C. For line etching, used either for simple lines as on graduated instruments, and the simple line decoration on tumblers, or for etched designs as a substitute for engraving, dilute HF is used, a suitable solution for deep etching being hydrofluoric acid 1, sulphuric acid 1, water 4–5.

Acid polishing may be carried out by hydrofluoric acid in the presence of strong sulphuric, the liquid being agitated to prevent the deposition of fluorides which normally produce the matt surface effect.

If a line design is to be etched, the glass surface must previously be coated with a resistant material, and the design then traced by an instrument with a fine point. Two such 'resists' are: (1) asphalt 5, resin 2, tallow 1, Venetian turpentine 2, turpentine 12; (2) asphalt 5, resin 3, Venetian turpentine 1, turpentine 8, beeswax 1.5.

Other designs may be applied by means of a 'transfer.' The latter is prepared by engraving the design on a copper plate, coating the

latter with a 'resist,' and removing the excess so that only the cut design remains filled, then applying a piece of tissue paper to the design whereby a wax impression is transferred to the paper. The 'transfer' so produced is applied to the glass surface, the remainder of the latter not covered by the transfer being protected by a wax coating before the application of the etching agent, frequently used in paste form. After a few minutes the etching agent is washed off, leaving a matt surface design.

The markings on graduated instruments are usually rendered more clearly visible by rubbing into them finely-powdered barium sulphate, red lead, &c., or the introduction of a soft enamel.

Silvering for the production of mirrors was introduced in 1843 by Drayton to replace the tin amalgam method, but made a commercial success only through Liebig in 1867. The freshly-polished sheets of glass must be thoroughly cleansed previous to the application of the silvering solution, which is prepared from two essential solutions, one of silver nitrate, usually ammoniacal, the other an organic reducing agent, most often sugar. The rate of deposition depends on the temperature. Silvermann and Howe (J. Ind. Eng. Chem. 1917, 9, 1032) recommend for work at ordinary temperature, solutions of silver nitrate 0.636 gram made up with water to 100 c.c.; cane sugar, 34.2 grams dissolved in water, and made up to 100 c.c.; 80 p.c. methyl alcohol, and 0.8 p.c. formaldehyde solution. For the mixture, the volume used of the above four solutions are, respectively, 165, 10, 5, and 20. About 20 p.c. of the total silver content can be deposited in 40 minutes.

Copper deposits are usually made electrolytically on a previous coating of silver, the copper solution for electrolysis being of copper sulphate in Rochelle salt, made alkaline with caustic soda. By Chattaway's process (Proc. Roy. Soc. 1907, A, 80, 88) the deposition may be made direct. A clear solution is made by warming 1 part of freshly-distilled phenylhydrazine with 2 parts of water. To it, half its volume is added of a warm saturated solution of cupric hydroxide in strong ammonia. A hot solution of 10 p.c. potassium hydroxide is now added until a slight permanent precipitate is obtained. This liquid, when warmed in contact with a perfectly clean glass surface, gives a bright deposit of copper.

Aluminium deposits may be made on copper deposits by the metallic spraying process.

Iridescent glass, which in antique specimens is produced by surface decay, is artificially obtained by the action of metallic vapours. After being made at the furnace and while still red hot, therefore, the article is rotated rapidly inside an iron box or oven in which suitable metallic salts are volatilised. Various mixtures of salts are employed, such as: (1) stannous chloride 90 parts, strontium nitrate 5, barium chloride 5; (2) stannous chloride 90 parts, barium chloride 2, bismuth nitrate 5. The bright iridescent coating may be made matt by reheating several times in the mouth of the furnace. The iridescence may be greatly varied, as in Tiffany glass, by treating coloured glasses or those with patterns. Brilliant metallic effects may be obtained by adding a silver or a bismuth salt to the glass batch and

reheating the object, before iridising, in a reducing flame whereby a metallic surface deposit is produced.

Glass painting is carried out by the various colouring oxides and compounds elsewhere described in this article. They are mixed with a suitable flux in which they may or may not dissolve. In the former case, when applied to glass, the painting is transparent, unless specially rendered opaque as by the addition of stannic oxide, whilst in the latter it is non-transparent. The flux for gold purple is obtained by melting a mixture of quartz 4 parts, red lead 3, borax 6; for other colours, a flux made from quartz 2, red lead 6-9, borax 1, may be employed. The colouring materials are both finely ground and thoroughly mixed, and the mixture may be used directly for painting, or it may first of all be sintered or fritted, and again finely powdered. In either case the fine powder is thoroughly ground with turpentine or other oil as medium, applied with a brush to the glass, and the latter then heated in a muffle oven to a temperature sufficient (about 800°C.) for the thorough fusion of the flux and colour to a brilliant surface. Slow cooling down is then desirable. The vitreous paints so applied should, for successful burning in, have a coefficient of expansion not greatly different from that of the glass treated.

Glass beads and artificial gems. Glass beads are made from previously drawn tubing of varying diameter and bore, and of various colours. The tubing is next cut into lengths suitable for the size of the bead. If the latter is to be cylindrical, the beads may be made at the lamp by merely softening the cut ends to round off the edges. For spherical beads, the cut lengths are kneaded in moist clay, or clay and ground charcoal, to prevent collapse of the walls during subsequent heating. The heating is carried out in a revolving drum, to redness, whereby the rounded shape is given and the edges melted.

The thin-walled spherical beads are made by blowing thin bulbs and either filling them with wax or coating them internally with 'essence of pearl,' consisting of ground fish scales in ammonium chloride. The second method produces the pearl beads. (For method of applying the pearl coating, see O. Parkert, Sprechsaal, 1919, 52, 23 and 191.)

Artificial gems are made by adding suitable colouring material to a glass with high lead content, and therefore of high refractive index and brilliance when cut. The colourless paste, or strass, may be made from sand 100 parts, red lead 150, potash 30, the materials being of high quality. The resulting glass may be ladled into water and subsequently re-melted to obtain homogeneity and then ground for admixture with the colouring agent. *Rubies* may be prepared from 1000 strass, 1 purple of Cassius, 5 stannous oxide, 10 antimony oxide; *emeralds* from 1000 strass, 1 green chromium oxide, 8 cupric oxide; *amethysts* 1000 strass, 8 manganese dioxide, 2 cobalt oxide. The strass and colouring matter must be thoroughly fused together and made homogeneous. Small porcelain pots holding up to 50 lbs. glass are used.

Quartz glass. Whilst ordinary glasses are produced by the fusion of basic oxides with silica, and in some cases boric oxide, it must be

borne in mind that the use of such basic oxides is primarily to permit fusion to take place at the temperatures at present commercially attainable. Silica in itself possesses so many valuable properties that if it could be fused readily it would displace many types of glass. The high temperature of fusion restricts the scale on which melting can be carried out, but already, silica ware has become a recognised article of commerce, being worked into tubing, rod, beakers, flasks, crucibles, and other types of scientific apparatus, quartz threads for galvanometric mirror suspensions, nitric acid stills, sulphuric acid condensation plant, and chimneys for incandescent lamps.

Two types of fused silica ware are on the market, the transparent, made from quartz, and the opaque or translucent, produced from sand or crushed quartz. The transparent form is worked in the oxy-hydrogen flame, and the size of the article capable of being made is restricted to small crucibles and dishes, and the smaller sizes of flasks, beakers, and similar articles. The non-transparent silica can now be worked in masses up to 200 lbs. and tubes 4 inches or more in diameter form a stock article. The starting point for tubes is a hollow core of plastic silica produced by fusing a mass of white sand round a central core electrically heated, the core being removed when the cylinder has been formed and drawn into tubing in the ordinary way. In the plastic condition such a silica cylinder can be drawn into lengths of 90 or 100 feet. The rough outer surface of the tube may be ground down and may be glazed, either electrically or by an oxy-hydrogen flame.

For articles other than tubing, the cylinder is closed at one end and blown in a mould by compressed air.

The temperature required for fusing and working the sand is $1800^{\circ}\text{C}.$ – $2000^{\circ}\text{C}.$ As only a plastic and not a completely fused condition is reached, the fine air bubbles are not removed, and reflection from them gives rise to the silky, lustrous appearance characteristic of this type of fused silica. (See F. Bottomley, J. Soc. Chem. Ind. 1917, 36, 577.)

Quartz glass has an extremely small coefficient of linear thermal expansion, namely, 5.2×10^{-6} , and articles made from it can be heated to redness and quenched in cold water without fracture. Hence its value for heat-resisting glassware. Unfortunately, fused silica ware cannot be maintained for any considerable period at temperatures higher than $1000^{\circ}\text{C}.$ owing to its tendency to revert to the crystalline form stable at such temperature, namely, tridymite, when the article is liable to break down.

Fused silica is practically unacted on by water, and all acids except hydrofluoric acid and phosphoric acid above $400^{\circ}\text{C}.$ It is, accordingly, of very great value in precise chemical analysis where water, neutral salt solutions, and acids are alone concerned. Further, as a consequence of its resistance to solubility by water, and its non-hygroscopic character, fused silica is a very good electrical insulator. As an acid material itself, it is naturally attacked by the alkalis, and the use of silica crucibles is therefore much restricted since metallic oxides cannot be fused in them.

Transparent quartz is transparent to ultra-violet light and on this account finds special use in the form of plates, lenses, and wedges or prisms in optical apparatus, and in mercury vapour lamps. The refractive index for the D-line is 1.45847, and the dispersion constant ν 67.92 (Gifford and Shenstone, Proc. Roy. Soc. 1904, 73, 201).

W. E. S. T.
GLASS OF ANTIMONY *v.* Antimony crocus, art. ANTIMONY.

GLASS, TOUGHENED, *v.* GLASS.

GLAUBER'S SALT. Sodium sulphate (*v.* SODIUM).

GLAUBERITE *v.* CALCIUM.

GLAUCINE $\text{C}_{21}\text{H}_{25}\text{O}_4\text{N}$ occurs in *Glaucium flavum* (Crantz) along with protopine (Battandier, Chem. Soc. Abstr. 1892, 62, i. 893). Crystallises in rhombic prisms, m.p. 119° – 120° , $[\alpha]_{\text{D}} +113.3^{\circ}$ in alcohol, is a tertiary base and contains four -OMe groups (Fischer, Arch. Pharm. 1901, 239, 426). It has been synthesised by Gadamer (*ibid.* 1911, 249, 680) and shown to be phenanthreno-*N*-methyltetrahydropapaverine, and therefore is closely related to dicentrine.

Glaucine is tasteless and induces narcosis, accompanied by some tetanising action.

GLAUCONITE. (*Glauconie*, Fr.; *Glaukonit*, Ger.) Hydrated silicate of iron, potassium, &c., of variable composition, but approximating to the formula $\text{KFe}^{+++}\text{Si}_2\text{O}_5\cdot\text{H}_2\text{O}$, found as small rounded grains in sedimentary rocks. It was named in 1828, from *γλαυκός*, bluish-green, on account of its characteristic colour, which is of various shades of dark green. The typical occurrence of the mineral is the Greensand formation (below the Chalk) of the Cretaceous system, but it is also met with in sands, sandstones, marls, and limestones of all ages from the Cambrian, and is forming at the present day on the floor of the ocean. The granules measure about $\frac{1}{4}$ to 1 mm. in diameter. Under the microscope they show a clear green or yellowish-green, slightly pleochroic and birefringent material embedded in a network of black, optically isotropic, organic matter, the latter having the composition of humic acid. Since the glauconite material has the property of taking up dyes and of absorbing water, up to 30 p.c., from a moist atmosphere, it is probably colloidal, the optical birefringence being the result of strain set up by the network of organic matter. The mineral is decomposed by hot concentrated hydrochloric acid, and before the blowpipe it is fusible with difficulty to a black magnetic slag.

Analysis I is of grains isolated from a calcareous sandstone in the Upper Greensand at Woodburn, Carrickfergus, Co. Antrim (A. P. Hoskins, Geol. Mag. 1895). II from the Cambridge Greensand (G. D. Liveing, Geol. Mag. 1866). III gives the extreme values shown in ten analyses of glauconite grains isolated from

Eocene, Cretaceous, and Jurassic sandstones and from Lower Silurian limestone from various Russian localities; sp.gr. 2.40–2.87, varying like the colour—yellowish-green and dark green—with the percentage of iron (K. D. Glinka, 1896). IV, grains forming 83 p.c. of a sandy deposit dredged at a depth of 556 fathoms from the Pacific off Panama (W. A. Caspari, Proc. Roy. Soc. Edin. 1910, xxx, 364). V, similar material dredged at 110 fathoms from the Agulhas Bank, South Africa (W. A. Caspari, *loc. cit.*). Numerous analyses of glauconite are quoted by C. K. Leith, Mon. U.S. Geol. Survey, 1903, xliii, 240. Analyses of Swedish glauconites, by N. Söhlbom, Bull. Geol. Inst. Univ. Upsala, 1916, xv, 211.

Closely allied to glauconite are the minerals celadonite (v. green-earth) and greenalite (*q.v.*).

The greensand of England, consisting mainly of sandy beds with quartz grains, intermixed with glauconite, is developed in the Wealden area, the Isle of Wight, and extends from Berkshire and Oxfordshire to Norfolk and Lincolnshire. Some of the limonitic iron-ores of these districts may possibly, like those of the Lake Superior region, have been derived by the alteration of glauconite. The same formation has also a wide distribution on the Continent. In America, greensand and glauconitic marls of Cretaceous and Tertiary age are developed in New Jersey, Virginia, Kentucky, and Tennessee. The glauconite marls of New Jersey contain K₂O 1.54–7.08 p.c. with P₂O₅ 0.19–6.87, and have been extensively used in the raw state as an agricultural dressing (*v. Ann. Rep. State Geologist New Jersey*, 1886, 1892, 1893). Those from Virginia have been used in the preparation of commercial fertilisers. Attempts have been made to extract potash from greensands (U.S. Geol. Survey, Min. Res. for 1911, 1912, ii, 901).

The frequent association of phosphatic nodules with glauconite deposits has some bearing on the origin of glauconite. The terrigenous deposits of green mud and sand formed on the floor of the ocean at depths of about 200 to 1000 fathoms, and found by the 'Challenger' Expedition to be of wide distribution, particularly off continental coast lines composed of igneous rocks, contain this mineral in considerable amount. The potash set free by the weathering of the feldspars and micas of these rocks and carried into the sea is conserved by the formation of glauconite, but apparently only through organic agencies, which at the same time gave origin to the phosphatic nodules. Grains of glauconite are frequently found filling the chambers of foraminifera and other organisms; and in the artificial production of the

mineral the presence of an organic acid seems to be essential (W. A. Caspari, *loc. cit.*).

L. J. S.

GLAZES *v.* FRITTS and GLAZES; also POTTERY.

GLIADIN *v.* GLUTEN.

GLOBULINS *v.* PROTEINS.

GLONOLIN. Syn. for nitroglycerin.

GLUCINUM (*Beryllium*); Gl.; 9.1 Parsons, 9.017 Hönlischmid, occurs in *beryl*, *euclase*, *phenacite*, *chrysoberyl*, *leucophane*, *helvite*, *davallite*, and other minerals. The element was detected by Vauquelin in 1798, but the metal was first isolated by Wöhler in 1828 by fusing the chloride with potassium. Glucinum can be prepared by the electrolysis of a fused mixture of the chloride with sodium or ammonium chloride (Borschers, Chem. Zentr. 1895, ii, 13), or of the fused double fluorides, GlF₂, NaF; or GlF₂, 2NaF (Lebeau, Compt. rend. 1898, 126, 744).

Glucinum may be prepared by electrolysis of the minerals containing it between metallic electrodes in the presence of fluorine or one of its compounds, either alone or with the addition of a halogen compound of an alkali or alkaline earth (Liebmann, J. Soc. Chem. Ind. 1899, 282; Eng. Pat. 3497).

Warren (Chem. News, 1895, 72, 310) describes the following process:—

Pulverised and lixiviated beryl is fused for 3 hours in a blast furnace with four times its weight of sodium carbonate, after which the solidified mass is decomposed by superheated steam, and then by hydrochloric acid, evaporated to dryness and extracted with water. The solution is now freed from iron and chromium by the acetate method, and excess of sodium carbonate added; the precipitate is treated with excess of sulphurous acid, whereby the alumina and glucina pass into solution. On boiling, the alumina is precipitated, excess of ammonium carbonate is now added to the filtered solution, which is well boiled. The precipitate of glucinum carbonate thus obtained is ignited with lampblack out of contact with air, then submitted to the action of bromine at a red heat in clay retorts, when glucinum bromide distils over and is reduced electrolytically. It is also prepared by the reduction of the oxide with aluminium (Just and Mayer, J. Soc. Chem. Ind. 1909, 528; D. R. P. 208402).

Or the finely powdered mineral is heated at 850° for half an hour with twice its weight of sodium silicofluoride. The product, which consists of silica and the double fluorides of sodium and aluminium and sodium and glucinum, is extracted three times with boiling water. The extract is filtered and to the filtrate boiling aqueous sodium hydroxide is added in slight excess. The oxide of glucinum precipitated, along with a little alumina and silica, is dissolved in sulphuric acid, and glucinum sulphate crystallises out on concentrating the solution (Copaux, Compt. rend. 1919, 168, 610).

Glucinum is a hard metal, with a bright silver-white colour, melting at 1278±5°; sp.gr. 1.93; sp.ht. 0.4246. Glucinum has the largest heat of fusion of any metal, corresponding with its high melting-point and low atomic weight. The powdered metal takes fire when heated in air, burning with great brilliancy, and dissolves readily in dilute acids, also in caustic alkalis,

with evolution of hydrogen; but it does not decompose water even at a red heat. It is generally regarded as divalent (Combes, *Compt. rend.* 1894, 119, 1221; Henry, *ibid.* 1895, 121, 600; Retgers, *Zeitsch. physikal. Chem.* 1896, 20, 481; Galecki, *Zeitsch. Elektrochem.* 1908, 14, 767). Tanatar (J. Russ. Phys. Chem. Soc. 1904, 36, 82; 1906, 38, 850), from various organic derivatives, regards the metal as tetravalent.

Glucinum yields useful alloys with various metals by heating the oxides with carbon in the electric furnace, or by the electrolysis of a mixture of the fused metal with the double fluoride of glucinum and sodium in a carbon crucible as anode. The 5 p.c. alloy with copper is malleable readily filed and polished, and unaffected by air; an alloy containing less glucinum is sonorous (Lebeau, *Compt. rend.* 1897, 125, 1172; 126, 744; Liebmann, D. R. P. 94507, 1896; *Chem. Zentr.* 1898, i. 484).

Glucinum alloys readily with aluminium (U.S. P. 1254987, 1918), and it is claimed that the alloys are harder, stronger, and lighter than aluminium, melt at a higher temperature, take a high polish, and make excellent castings.

Compounds. *Glucinum oxide* or *glucina* GlO is obtained from beryl by heating the coarsely powdered mineral with 6 parts of ammonium hydrogen fluoride for 10–12 hours at a temperature not exceeding a dull red heat. The mass is then treated with water, and the insoluble aluminium fluoride removed by filtration. The filtrate is evaporated to dryness, and heated with strong sulphuric acid, thus removing fluorine and silica. The solution obtained on adding water is treated with nitric acid to oxidise iron, and the filtered liquid is poured into an excess of ammonium carbonate solution. Hot water is now added, after which the solution is filtered, mercuric chloride added, and the remaining iron is precipitated with ammonium sulphide. The filtered solution is boiled, whereupon basic glucinum carbonate is precipitated, which, on ignition, yields pure glucina (Gibson, *Chem. Soc. Trans.* 1893, 909; Lebeau, *Compt. rend.* 1895, 121, 641; Pollok, *Chem. Soc. Trans.* 1904, 603). Various other methods of preparing glucina from minerals have been described by Krüss and Moraht (*Ber.* 1890, 23, 727), and by Bran and Oordt (*J. Soc. Chem. Ind.* 1906, 1147; *Eng. Pat.* 15973, 1906).

It is a white amorphous powder of sp.gr. $3\cdot016$, which fuses at $2450 \pm 50^\circ$, volatile near its melting-point, and forming, after cooling, a crystalline mass, which is harder than ruby. In the electric furnace it is reduced by, and forms crystalline compounds with, boron, silicon, and carbon (Lebeau, *Compt. rend.* 1896, 123, 818). Heat of formation $135\cdot9 \pm 0\cdot9$ p.c. (Mielenz and v. Wartenberg).

The oxide acts as a feeble acid towards strong bases, forming the salts $\text{Gl}(\text{OK})_2$, whilst with feeble acids it acts as a base, yielding such salts as $(\text{GISO}_2)_2\cdot\text{GlO}$ (Krüss and Moraht, *l.c.*; Seubert and Elten, *Zeitsch. anorg. Chem.* 4, 44). It is insoluble in water, but dissolves in strong sulphuric acid, yielding the sulphate, and also in fused potassium fluoride (Duboin, *Compt. rend.* 1896, 123, 698). According to Winkler (*Ber.* 1891, 24, 1966), when the oxide is heated

with magnesium at red heat in a current of hydrogen, *glucinum hydride*, having an unpleasant smell and slowly decomposed by warm water is formed.

Glucinum hydroxide $\text{Gl}(\text{OH})_2$ is formed by precipitating glucinum salts with ammonia, and can be separated from aluminium and iron by digestion with glacial acetic acid, when it is converted into a basic glucinum acetate, which is readily soluble in chloroform (Haber and Oordt, *Zeitsch. anorg. Chem.* 1904, 40, 465; D. R. P. 155466; Oordt, *J. Soc. Chem. Ind.* 1904, 799).

Glucinum hydroxide, when freshly precipitated, is gelatinous, readily absorbs carbon dioxide, and is soluble in dilute acids, alkalis, and alkali carbonates. On being heated with water, alkali carbonates, or ammonia, or when allowed to stand for some time at the ordinary temperature, it loses the above-described properties (Haber and Oordt, *Zeitsch. anorg. Chem.* 1904, 38, 377; D. R. P. 165488; cf. Bleyer and Kaufmann, *Zeitsch. anorg. Chem.* 1913, 82, 71). Unlike aluminium hydroxide, glucinum hydroxide is quite insoluble in ammonia, or in methyl- or ethylamine (Renz, *Ber.* 1903, 36, 2751). It combines with hydrogen peroxide to form the compound $3\text{GlO}\cdot 4\text{H}_2\text{O}_2\cdot 8\text{H}_2\text{O}$, containing hydrogen peroxide of crystallisation. A *basic peroxide* $2\text{GlO}_2\cdot 3\text{GlO}\cdot 8\frac{1}{2}\text{H}_2\text{O}$ is formed by treating basic glucinum carbonate $\text{GlCO}_3\cdot 5\text{GlO}\cdot 8\text{H}_2\text{O}$ with hydrogen peroxide which is moderately stable and exhibits all the usual properties of peroxides (Komarovski, *J. Russ. Phys. Chem. Soc.* 1913, 45, 608).

Glucinum chloride GlCl_2 is formed by passing a current of dry chlorine over a mixture of the oxide and sugar charcoal, heated to bright redness in a porcelain tube (Pollok, *Chem. Soc. Trans.* 1904, 604). Heat of formation $112\cdot6 \pm 0\cdot4$ p.c. (Mielenz and v. Wartenberg; *Zeitsch. anorg. Chem.* 1921, 116, 267). It forms white needle-shaped crystals, melting at 400° , and boiling at about 500° . It forms a hydrated chloride $\text{GlCl}_2\cdot 4\text{H}_2\text{O}$, and also double salts with platinum, tin, and mercuric chloride, and with iodine trichloride (Weinland and Schlegelmilch, *Zeitsch. anorg. Chem.* 1902, 30, 134).

Glucinum iodide GlI_2 is obtained by heating the carbide in a stream of hydriodic acid, carrying iodine vapour; it melts at 510° , combines with ammonia to form $2\text{GlI}_2\cdot 3\text{NH}_3$; and yields crystalline compounds with aniline, pyridine, and other organic bases. With bromine it yields the corresponding bromide (Lebeau, *Compt. rend.* 1898, 126, 1272). It forms a double salt with lead iodide (Mosnier, *Ann. Chim. Phys.* 1897, 12, [vii.] 374).

Glucinum fluoride is obtained by the action of hydrofluoric acid on the oxide. It is soluble in water and alcohol, melts at 800° , and is converted by oxygen into the oxyfluoride $5\text{GlF}_2\cdot 2\text{GlO}$ (Lebeau, *l.c.*; and 1418).

Glucinum carbonates. Basic carbonates are formed when a glucinum salt is treated with an alkali carbonate. If carbon dioxide be passed through the aqueous solution or suspension of the basic carbonate, and the solution then evaporated in an atmosphere of carbon dioxide, the normal salt $\text{GlCO}_3\cdot 4\text{H}_2\text{O}$ separates.

The glucinum borate $5\text{GlO}\cdot \text{B}_2\text{O}_3$, described

by Krüss and Moraht, is probably a solid solution of boric acid in glucinum hydroxide. According to Bleyer and Paczusi, no definite compounds are formed by the interaction of glucinum hydroxide with aqueous solutions of boric acid.

Glucinum sulphide is a white amorphous mass, not decomposed by water, but readily by acids, even carbonic acid. It burns with a bright flame in contact with strong nitric acid and is decomposed by chlorine or bromine with formation of the respective haloid compounds. It is prepared by heating glucinum chloride in a current of hydrogen sulphide (Miebelner and Steinmetz, *Zeitsch. anorg. Chem.* 1913, 82, 92).

Glucinum sulphates. The following sulphates have been obtained: $\text{GlSO}_4\cdot 6\text{H}_2\text{O}$; $\text{GlSO}_4\cdot 4\text{H}_2\text{O}$; $\text{GlSO}_4\cdot 2\text{H}_2\text{O}$; $\text{GlSO}_4\cdot \text{H}_2\text{O}$; GlSO_4 (Parsons, *J. Amer. Chem. Soc.* 1904, 26, 1433; Leri Malvano, *Zeitsch. anorg. Chem.* 1906, 48, 446). The anhydrous salt obtained at 250° is stable up to 530° – 540° , and thus allows of the estimation of glucinum in the form of its sulphate. Glucinum sulphate does not form acid salts even when dissolved in sulphuric acid. Also the *thio-sulphate* $\text{GlS}_2\text{O}_3\cdot 11\text{H}_2\text{O}$ (Faktor, *Chem. Zentr.* 1901, ii, 878); and *sulphites* (Seubert and Elten, *Zeitsch. anorg. Chem.* 4, 44).

Glucinum chromate $\text{GlCrO}_4\cdot \text{H}_2\text{O}$ has been obtained by evaporating a solution of the carbonate in concentrated chromic acid. It forms reddish-yellow crystals, which are decomposed by water, forming the basic salt $\text{GlCrO}_4\cdot 6\text{Gl}(\text{OH})_2$, which can also be obtained by precipitating glucinum sulphate with ammonium chromate (Glassmann, *Ber.* 1907, 40, 2402).

Glucinum carbide GlC_2 is obtained by heating the oxide with carbon in the electric furnace (Henry, *Compt. rend.* 1895, 121, 600; Lebeau, *ibid.* 496). It forms microscopic yellowish-brown crystals, which scratch quartz, and are decomposed by water with formation of pure methane. Also decomposed by hot concentrated alkalis, and by halogen acids, yielding the corresponding halide.

Glucinum nitride Gl_3N_2 is obtained by heating the metal in nitrogen, or, better, in ammonia or cyanogen. Melts at 2200° , and solidifies to colourless crystals which scratch glass, stable in air, and only slowly decomposed by boiling water. Chemical properties similar to those of aluminium nitride, but is decomposed more readily by dilute acids and hot concentrated alkali hydroxides.

Glucinum borocarbide $\text{C}_4\text{B}_2\text{Gl}_6$, obtained when glucina is heated with boron in a carbon boat in the electric furnace, forms brilliant crystals with a metallic lustre; sp.gr. 2.4, readily soluble in acids, and not decomposed by water (Lebeau, *Compt. rend.* 1898, 126, 1347).

Glucinum phosphates (Rammelsberg, *Chem. Zentr.* 1891, ii, 790; Sestini, *Gazz. chim. ital.* 20, 313; Ouvrard, *Compt. rend.* 1890, 110, 1333); *arsenates* (Bleyer and Müller, *Zeitsch. anorg. Chem.* 1912, 75, 285); *phosphates*, *phosphite*, and *hypophosphite* (*ibid.* 1912, 79, 263); *tungstates* and *silico-tungstates* (Tanatar and Kurowski, *J. Russ. Phys. Chem. Soc.* 1909, 41, 813; Wyruboff, *Bull. Soc. Franc. Min.* 1896, 19, 240), *molybdates* (Rosenheim and Wose, *Zeitsch. anorg. Chem.* 1897, 15, 283, 306, 307), and

columbates (Larsson, *ibid.* 1896, 12, 188), *metavanadate* (Brinton, *J. Amer. Chem. Soc.* 1916, 38, 2361) have been obtained. Organic acids react with glucinum carbonate, forming salts of the type Gl_4OX_6 , $\text{Gl}_4\text{OX}_3\text{X}'_3$, and $\text{Gl}_4\text{OX}_3\text{X}'_3$ (X, X' being organic radicles) (Tanatar and Kurowski, *J. Russ. Phys. Chem. Soc.* 1907, 39, 936; Lacombe, *Compt. rend.* 1902, 134, 772; Glassmann, *Ber.* 1908, 41, 33; Parsons and Sargent, *J. Amer. Chem. Soc.* 1909, 31, 1203).

Glucinum basic acetate $\text{GlO}_4(\text{CH}_3\text{CO}_2)_3$ is readily soluble in chloroform and may be distilled unchanged (b.p. 330°). By this means glucinum may be separated quantitatively from iron and aluminium.

Other organic compounds of glucinum are described by Wyruboff (*l.c.*); Kurowski (*J. Russ. Phys. Chem. Soc.* 1907, 39, 1630; 1908, 40, 580, 787); Curtius and Rissom (*J. pr. Chem.* 1898, [ii.] 58, 261); Glassmann (*Ber.* 1907, 40, 3059; *Chem. Zeit.* 1907, 31, 8).

GLUCONASTURTHIN, GLUCOTROPÆOLIN v. GLUCOSIDES.

GLUCOSAMINE v. CARBOHYDRATES.

GLUCOSE v. CARBOHYDRATES.

GLUCOSIDES. The glucosides are a large and important group of substances occurring almost exclusively in the vegetable kingdom, which, by the operation of hydrolysis, involving the addition of the elements of water, are resolved into sugar and another compound not belonging to the class of carbohydrates. The sugar thus formed is usually glucose or rhamnose; certain glucosides yield other carbohydrates, some of which have not yet been identified.

The hydrolysis may often, but not always, be rapidly effected by heating with dilute acids. It may also be brought about by the action of appropriate enzymes, such as emulsin, myrosin, &c.

Glucosides are, in many cases, far more resistant to hydrolysis by acids than is generally supposed, and almost invariably their behaviour towards acids is in marked contrast to the ease with which they are hydrolysed by the appropriate enzyme. There is some evidence that the nature of the acid is not without influence, some glucosides being more easily hydrolysed by hydrochloric than by sulphuric acid.

As a rule, a plant containing a glucoside also contains a corresponding enzyme capable of hydrolysing it, the enzyme being present also in allied species which do not contain the glucoside. On the other hand, the elder (*Sambucus nigra*, Linn.) affords an example of a plant containing a glucoside, accompanied by very little of the corresponding enzyme. Enzyme and glucoside do not exist in the same cell, but they are brought together should the cellular structure be damaged or rendered permeable.

In the greater number of cases only one variety of sugar is formed on hydrolysing a glucoside, although, in some instances, two different carbohydrates are produced, or possibly two or more glucose molecules; in such cases the simple sugar molecules are probably united as di- or tri-saccharides. Using appropriate enzymes or acids of different degrees of concentration, it is possible to remove the sugar groups one at a time, and so form new glucosides. Thus, from amygdalin, by the action of the

enzyme amygdalase, which is present in some varieties of yeast, the glucoside of mandelonitrile is formed together with glucose.

The majority of the glucosides are colourless, crystalline neutral compounds, one or two are basic, and a few are acidic. They are usually soluble in water and alcohol, and but very sparingly soluble in ether. They crystallise with one or more molecules of water, which is lost on heating. They are charred when heated to a moderately high temperature, occasionally a sublimate of the non-sugar component being obtained. They are not acted upon by Fehling's solution, so far as the sugar part of the molecule is concerned. Many of them are optically active, and, as a rule, rotate rays of polarised light to the left, although derived from a dextro-rotatory carbohydrate. Pictet and Goudet (Helv. Chim. Acta, 1919, 2, 698) consider that this property may be due to the glucosides containing a glucosan rather than a glucose ring structure, since they have obtained *l* glucosan by distillation under reduced pressure of a number of glucosides. They have often a bitter taste, and a therapeutic action, being the active principle of many plant extracts used in pharmacy. The general behaviour of the glucosides and their close relations to the synthetic methyl glucosides (*v.* CARBOHYDRATES) establishes their structure beyond doubt as :

In many instances the radicle R is a polyhydroxy-compound, and it is not in all cases certain to which of the hydroxyl groups the sugar residue is attached.

It is further of interest that no natural glucoside has been found in two stereoisomeric forms corresponding to the α - and β -methyl glucosides. Judging from their behaviour towards the emulsin of almonds, many of the natural compounds are considered to be derived from β -glucose. This view has been confirmed in some instances by the fact that glucose is first separated as the β -form of low rotatory power on hydrolysing the glucoside, and afterwards undergoes isomeric change to the equilibrated mixture of α - and β -glucose. In fact,

no glucosidic derivative of α -glucose has yet been described as occurring naturally.

In addition to a few of the natural glucosides of plants, other glucosides have been prepared in the laboratory. The isomeric α - and β -methyl glucosides are discussed under CARBOHYDRATES; glucosides of primary alcohols, *e.g.* ethyl, glyceryl, and benzyl glucosides, are obtained by the same method by the interaction of glucose and alcohol in presence of hydrogen chloride.

An alternative method first used by Colley involves the interaction of tetraacetylchloroglucose $\text{C}_6\text{H}_7\text{OCl}(\text{OAc})_4$, and the sodium derivative of alcohols or phenols. Sodium chloride and the tetracetate of the desired glucoside are formed, and the latter is subsequently hydrolysed to eliminate the acetyl groups. In this way the natural compounds, helicin, methylarbutin, and a number of new glucosides, including those of the terpenes and of some thiophenols, have been prepared.

Acetylglucoside. The employment of crystalline acetylglucoside in synthetic work has been extensively adopted, and Emil Fischer in particular has prepared a number of new types of glucoside by this means. The method has been modified according to the nature of the non-sugar compound employed, and the variants on the general method may be summarised as follows :—

(a) Treatment of silver salts of purines, thiourethanes, &c., with acetobromoglucose ;

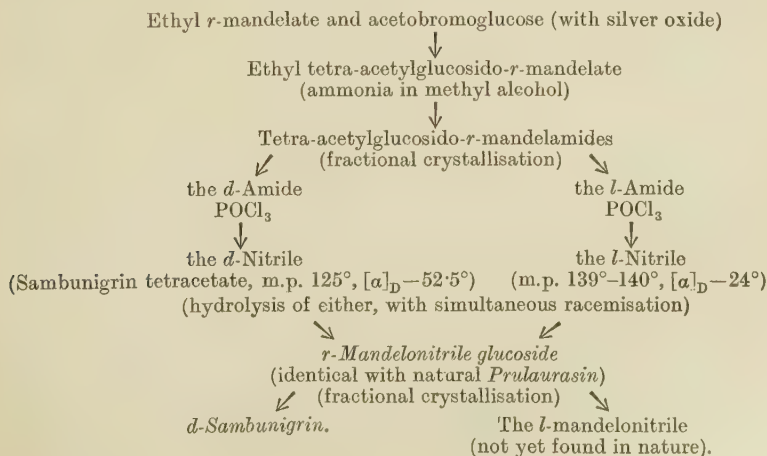

(b) Treatment of alcohols or phenols with the reagent and silver oxide in ether ;

(c) Shaking an alkaline solution of a phenol with an ethereal solution of acetobromoglucose ;

(d) Treatment of phenolic compounds and the reagent in presence of a small quantity of quinoline.

The main types of synthetic glucosides obtained by these reactions can be classified in a few groups :—

Mandelonitrile glucosides (E. Fischer and Bergmann, Ber. 1917, 50, 1047). An interesting sequence of reactions has led to the synthesis of several of the naturally-occurring mandelonitrile glucosides ; the work may be represented schematically as follows :—

The glucoside *linamarin*, which occurs in nature, has also been synthetically prepared by E. Fischer by a similar series of reactions.

Purine glucosides (E. Fischer, Ber. 1914, 47, 210, 1058, 1377, 3193). By union of the silver derivatives of purines with acetobromoglucose, followed by removal of the acetyl groups by means of ammonia, glucosides, galactosides, and rhamnosides of adenine, guanine, hypoxanthine, theophylline, theobromine, &c., have been prepared; theophylline glucoside was further condensed with phosphoryl chloride in pyridine solution, yielding thereby *hydrated theophyllineglucosidophosphoric acid* (a synthetic nucleotide). The method of preparation has been patented by Bayer & Co. (D. R. P. 281008).

Glucosides of complex alcohols. Glucosides of geraniol, cyclohexanol, &c., have been prepared by treating the ethereal solution of the alcohol and acetobromoglucose with silver oxide (E. Fischer and Helferich, Annalen, 1911, 383, 69).

Sitosterol and cholesterol glucosides, closely resembling the phytosterolines, were synthesised by Salway (Chem. Soc. Trans. 1913, 103, 1022).

Phenol glucosides. Phloroglucinol-, resorcinol-, and 2,4,6-tribromophenol-*d*-glucosides were obtained by E. Fischer and Strauss (Ber. 1912, 45, 2467) by shaking the alkaline phenolic solution with an ethereal solution of acetobromoglucose and subsequent removal of acetyl groups. The former compound is identical with the glucoside obtained from phloridzin by Cremer and Seuffert (Ber. 1912, 45, 2565), and is capable of producing diabetes.

A mixture of α - and β -glucosides was prepared by warming phenols (e.g. resorcinol) or menthol with acetobromoglucose in presence of quinoline (E. Fischer and von Mechel, Ber. 1916, 49, 2813; E. Fischer and Bergmann, Ber. 1917, 50, 711).

Arbutin has been prepared completely free from methyl arbutin by synthesis from acetobromoglucose and quinol in presence of alkali (Mannich, Arch. Pharm. 1912, 250, 547).

Gluco-*p*-oxybenzophenone, m.p. 178°–179°, α_D^{20} –56°, and **gluco-*p*-acetophenone** have been similarly synthesised. The latter, synthesised by Mauthner in 1912, is identical with Tanret's *picein*, isolated from pine needles (Mauthner, J. pr. Chem. 1913, [ii.] 88, 764).

Glucosides of phenolcarboxylic acids have been similarly prepared by employing the glucose reagent with an alkaline solution of the methyl ester of the acid, followed by subsequent hydrolysis; **gluco-*m*-oxybenzoic acid**, $C_{13}H_{16}O_8$, melts at 143°–144°, and has $[\alpha]_D^{20}$ –68° (Mauthner, J. pr. Chem. 1911, [ii.] 83, 556).

Interaction of acetobromoglucose and silver salicylate (P. Karrer, Ber. 1917, 50, 833) in boiling toluene solution yields two isomeric substances, *tetra-acetylglucose salicylate*

crystals, m.p. 185°, and *salicylic acid tetra-acetylglucoside* $COOH \cdot C_6H_4 \cdot O \cdot C_6H_7O_5Ac_4$, laevorotatory, m.p. 167°.

The former gives a violet coloration with ferric chloride, and with methyl alcoholic ammonia yields salicylamide; the latter gives no coloration, and is soluble without fission in very dilute aqueous ammonia.

The formation of these two isomerides is attributed to the coexistence of two modifications of silver salicylate:—

It has been shown in addition (Karrer, Nägeli and Weidmann, Helv. Chim. Acta, 1919, 2, 242; 1921, 4, 130) that the silver salts of many *d*-hydroxy- and *d*-amino- acids give a mixture of glucoside and glucose esters of the acids, whereas *m*- or *p*-hydroxy acids yield only glucose esters.

Mustard oil glucosides. Schneider and collaborators (Ber. 1914, 47, 1258, 2218, 2225) have synthesised glucosides of the general formula $R.N : C(OEt).S.C_6H_{11}O_5$ from acetyl bromoglucose and silver salts of thiourethanes, the silver salt of thioglucose being obtained as a by-product.

Anhydromethylglucoside (E. Fischer and Zach, Ber. 1912, 45, 456, 2068). When triacetylglucoside bromohydrin is warmed with baryta solution, anhydromethylglucoside is produced, and distils without decomposition at very low pressures. The anhydrosorbitol obtained from it by reduction is isomeric with *styracitol* (found in *Styrax obassia*) (Asahina), and suggests that anhydrides of dextrose and of glucosides may occur in nature.

A number of glucoside-like derivatives of glucosamine, synthesised from triacetyl bromoglucosamine, have been described, chiefly by J. C. Irvine and co-workers.

Aminomethylglucosides. An aminomethylglucoside was produced by methylation of triacetyl bromoglucosamine (Irvine, McNICOLL and Hynd, Chem. Soc. Trans. 1911, 99, 250; 1912, 101, 1128).

A second, different, aminomethylglucoside was formed by the action of ammonia upon methylglucoside (E. Fischer and Zach, Ber. 1911, 44, 132).

α -Aminohelicin and α -aminosalicin. These were obtained synthetically from triacetyl bromoglucosamine hydrobromide and salicyl aldehyde and saligenin respectively (Irvine and Hynd, Chem. Soc. Trans. 1913, 103, 41).

Morphine glucosamine. In the preparation of aminohelicin and aminosalicin morphine was employed as the alkaline or basic condensing agent, and as by-product there appeared morphineglucosamine (Irvine and Hynd, Chem. Soc. Trans. 1913, 103, 41).

Enzyme syntheses. The synthesis of glucosides from their components by means of enzyme action has been developed by several workers, especially Bourquelot and his collaborators, whose results are described in the following papers:—

Ann. Chim. Phys. 1913, [viii.] 28, 145; Compt. rend. 1912, 155, 1552; 1913, 157, 72, 732; 156, 957; 1915, 160, 742; 161, 184.

It has been found that the same enzyme which hydrolyses a glucoside in presence of excess of water will synthesise it in presence of excess of the hydroxy-component of the glucoside; moreover, if conditions are employed in which the reagents are present in equimolecular or other definite quantities a state of equilibrium is reached which can be approached from either set of components—glucoside and

water, or sugar and non-sugar component of the glucoside.

An interesting suggested application of this method as a qualitative polarimetric test for glucosides in plants has been made as follows:—the suspected material is hydrolysed by an enzyme, the change in rotation is observed, the solution heated to 100°C., and cooled, more enzyme is added, and if displacement of the rotatory power towards the original value occurs, it may be taken as an indication of the presence of a glucoside in the original material.

It may be mentioned here that Bertrand and Compton (Compt. rend. 1912, 154, 1646) assert that hydrolysis by emulsin of glucosides is not reversible.

A point arising in the course of Bourquelot's work was the discovery that, contrary to general assumption, the activity of emulsin is not invariably and completely inhibited by alcohol. Thus, *gentiopicrin* and *salicin* may be hydrolysed, at all events partially, by emulsin in comparatively concentrated alcoholic solution (Bourquelot and Bridel, J. Pharm. chim. 1911, [vii.] 4, 385; Compt. rend. 1912, 154, 944).

As examples of the general method of glucoside synthesis by enzyme action may be mentioned the preparation of methyl-, geranyl-, and cinnamyl- β -glucosides and of benzyl- β -galactoside from the corresponding alcohols and sugars in presence of emulsin. On the other hand, similar α -glucosides have been produced by the action of the enzyme (α -glucosidase) contained in the aqueous extract of bottom yeast.

The synthesis of glucosides of glycol and glycerol, difficult by other means, was effected by the enzyme method, emulsin being used. α -Glycol monoglucoside was obtained crystalline, $[\alpha]_D + 135^\circ$, and two different glyceryl monoglucosides were prepared from an aqueous solution of glycerol and glucose in presence of emulsin in the course of nine months' reaction, in the form of a hard amorphous mass, $[\alpha]_D + 27^\circ$.

Hämäläinen (Biochem. Zeitsch. 1913, 49, 398; 50, 209; 52, 409; 53, 423) has synthesised a number of glucosides of terpene alcohols by the enzyme method (emulsin), including those of: *l*-borneol, *r*-isoborneol, camphene, *d*-citronellol, cyclohexanol, dihydrocarveol, *l*-fenchyl alcohol, sabinol, santenol, *cis*-terpin, and terpineol.

The function of glucosides has been a subject of considerable discussion. They have been regarded as reserve materials; as antiseptics, and, therefore, bactericidal in character; and as protectives, on the assumption that the bitter taste and poisonous properties of many would act as a warning to animals. A more recent view is that the non-sugar constituents function as hormones; that is, they are able to penetrate the plant cells and stimulate the protoplasm to greater activity; much evidence has been adduced in favour of this view (see E. F. Armstrong, The Simple Carbohydrates and Glucosides, London, Longmans, 1919).

Preparation.—Glucosides are obtained from plants by extraction with water or alcohol, the abstract being subsequently purified in a variety of ways to eliminate other soluble substances. The extraction of the plant material is often conveniently performed in a Soxhlet apparatus;

and ethyl acetate will sometimes be found to be a convenient solvent. It is essential in most cases to destroy the accompanying enzyme before extracting with water, so that hydrolysis may not take place.

For convenience of reference only the most important glucosides are here described in alphabetical order. They are, perhaps, better classified in groups according to the nature of the non-sugar constituent, and brief reference may therefore be made to these groupings. Special works dealing with the glucosides are: *Van Rijn*, Die Glucoside, Berlin, 1900; *Roscoe-Schorlemmer's Chemie*, Band 8, Pflanzen Glucoside, Braunschweig, 1901; *Armstrong*, The Simple Carbohydrates and Glucosides, London, 1919, in all of which numerous references to the original literature will be found.

Phenols occur very frequently as constituents of glucosides, especially those containing two and more hydroxyl groups. The sugar residue is attached to a phenolic hydroxyl rather than to an aliphatic alcohol group in a side chain, e.g. *salicin*, *coniferin*.

Aldehydes. A number of glucosides of benzaldehyde exist, but in most of these hydrogen cyanide is attached to the aldehyde group. The relationship of amygdalin, and the three amygdonitrile glucosides, *prulaurasin*, *sambunigrin*, and *prunasin*, is of considerable interest. *Salinigrin*, the glucoside of *m*-hydroxybenzaldehyde, is isomeric with *helicin*, the glucoside of *o*-hydroxybenzaldehyde, obtained by oxidising *salicin*, but not yet found in plants. *Dhurrin* is a derivative of *p*-hydroxybenzaldehyde.

Acids. Glucosides of the higher fatty acids are characteristic of the *Convolvulaceæ*, and are used as purgatives.

Coumarins. The glucosides of the coumarin group are interesting. That of coumarin itself has not yet been isolated, though there can be little doubt that coumarin, which is so widely distributed in plants, is present in this form. Skimmin is a monohydroxycoumarin; *æsculin* and *daphnin* are isomeric dihydroxycoumarins; *fraxin*, a trihydroxycoumarin. *Scopolin* is the methyl ether of *æsculin*.

Hydroxyanthraquinone glucosides are madder, frangulin, and others, like aloe, which form emodin on hydrolysis.

Hydroxyflavone glucosides all give yellow dye-stuffs. Those described are apiin, fustin, gossypitrin, incarnitrin, quercimeritrin, quercitrin, isoquercitrin, robinin, rutin, serotin, vixetin, xanthorhamnin. They are mostly rhamnositides.

The following glucosides contain rhamnose: *Baptisin*, *convallamarin*, *datiscin*, *frangulin*, *fustin*, *glycyphyllin*, *hesperidin*, *kampheritrin*, *ouabain*, *naringin*, *quercitrin*, *robinin*, *rutin*, *solanin*, *strophantin*, *trifolin*, *α -turpethin*, *xanthorhamnin*.

Those containing pentoses other than rhamnose are: *Aloin*, *antiarin*, *convolvulin*, *gentiin*, *helleborein*, *jesterin*, *quinovin*, *saponin*, *β -turpethin*, *vicianin*.

The following contain galactose: *Convallamarin*, *digitonin*, *robinin*, *sapotoxin*, *solanin*. Lævulose has so far only been obtained from *allin*, the glucoside of garlic (Rindquist, Apoth. Zeit. 1910, 25, 105).

The glucosides hydrolysed by emulsin are:

Æsculin, *amygdalin*, *amygdonitrile glucoside*, *androsin*, *arbutin*, *aucubin*, *bankansin*, *calamatambin*, *coniferin*, *daphnin*, *dhurrin*, *gentiopicrin*, *incarnatrin*, *indican*, *meliatin*, *oleuropein*, *picein*, *prulaurasin*, *salicin*, *sambunigrin*, *syringin*, *taxitarin*, *verbenalin*.

Adonin $C_{24}H_{40}O_9$, from *Adonis amurensis* (Reg and Rada) (v. Tahara, Ber. 24, 2579).

Æsculin $C_{15}H_{16}O_9 \cdot 2Aq$, m.p. 205° , is found in the bark of the horse chestnut (*Æsculus hippocastanum*, Linn.), and in the roots of the wild jasmine (*Gelsemium sempervirens*, Ait.). It is very sparingly soluble in cold water, and crystallises in lustrous colourless prisms. Characteristic is the blue fluorescence of the aqueous solution, even when very greatly diluted; it is evident in a solution of 1 part of æsculin in 15 million parts of water. Alkali increases the fluorescence, acids destroy it. The aqueous solution is faintly acid. It gives a yellow solution with nitric acid, which, on the addition of ammonia, acquires a deep blood-red colour (comp. Schunck and Marchlewski, Annalen, 1894, 278, 353; Gattermann and Köbner, Ber. 1899, 32, 288). By the action of warm dilute mineral acids or of emulsin at 30° , æsculin is hydrolysed to glucose + æsculetin (a dihydroxycoumarin)

Æsculetin has the formula :

Æsculin is isomeric with daphnin.

Aloin, Barbaloin. The glucosides from the various species of aloe are but indefinitely characterised. They are decomposed into aloe emodin, which is a trihydroxymethyl anthraquinone identical with that derived from frangulin, and a sugar which is sometimes dextrose, sometimes a pentose. Léger (Bull. Soc. chim. 1910, 7, 479; and Compt. rend. 1910, 150, 1695) ascribes to barbaloin the formula $C_{26}H_{16}O_9$, and obtained from it on hydrolysis, emodin and *d*-arabinose. Since the arabinose, which is a constituent of gums, &c., is *l*-arabinose, the occurrence of the *d*-isomeride is remarkable, as showing that sugars of both *d*- and *l*-series occur naturally.

Amygdalin $C_{20}H_{27}O_{11}N \cdot 3Aq$, m.p. 200° , $[\alpha]_D^{28} = -38.3^\circ$, is the oldest known glucoside; it was first found by Robiquet and Boutron in 1830 in bitter almonds. The composition and mode of decomposition by emulsin into glucose, oil of bitter almonds, and hydrogen cyanide, was first indicated by Wöhler and Liebig. Besides the bitter almond, it is contained in the kernels of peaches, cherries, plums, apples, and in the fruits of most of the *Rosaceæ*. It crystallises from water in transparent rhombic prisms, from alcohol in glistening platelets. It is soluble in water, sparingly soluble in cold alcohol.

It is very readily hydrolysed by the emulsin of almonds to glucose (2 mols.), hydrogen cyanide, and benzaldehyde

Yeast contains an enzyme amygdalase, which

hydrolyses it to glucose and amygdonitrile glucoside (*prunasin*)

which has since been found to occur naturally, and is, in its turn, hydrolysed by emulsin. Almond emulsin has been shown to be a mixture of three enzymes, which act consecutively.

Amygdalase first splits off one molecule of glucose, a β -glucase hydrolyses the amygdonitrile glucoside to β -glucose and *d*-mandelonitrile, and *cyanase* hydrolyses this last to benzaldehyde and hydrogen cyanide. It has not been possible to obtain the two glucose molecules from amygdalin united in the form of a disaccharide by means of plant enzymes, but using the digestive juices of the snail *Helix pomatia*, Giaja (Compt. rend. 1910, 150, 593) has demonstrated that a non-reducing disaccharide of the trehalose type is first formed, though subsequently hydrolysed to glucose. The disaccharide of amygdalin is definitely not maltose nor cellobiose. Dilute acids act as almond emulsin does; strong hydrochloric acid hydrolyses amygdalin to *l*-mandelic acid, glucose, and ammonia. Concentrated sulphuric acid gives glucose and *d*-mandelonitrile.

On treatment with baryta, the *d*-mandelonitrile group in amygdalin is racemised and *iso*amygdalin is obtained. This is hydrolysed by amygdalase to prulaurasin. (For bibliography, see E. F. Armstrong, The Simple Carbohydrates and Glucosides; also Walker and Kriebel, Chem. Soc. Trans. 1909, 95, 1437.)

Amygdonitrile glucoside (Prunasin)

m.p. 147° , $[\alpha]_D^{20} = -26^\circ$, occurs in the young branches of *Prunus* (*Cerasus*) *Padus* (Linn.) (Hérissey, Arch. Pharm. 1907, 245, 641) and in the bark of the wild cherry, *Prunus serotina* (Ehrh.) (Power and Moore, Chem. Soc. Trans. 1909, 95, 243). It is obtained from amygdalin by the action of an extract of dried yeast (Fischer, Ber. 1895, 28, 1508). This enzyme amygdalase is only present in some specimens of brewers' yeast (top fermentation). Amygdonitrile glucoside is the β -glucose ether of *d*-mandelonitrile, i.e. the nitrile of *l*-mandelic acid (cf. prulaurasin and sambunigrin).

Androsin $C_{15}H_{20}O_8 \cdot 2Aq$, m.p. $218^\circ - 220^\circ$, found in the rhizome of *Apocynum androsaemifolium* (Linn.) (Moore, Chem. Soc. Trans. 1909, 95, 734), forms long colourless needles, sparingly soluble in cold water or alcohol, readily in hot water. On hydrolysis by emulsin or sulphuric acid, it yields glucose and acetovanillone

Antiarin. The latex of *Antiaris toxicaria* (Lesch.), an arrow poison, contains two glucosides. α -Antiarin $C_{27}H_{38}O_{10} \cdot 4Aq$ crystallises in leaflets or plates; m.p. $220^\circ - 225^\circ$; it is hydrolysed to antiarose, i.e. a methyl pentose, and antiarigenin $C_{21}H_{30}O_5$. β -Antiarin

or $C_{28}H_{38}O_{10} \cdot 3Aq$, crystallises in slender needles; m.p. $206^\circ - 207^\circ$. Emulsin has no action on either glucoside; both are toxic, their action resembling strophantin (Kiliani, Ber. 1910, 43, 3574).

Apin $C_{26}H_{28}O_{14}$ (?), m.p. 228° , found in the leaves and seeds of parsley [*Carum* (*Apium*) *Petroselinum* (Bentl. and Hook.)], in celery [*A.*

graveolens (Linn.), and other umbelliferous plants; crystallises in small colourless needles; sparingly soluble in cold, easily soluble in hot water and alcohol. The solutions readily gelatinise; they are strongly dextro-rotatory. It is hydrolysed by mineral acids with difficulty to glucose, apiose, a C_6 sugar with a branched chain of carbons (*v. CARBOHYDRATES*), and apigenin $C_{15}H_{10}O_5$, a hydroxyflavone derivative of the constitution

The sugar residue is probably united to the hydroxyl-group marked \times (*see* Perkin, Chem. Soc. Trans. 1897, 71, 817).

Aralin, m.p. 260°, occurs in *Aralia japonica*. It is insoluble in water, contains no nitrogen, and does not reduce Fehling's solution. On hydrolysis it yields glucose and an acidic compound *aralidin*, which forms white crystals, m.p. 246°–248° (Danzel, J. Pharm. Chim. 1912, [vii.] 5, 530).

Arbutin $C_{12}H_{18}O_7$, 1Aq, m.p. 142°, and again at 194°, $[\alpha]_D -63.5^\circ$, occurs in the leaves of the bear-berry [*Arctostaphylos Uva-ursi* (Spreng)], in a number of *Ericaceæ*, and in the roots, trunks, and leaves of most pear species (Bourquelot, Compt. rend. 1911, 153, 468). Excepting in the pear, it is found associated with methyl arbutin, from which it cannot be separated by crystallisation. Hérissé effects this by the addition of potassium hydroxide to crude arbutin dissolved in alcohol. The syrupy precipitate is heated with acetic acid in alcohol, calcium carbonate added when it is in solution, the alcohol distilled off, and the residue extracted with water (Bull. Soc. chim. 1910, 7, 1054). Arbutin crystallises in long silky needles, gives a blue coloration with ferric chloride, and a sapphire-blue colour with Jungmann's reagent. It is hydrolysed by emulsin or by mineral acids to glucose and quinol; owing to the presence in emulsin of a small amount of oxydase, the quinol formed in this way becomes slightly oxidised, and the solution assumes a yellowish- or reddish-brown colour (*see* Bourquelot and Hérissé, Compt. rend. 1908, 146, 764; Bourquelot and Fichtenholz, J. Pharm. Chim. 1910, [vii.] 1, 62, 104; Hérissé, Compt. rend. 1910, 151, 444).

Arbutin is readily detected by moistening the powdered material with dilute hydrochloric acid, heating cautiously on an object-glass, and collecting the sublimate of quinol which forms upon a second object-glass (Tunmann, Ber. Deut. pharm. Ges. 1911, 21, 312).

Hérissé's method for separating the arbutin of bearberries from methyl arbutin does not give pure arbutin. A better, but still imperfect, process is to separate the arbutin in the form of its additive compound with hexamethylene-tetramine. Pure arbutin is produced synthetically from acetobromoglucose and quinol in presence of alkali; the compound (+1Aq) melts at 163°–164°, and again at 200°, $[\alpha]_D -60^\circ$.

Pure methyl arbutin melts at 158°–160°, and again at 175° (Mannich, Arch. Pharm. 1912, 250, 547).

Methyl arbutin $C_{13}H_{18}O_7$, 1Aq, m.p. 175°, $[\alpha]_D -64^\circ$, crystallises in needles; it gives no coloration with either ferric chloride or Jungmann's reagent. It is hydrolysed by emulsin more quickly than arbutin, yielding glucose and quinolmethyl ether (Hlasiwetz and Habermann, Annalen, 1875, 177, 334). It does not darken in colour on hydrolysis in presence of an oxydase. Methyl arbutin was synthesised by Michael by the interaction of acetochloroglucose with potassium quinol methyl ether (Amer. Chem. J. 1885, 6, 336).

Aucubin $C_{13}H_{18}O_8$, 1Aq, m.p. 181° $[\alpha]_D -174^\circ$, is found in the seed, leaves, stem, and roots of the Japanese variegated laurel, *Aucuba japonica* (Thunb.) and allied species. It also occurs in *Garrya* and *Plantago* species. It is hydrolysed by mineral acids and by emulsin to glucose and aucubigenin ($C_7H_8O_3$). The latter has not been isolated; it is condensed to an intense black-coloured product immediately it is formed. It is this compound which causes *aucuba* leaves to become black when put in an atmosphere of chloroform for a few minutes. (Literature summarised by Bourquelot and Hérissé, Ann. Chim. 1905, [viii.] 4, 289.)

Baptisin $C_{26}H_{32}O_{14}$, 9Aq, m.p. 240°, $[\alpha]_D -61^\circ$, found in the roots of *Baptisia tinctoria* (R.Br.), crystallises in reniform aggregates of slender needles, sparingly soluble in water; it is hydrolysed to rhamnose (2 mols.) and baptigenin $C_{14}H_{12}O_6$, a phenol containing three hydroxyl groups (Gorter, Arch. Pharm. 1897, 235, 303). ψ -*Baptisin* $C_{27}H_{30}O_{14}$, 4Aq, m.p. 247°, which occurs in the same root is hydrolysed to glucose, rhamnose, and ψ -baptigenin $C_{15}H_{16}O_8$ or $C_{12}H_8 \begin{array}{c} \diagup \text{O} \cdot \text{CH} : \text{CH} \cdot \text{OH} \\ \diagdown \text{O} \cdot \text{CHO} \end{array}$ (Gorter, Arch. Pharm. 1907, 245, 561).

Calmatambin $C_{19}H_{28}O_{13}$, 2Aq, m.p. 144°, $[\alpha]_D -130^\circ$, found in the bark of *Canthium glabriflorum* (Hiern.) from Sierra Leone, crystallises in colourless prismatic needles. It is hydrolysed by mineral acids and by emulsin to glucose and *Calmatambetin* $\text{CH}_3\text{O} \cdot \text{C}_{12}\text{H}_{10}\text{O}_2(\text{OH})_5$. It is physiologically inactive (Pyman, Chem. Soc. Trans. 1907, 91, 1228).

Cedrin $C_{21}H_{26}O_8$, crystals, m.p. 265°, is found in *Sinaba cedron*, and gives by hydrolysis a sugar which has not yet been identified (Viehoefer, Geiger, and Johns, J. Biol. Chem. 1916, 24).

Clavicepsin $C_{18}H_{34}O_{16}$, 2Aq, m.p. 91°, and (anhydrous) at 198°, is found in *Secale cornutum*; it is not hydrolysed by emulsin, but with acids gives 2 molecules of glucose and 1 molecule of mannitol (Marino-Zuco and Pasquero, Gazz. chim. ital. 1911, 41, [ii.] 368).

Coniferin $C_{16}H_{22}O_8$, 2Aq, m.p. 185°, $[\alpha]_D -67^\circ$, was discovered in the cambial sap of *Larix decidua* (Mill.), and occurs in the saps of the conifers in general; it is found also in beetroot and asparagus.

It crystallises in colourless rosettes of pointed needles, sparingly soluble in cold water. The aqueous solution has a slightly bitter taste. When moistened with phenol and concentrated hydrochloric acid, an intense blue colour is formed; it is soluble in concentrated sulphuric acid with a red coloration. It is decomposed

by heating with mineral acids, but emulsin hydrolyses it to glucose and coniferyl alcohol $C_6H_3(OH)(OMe)C_3H_4 \cdot OH$.

On oxidation with permanganate, glucovanillic acid $C_6H_3(OMe)(CO_2H)OC_6H_{11}O_5$ is obtained, m.p. 211°. Chromic acid oxidises coniferin to glucovanillin, m.p. 192°, which is hydrolysed by emulsin or by acids to glucose and vanillin (see Tiemann and Haarmann, Ber. 1874, 7, 608; 1875, 8, 509, 1127; 1876, 9, 408, 1278).

Convallamarin and **Convallarin** are two glucosides occurring in *Convallaria majalis*; the former is soluble in water and alcohol, and has a physiological action similar to that of digitalin, whilst the latter is insoluble in water and acts only as a purgative (Reichard, Pharm. Zeit. 1911, 52, 183).

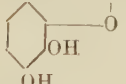

Convovulin $C_{54}H_{96}O_{37}$, m.p. 150°, is found in jalap root, *Ipomœa purga* (Hayne). It is a colourless amorphous powder, very sparingly soluble in water, but readily soluble in alcohol and acetic acid, and dissolves in concentrated sulphuric acid with a red coloration. It is hydrolysed by acids to dextrose, rhodose, and convovulinic acid $C_{15}H_{30}O_3$. This acid, on oxidation, takes up 2 molecules of oxygen, forming methylethyl acetic acid and ipomic acid $C_{17}H_{34}O_4$, an isomeride of sebacic acid (cf. Votoček, Ber. 1910, 43, 476).

Convovulin is hydrolysed by aqueous baryta to convovulinic acid, α -methyl butyric acid, and purgic acid. The first-named acid yields rhamnose and rhodose by the action of mineral acids, whilst the third similarly gives isorhodose (Votoček, Ber. 1910, 43, 476).

Cymar $C_{30}H_{44}O_9$, m.p. 130°–138°, $[\alpha]_D +23^\circ$, occurs in *Apocynum cannabinum*; by hydrolysis are produced **Cymarose** $C_7H_{14}O_4$, m.p. 88°, which is probably a methyl ether of digitoxose, and **cymarigenin**, $C_{23}H_{36}O_5$, melting at 171°, a lactone, said to be identical with the strophanthidin of Feist (whose formula $C_{27}H_{38}O_8$ is said to be wrong). Cymar is similar in physiological action to strophanthin and digitoxin; the only difference between cymar and strophanthin is the different sugar constituent (Windaus and Hermanns, Ber. 1915, 48, 979, 991).

Daphnin $C_{15}H_{16}O_9$, 2Aq, m.p. 200°, is a constituent of the bark of *Daphne mezereum* (Linn.) and *D. alpina* (Linn.). It forms long colourless needles or prisms, sparingly soluble in water, easily soluble in alcohol. It is faintly acid, and has a bitter astringent taste. It is soluble in alkalis and their carbonates with a golden-yellow colour, the solutions decompose on boiling. On hydrolysis by acids or by emulsin, glucose and daph-

netin  are formed (comp. Stünkel,

Ber. 1879, 12, 109).

Datiscin $C_{21}H_{34}O_{11} \cdot 2Aq$, m.p. 190°, present in the leaf and roots of *Datisca cannabina* (Linn.), forms colourless lustrous needles. On hydrolysis by acids rhamnose and datiscetin

are formed (Schunck and Marchlewski, Annalen, 1893, 277, 261; 1894, 278, 351).

Dhurrin $C_{14}H_{17}O_7N$ was obtained from the great millet, *Sorghum vulgare* (Pers.), by Dunstan and Henry (Phil. Trans. 1902, A, 199, 399). It is hydrolysed by emulsin and by dilute hydrochloric acid to glucose, hydrogen cyanide, and *p*-hydroxybenzaldehyde. It is the glucoside of *p*-hydroxymandelonitrile.

Dibenzoylglucoselyse, $C_{25}H_{28}O_{12} \cdot 1Aq$, described by Power and Salway (Trans. Chem. Soc. 1914, 105, 767, 1062), is an entirely new type of naturally-occurring glucoside. It occurs in *Daviesia latifolia*. M.p. 147°–148°, $[\alpha]_D -107^\circ$, in methyl alcohol. It has a very bitter taste, is sparingly soluble in cold water, ether, or chloroform, but readily in hot water or in alcohol. It does not reduce Fehling's solution. The penta-acetate has m.p. 203°.

Digitalis glucosides. The leaves and seed of the foxglove, *Digitalis purpurea* (Linn.), contain glucosides, which increase the activity of all forms of muscle tissue, more especially that of the heart and arterioles. The leaves contain digitalin, digitoxin, and, perhaps, digitalein, the existence of this as an entity being uncertain. The seeds contain digitalin and digitonin, a glucoside of the saponin class, which is possibly also present in the leaves (v. DIGITALIS).

Digitalin $C_{33}H_{56}O_{14}$ or $C_{36}H_{58}O_{14}$, m.p. 217°, is obtained from commercial German digitalin by extraction with ether-alcohol. It occurs in characteristic colourless granular masses, and crystallises in needles from 85 p.c. methyl alcohol. It is very sparingly soluble in cold water, readily in alcohol. Concentrated sulphuric acid dissolves it with a golden-yellow coloration, which changes to a magnificent rose-red or violet-red on the addition of potassium hypobromite. Sulphuric acid containing a little ferric oxide gives, with digitalin, at first an intense golden-yellow, and then a red colour changing to a permanent reddish-violet.

It is hydrolysed on heating with dilute alcoholic hydrogen chloride to glucose, a sugar $C_7H_{14}O_5$ named digitalose, and digitaligenin $C_{22}H_{30}O_3$ or $C_{23}H_{32}O_3$, which last crystallises in granular aggregates of needles; m.p. 210°. Digitalin possesses the characteristic action on the heart without being cumulative.

Digitonin $C_{54}H_{92}O_{28}$ or $C_{55}H_{94}O_{28}$, m.p. 225°, $[\alpha]_D -50^\circ$, forms one-half of the mixed glucosides from digitalis seed, and the principal proportion of commercial German digitalin. To obtain it the commercial product is dissolved in 85 p.c. alcohol at 50°–60°, and allowed to crystallise slowly; digitonin then separates. When pure it crystallises in crusts of slender needles, very sparingly soluble in water, readily soluble in alcohol. The hot aqueous solution is opalescent, and the glucoside does not separate on cooling. The aqueous solution froths like that of saponin. It gives a red coloration with concentrated sulphuric acid, and, on heating with concentrated hydrochloric acid, becomes yellow, then red, and finally somewhat blue. It is hydrolysed on heating with alcoholic hydrogen chloride to glucose (2 mols.), galactose (2 mols.), and digitogenin $C_{30}H_{48}O_6$ or $C_{31}H_{50}O_6$, crystallising in slender needles, which soften at 250°. Digitonin is poisonous, but does not possess the action on the heart peculiar to digitalis. It forms crystalline compounds with amyl alcohol and other alcohols, and with phenol, and combines with 1

mol. cholesterol in alcoholic solution to give a crystalline precipitate, which is no longer poisonous. This is a valuable test for digitonin.

Digitoxin $C_{44}H_{64}O_{11}$, the most active principle of digitalis leaves, is cumulative in its action; it is the chief constituent of 'Nativelle's crystallised digitalin,' or 'French digitalin.' It is obtained by extracting the leaves with water, and then with alcohol, precipitating the alcoholic solution with lead acetate, evaporating and extracting the residue with chloroform. It crystallises from chloroform in thin anhydrous prisms, which are not melted at 240° , and from dilute alcohol in hydrated crystals; m.p. 145° . It is insoluble in hot or cold water, soluble in alcohol, chloroform, or ether. When it is dissolved in glacial acetic acid, a drop of ferric chloride added, and then concentrated sulphuric acid is cautiously poured down so as to form a layer under the acetic acid, a dirty brownish-green band appears, which alters to a broad intense bluish-green band at the dividing zone. It is hydrolysed by alcoholic hydrogen chloride at the ordinary temperature to digitoxigenin $C_{22}H_{32}O_4$, colourless crystals, m.p. 230° , and 2 molecules digitoxose $C_6H_{12}O_5$, a sugar having the constitution:

It crystallises in prisms, m.p. 102° , and is dextro-rotatory (cf. Kiliani, Arch. Pharm. 1913, 251, 562-580; Ber. 1915, 48, 334).

Frangulin $C_{21}H_{30}O_9$, m.p. 228° , found in the bark, root bark, seeds, and fruit of the berry-bearing alder, *Rhamnus frangula* (Linn.), and also in *R. carthartica* (Linn.), is a yellow silky glistening microcrystalline powder, nearly insoluble in water, readily soluble in alcohol and benzene. It dissolves in alkalis with an intense cherry-red colour. It is hydrolysed by acids to rhamnose and emodin (trihydroxy-methylantraquinone) (comp. Schweabe, Arch. Pharm. 1888, 226, 569; Thorpe and Miller, Chem. Soc. Trans. 1892, 61, 1).

Fraxin $C_{16}H_{18}O_{10}$, m.p. 320° , obtained from the bark of the ash *Fraxinus excelsior* (Linn.), and from several *Aesculus* and *Pavia* species, crystallises in colourless needles, sparingly soluble in cold water, but easily in hot water and alcohol. The solutions, like those of *æsculin*, fluoresce blue. It is hydrolysed by dilute sulphuric acid to glucose and fraxetin $C_{10}H_8O_5$, the monomethyl ether of a trihydroxycoumarin. It contains a methoxyl group more than daphnin or *æsculin* (see Rochleder, Wien. Akad. Ber. 1863, 48, 236).

Fustin $C_{36}H_{26}O_{14}$, m.p. 218° , the glucoside of fustic (*Rhus cotinus* [Linn.]), forms small needles of silvery lustre. Dilute sulphuric acid hydrolyses it to rhamnose and 2 molecules of fisetin $C_{18}H_{16}O_6$, which is a 3 : 3' : 4'-trihydroxyflavonol of the following constitution:

(see Perkin, Chem. Soc. Trans. 1897, 71, 1194).

Gaultherin $C_{41}H_{58}O_8$, 1Aq, decomposes at 100° , found in *Gaultheria procumbens* (Linn.), *Betula lenta* (Linn.), *Monotropa Hypopitys* (Linn.), *Spiraea ulmaria* (Linn.), *S. filipendula*

(Linn.), and other plants, forms prismatic crystals, easily soluble in water and alcohol. It is hydrolysed by mineral acids and by a specific enzyme, gaultherase, which accompanies it in plants. Emulsin is without action. The products of hydrolysis are glucose and methyl salicylate $C_6H_4(\text{OH})\text{CO}_2\text{CH}_3$ (see Bourquelot, Compt. rend. 1896, 122, 1002).

Gentiacaulin, $[\alpha]_D - 64^{\circ}$, occurs in *Gentiana acaulis*, and gives glucose and xylose on hydrolysis; the non-sugar constituent is not stated (Bridel, J. Pharm. Chim. 1914, [vii.] 10, 329).

Gentiin $C_{25}H_{28}O_{14}$, m.p. 274° , occurring in the root of the gentian (*Gentiana lutea* [Linn.]), crystallises in yellow needles. It is hydrolysed to dextrose, xylose, and gentienin $C_{14}H_{10}O_5$, which is isomeric with gentisin.

Gentiopierin $C_{16}H_{20}O_9$, 1Aq, m.p. 120° - 125° , or anhydrous at 191° , $[\alpha]_D - 198^{\circ}$, which is likewise a constituent of gentian root (Tanret, Chem. Soc. Abstr. 1905, i. 655, 714), occurs also in a number of species of *Gentiana*, and in *Blackstonia* (*Chlora*) *perfoliata* (Huds.). It is hydrolysed by emulsin to dextrose and gentiopierin (comp. Bourquelot and Bridel, J. Pharm. Chim. 1910, [vii.] 1, 156).

Gitalin $C_{25}H_{40}O_{10}$, m.p. 150° - 155° , was obtained from *Digitalis* leaves by extraction with cold water and then with chloroform. It is said to be the chief constituent of commercial digitalin, is a white, neutral amorphous powder, soluble in 600 parts of water. It crystallises from a mixture of 2 parts alcohol and 1 part water with $4\text{H}_2\text{O}$, the hydrate melting at 75° .

When an alcoholic solution of gitalin is evaporated in a vacuum *anhydrogitalin*, $C_{25}H_{40}O_9$, m.p. 255° , is produced; this is insoluble in water and chloroform, but dissolves in 800 parts of boiling alcohol.

Hydrolysis in alcoholic HCl solution of *anhydrogitalin* yields digitoxose and *anhydrogitaligenin* $C_{22}H_{34}O_5$, melting at 216° - 219° (Kraft, Schweiz. Wochensh. Chem. Pharm. 1911, Nos. 12, 13, and 17; Arch. Pharm. 1912, 250, 118).

Kiliani (Arch. Pharm. 1913, 251, 562) did not succeed in transforming Kraft's *gitalin* into *anhydrogitalin* by absolute alcohol; the same writer (Arch. Pharm. 1914, 252, 13) separated *gitalin* into a number of fractions differing in physiological action, solubility and behaviour on hydrolysis by treatment with water and a mixture of methyl alcohol, chloroform, and ether.

Kiliani is supported by the similar work of Rosenthaler (Chem. Zeit. 1914, ii. 328).

Gitin, m.p. 265° , was also extracted from *Digitalis* leaves by Kraft (Arch. Pharm. 1912, 250, 118). It crystallises in long needles, insoluble in water; it is isomeric with *digitonin*, but contains galactose in place of glucose. It is physiologically inactive.

Gitonin $C_{40}H_{56}O_{23}$, decomposes at 272° , $[\alpha]_D - 51^{\circ}$, is an amorphous glucoside found in Merck's digitonin. It forms an additive compound with cholesterol, and on hydrolysis is resolved into 3 molecules galactose, 1 molecule pentose, and *gitogenin* $C_{26}H_{42}O_4$, a crystalline compound melting at 271° - 272° (Windaus and Schreckenburger, Ber. 1913, 46, 2628).

Glucocheirolin $C_{11}H_{20}O_{11}NS_3K$, Aq., colourless needles, m.p. 153° – 160° , $[\alpha]_D -21^{\circ}$, occurs in wallflower seeds. Its constitution is probably:

(Schneider and Schütz, Ber. 1913, 46, 2634).

It gives cheirolin and glucose on hydrolysis (Schneider and Lohmann, Ber. 1912, 45, 2954).

Glucotropæolin $C_{14}H_{15}O_6NS_2K$, the glucoside of benzylthiocyanide, occurs in *Tropæolum majus* (Linn.), and *Lepidium sativum* (Linn.). It is known only in solution; with silver nitrate a precipitate is formed at first soluble in ammonia, but subsequently the ammonium compound

separates in glistening crystals. The glucoside is hydrolysed by myrosin to glucose, potassium hydrogen sulphate, and benzylisothiocyanate (Gadamer, Ber. 1899, 32, 2336). *Nasturtium officinale* (R. Br.), and *Barbarea præcox* (R. Br.), are said to contain a glucoside, *glucanasturtiin*, which differs from glucotropæolin only in yielding phenylethylisothiocyanate $C_6H_5 \cdot CH_2 \cdot CH_2 \cdot NCS$ on hydrolysis by myrosin.

Glycyphyllin $C_{21}H_{32}O_{13}$, 3Aq., m.p. 175° , occurs in the leaves of *Smilax glycyphylla* (Sm.); on hydrolysis it yields rhamnose and phloretin identical with that obtained from phloridzin, in which it is combined with glucose (Wright and Rennie, Chem. Soc. Trans. 1886, 49, 857).

Gossypitrin $C_{21}H_{30}O_{13}$, m.p. 200° – 202° , occurs together with quercitrin and isoquercitrin in Egyptian cotton flowers, *Gossypium herbaceum* (Linn.). It consists of pale orange-yellow needles, gives a deep red precipitate with aqueous lead acetate, and an olive-green coloration with ferric chloride (Perkin, Chem. Soc. Trans. 1909, 2181). It is hydrolysed by boiling dilute sulphuric acid to glucose and gossypetin $C_{15}H_{10}O_8$, a hydroxyflavone derivative. The glucoside exists in the flowers as a potassium salt (A. G. Perkin, Chem. Soc. Trans. 1899, 75, 825; 1902, 81, 205; 1910, 95, 1855, 2181).

Gynocardin $C_{13}H_{19}O_9N \cdot \frac{1}{2}Aq$, m.p. 162° , $[\alpha]_D +72.5^{\circ}$, is found in *Gynocardia odorata* (R. Br.) and *Pangium edule* (Rein.), (Power and Lees, *ibid.* 1905, 87, 349; De Jong, Rec. trav. chim. 1909, 28, 24). It is hydrolysed by acids and by a specific enzyme gynocardase to glucose, hydrogen cyanide and a complex $C_6H_8O_4$, which spontaneously resinifies.

Helicin v. Salicin.

Helleborein is an amorphous glucoside, $[\alpha]_D -3^{\circ}$, and yields on hydrolysis 1 molecule acetic acid, 2 molecules glucose, 2 molecules arabinose, and two *helloboretins*, one of which, $C_{21}H_{36}O_7$, is an acidic lactone, the other, $C_{15}H_{24}O_3$, being a neutral compound (Sieburg, Arch. Pharm. 1913, 251, 154).

Hesperidin $C_{50}H_{60}O_{27}$, m.p. 251° , $[\alpha]_D -89^{\circ}$, is found generally in the fruit of the *Aurantaceæ*. It was discovered in unripe oranges, and occurs in most species of *Citrus* except *C. decumana* (Murr.). It is a colourless, microcrystalline, tasteless, hygroscopic powder, almost insoluble in water, readily soluble in hot acetic acid. It is faintly acid, and therefore soluble in alkalis, from which it is precipitated by carbon dioxide. It

is hydrolysed by acids to glucose (2 mols.), rhamnose, and (2 mols.) hesperitin $C_{16}H_{14}O_6$, which has the structure

and is decomposed on boiling with alkali into phloroglucinol and hydroxymethoxycinnamic acid (Will, Ber. 1887, 20, 1186; Tiemann and Will, Ber. 1881, 14, 946).

Incarnatin $C_{21}H_{20}O_{12}$, 3Aq., m.p. 242° , occurs in the flowers of *Trifolium incarnatum* (Linn.), the so-called 'carnation or crimson clover' (Rogerson, Chem. Soc. Trans. 1910, 1004), and forms faintly yellow prismatic needles. It is readily hydrolysed by acids and by emulsin to glucose and quercetin.

Indican $C_{14}H_{17}O_6N \cdot 3Aq$, m.p. 100° – 102° , the glucoside of woad (*Isatis tinctoria* [Linn.]) is also found in *Indigofera tinctoria* (Linn.) and other species of *Indigofera*, in *Polygonum tinctorium* (Ait.), and in *Wrightia tinctoria* (R. Br.). It is conveniently extracted from the leaf by means of acetone. It is hydrolysed by acids, by a specific enzyme, *indemulsin*, present in the leaves of the indigo plant, and more slowly by the emulsin of almonds, to glucose and indoxyl. Indoxyl (colourless) undergoes oxidation to indigotin (blue) when exposed to the air $2C_8H_7ON + O_2 = 2H_2O + C_{16}H_{10}O_2N_2$. The yield of indigotin obtained from the leaves is of great importance commercially; it is below the theoretical when hydrolysis is slow, owing to the great instability of indoxyl, and in part to the occlusion of indoxyl by the enzyme. It is improved by adding a small quantity of sulphuric acid to the mixture at the commencement of the reaction (*see* Perkin and Bloxam, Chem. Soc. Trans. 1907, 91, 715; 1909, 95, 793, 824; also references to Indican given by Armstrong, The Simple Carbohydrates and Glucosides, London, 1919).

Iridin $C_{24}H_{36}O_{13}$, m.p. 208° , occurs in the root of the violet (*Iris florentina* [Linn.]) (De Laire and Tiemann, Ber. 1893, 26, 2010), and crystallises in colourless needles, very sparingly soluble. It is hydrolysed by acids to glucose and irigenin $C_{15}H_{16}O_8$, which has the constitution:

The sugar residue is attached to the hydroxyl marked*.

Jalapin (*Scammonin*) $C_{34}H_{56}O_{16}$, m.p. 131° , $[\alpha]_D -23^{\circ}$, is the active principle of the root stalks of *Convolvulus orizabensis* (Led.), and of scammony, the dried sap of *Convolvulus scammonia* (Linn.). It is an amorphous resinous powder, translucent in thin plates; slightly soluble in water, readily soluble in alcohol and ether. It dissolves in concentrated sulphuric acid with a purple or maroon red colour, changing to brown and becoming finally black. It is hydrolysed by acids to glucose (3 mols.) and jalapinic acid $C_{16}H_{30}O_8$, possibly hydroxyhexadecylic acid; this yields methylethylacetic acid, sebacic acid, and an isomeride of this acid on oxidation.

Jesterin $C_{26}H_{30}O_{13}$, m.p. 205° – 218° , occurs in the berries of *Rhamnus cathartica* (Linn.). It is hydrolysed to a hexose, a pentose, and

emodinanthranol $C_{15}H_{12}O_4$ (Krasowsky, J. Russ. Phys. Chem. Soc. 1908, 40, 1510).

Kaempferin $C_{27}H_{30}O_{18}$, 6Aq is found in Senna leaves, melts at 185° – 195° , and gives kaempferol and glucose on hydrolysis.

(Glucosides of rhein and aloë-emodin are also present in Senna leaves (Tutin, Chem. Soc. Trans. 1913, 103, 2006).

Kampferitrin $C_{27}H_{30}O_{14}$, m.p. 201° , is found in *Indigofera arrecta* (Hochst.) (Perkin, Chem. Soc. Trans. 1907, 91, 438), and forms almost colourless sparingly soluble needles; on hydrolysis rhamnose (2 mols.) and kaempferol $C_{15}H_{10}O_6$ are formed—the latter has the constitution

Kampferitrin closely resembles robinin, which, according to Perkin, is also a glucoside of kaempferol.

Linamarin (*Phaseolunatin*) $C_{10}H_{17}O_6N$, m.p. 141° , $[\alpha]_D -26^{\circ}$, found in *Phaseolus lunatus* (Linn.), the so-called Java beans, in flax, *Linum usitatissimum* (Linn.), and in cassava. It is hydrolysed by an enzyme, linase, present in *Phaseolus* and some *Linum* species, which is allied to but not identical with emulsin, and also by mineral acids, to glucose and acetonecyanohydrin. It is a derivative of β -glucose and not of α -glucose, as originally supposed (comp. Armstrong and Horton, Proc. Roy. Soc. 1910, B82, 349; Dunstan and Henry, *ibid.* 1903. 72, 285; 1906, B78, 145; 1907, B79, 315; Jorissen and Hairs, Bull. Akad. Roy. Belg. 1891, 21, 529).

Lotusin $C_{25}H_{31}O_{16}N$, obtained from *Lotus arabicus* (Linn.) (Dunstan and Henry, Phil. Trans. 1901, B, 194, 515), crystallises in pale yellow needles. It is hydrolysed by a specific enzyme, lotase, to glucose (2 mols.), hydrogen cyanide and lotoflavin, an isomeride of fisetin, which has the constitution

Apparently the hydrogen cyanide is attached to the sugar residue, as on alkaline hydrolysis heptagluconic acid is obtained.

Meliatin $C_{15}H_{22}O_8$, colourless, bitter crystals, m.p. 222° , occurs in the Marsh Trefoil (*Menyanthes trifoliata*). Upon hydrolysis with emulsin, glucose is produced (Bridel, Compt. rend. 1911, 152, 1694).

Morindin $C_{26}H_{38}O_{14}$ or $C_{27}H_{30}O_{15}$, m.p. 245° , found in *Morinda citrifolia* (Linn.), *M. tinctoria* (Roxb.), and *M. umbellata* (Linn.). crystallises in lustrous silky yellow needles, soluble in hot water and in alcohol. It dissolves in alkalis with an orange-red colour which is not changed on boiling, and in concentrated sulphuric acid with a purple-blue coloration. It is hydrolysed by acids to a sugar which has not yet been definitely identified, and morindone, a trihydroxymethylanthraquinone, isomeric with emodin. On distillation with zinc dust, β -methylanthracene is formed. According to Perkin, morindin from *M. citrifolia* and *M. umbellata* is not the same (see Perkin and

Hummel, Chem. Soc. Trans. 1894, 65, 851; Thorpe and Smith, *ibid.* 1888, 53, 171; Oesterle and Tisza, Arch. Pharm. 1907, 245, 534).

Myrticorin v. *Rutin*.

Naringin, formula uncertain $\mp 4\text{Aq}$, m.p. 170° , is found in the flowers and other parts only of the Java orange, *Citrus decumana* (Murr.). It forms colourless microscopic prisms of bitter taste, sparingly soluble in water, which are strongly lævo-rotatory. It dissolves in alkalis with a yellowish-red coloration and is precipitated by carbon dioxide. It is readily hydrolysed by acids to rhamnose and possibly also glucose and naringenin, which is the phloroglucinol ester of paracoumaric acid

It is closely allied to hesperitin (comp. Will, Ber. 1887, 20, 297, 1186).

Osyritrin v. *Rutin*.

Phloridzin $C_{21}H_{24}O_{10}$, 2Aq, m.p. 108° and again 170° , was discovered in 1835 in the bark and particularly the root bark of the apple, pear, cherry, and plum tree. It forms long silky needles of bitter taste, sparingly soluble in cold, readily in hot water; it is lævo-rotatory $[\alpha]_D -50^{\circ}$. Emulsin is without action, but acids hydrolyse it to glucose and phloretin

(Rennie, Chem. Soc. Trans. 1887, 51, 636; Fischer, Ber. 1888, 21, 988). Glycephyllin is the rhamnose ether of phloretin.

Phytosterolins. The following substances, believed to be phytosterols, were shown to be glucosides (phytosterolins) (Power and Salway, Trans. Chem. Soc. 1913, 103, 399):—

Substance.	Found in:	M.P.
Ipuranol	Olive bark, <i>Ipomoea Purpurea</i> , &c.	285° – 290°
Citrullol	Colocynth, <i>Euonymus atropurpureus</i> , &c.	285° – 290°
Bryanol	Bryony root	210° – 212°
Cluytianol	<i>Taraxacum</i>	297°

Picein. Gluco - *p* - hydroxyacetophenone, synthesised by Mauthner in 1912, was shown by him to be identical with Tanret's picein, isolated from pine needles (J. pr. Chem., 1913 (ii.), 88, 764).

Polygonin $C_{21}H_{20}O_{10}$, m.p. 202° , from *Polygonum cuspidatum* (Sieb. and Zucc.), crystallises in lustrous yellow needles. It is hydrolysed by acids to glucose and emodin, identical with that obtained from frangulin, where it is combined with rhamnose (Perkin, Chem. Soc. Trans. 1895, 67, 1084).

Populin $C_{20}H_{22}O_8$, 2Aq, m.p. 180° , has been found in the bark and leaves of *Populus tremula* (Linn.), *P. nigra* (Linn.), and *P. balsamifera* (Linn.), and other species of *Populus*. It is prepared synthetically from salicin by heating with benzoylchloride (Schiff, Annalen, 1870, 154, 5). It crystallises in minute needles, sparingly soluble in cold water, more soluble in hot water. It is lævo-rotatory, and dissolves in concentrated sulphuric acid with an amaranth-red coloration. Emulsin is without action, but acids hydrolyse it to glucose, saligenin, and benzoic acid. Nitric acid oxidises it to benzoyl helicin (Piria, *ibid.* 1852, 81, 245; 1855, 96, 375). This proves the benzoyl group

to be in the sugar and not in place of the hydroxyl as often supposed. Populin is hydrolysed by the enzyme of *Populus monilifera* (Ait.) (Weevers, Proc. K. Akad. Wetensch. Amsterdam, 1909, 12, 193).

Prulaurasin $C_{14}H_{17}O_6N$, m.p. 122° , $[\alpha]_D -52.75^\circ$, occurs in the leaves of the common cherry laurel, *Prunus laurocerasus* (Linn.) (Hérissey, Compt. rend. 1905, 141, 959). It is hydrolysed by emulsin and by an enzyme prunase of the emulsin type, as also by mineral acids, to glucose, benzaldehyde, and hydrogen cyanide. It is the glucoside of racemic mandelonitrile, and in view of the fact that it is readily obtained from sambunigrin or from amygdonitrile glucoside by the action of traces of alkali (Caldwell and Courtauld, Chem. Soc. Trans. 1907, 91, 671), it is not impossible that it is present in the plant in one of these active forms, and undergoes racemisation during extraction.

Prunasin v. *Amygdonitrile glucoside*.

Prunitrin $C_{22}H_{24}O_{11}4Aq$, found in the bark of *Prunus emarginata* (Walp.) (Finnemore, Pharm. J. 1910, 85, 604), is hydrolysed by acids to glucose and prunetin.

Quercimeritrin $C_{21}H_{20}O_{12}3Aq$, m.p. 247° , obtained from the flowers of *Gossypium herbaceum* (Linn.), forms small glistening bright yellow plates, almost insoluble in cold and fairly readily soluble in boiling water (Perkin, Chem. Soc. Trans. 1909, 95, 2181). The alkaline solutions are deep yellow; it gives a bright-red precipitate with aqueous lead acetate. It is very stable towards mineral acids, but is eventually hydrolysed to glucose and quercetin. The glucoside exists in the flowers in a readily soluble condition in the form of a potassium salt. Quercimeritrin contains the quercetin hydroxyl groups in the 3', 4', and 3- positions intact, the sugar residue R being united to one of the hydroxyl groups marked *

Quercitrin $C_{21}H_{20}O_{11}2Aq$, m.p. 183° – 185° , or anhydrous 250° – 252° , $[\alpha]_D -140.9^\circ$, found in the bark of *Quercus discolor* (Ait.) and elsewhere; crystallises in bright-yellow lustrous needles, almost insoluble in cold, sparingly soluble in hot water, and easily soluble in alcohol. It shows an intense green coloration with ferric chloride. Emulsin is without action, acids readily hydrolyse it to rhamnose and quercitin (tetrahydroxyflavonol). In quercitrin, the sugar group is not attached to the phloroglucinol residue, but to one or other of the three remaining hydroxyls (Hlasiwetz and Pfaundler, Ann. 1863, 127, 362; Liebermann and Hamburger, Ber. 1879, 12, 1178, &c.).

isoQuercitrin $C_{21}H_{20}O_{12}$, m.p. 217° – 219° , also found in the flowers of *Gossypium herbaceum* (Perkin, Chem. Soc. Trans. 1910, 95, 2181), crystallises in pale-yellow needles almost insoluble in cold and but sparingly in boiling water. With lead acetate it gives a bright-yellow precipitate, very different from the deep-red

deposit produced from quercimeritrin. The glucoside is isomeric with quercimeritrin, and, like it, yields glucose and quercetin on hydrolysis, but differs in being readily attacked. The shades produced with the glucoside on mordanted wool closely resemble those yielded by quercitrin, but are entirely distinct from those given by quercimeritrin. The sugar is attached to either the 3', 4', or 3- positions, and not to the phloroglucinol nucleus.

Quinovin (*Chinovin*) $C_{30}H_{42}O_8$ or $C_{33}H_{62}O_{11}$, *a*-quinovin accompanies the cinchona alkaloids; it is obtained from the bark of *China nova*, which, after extraction with water, is boiled with milk of lime. The glucoside is precipitated on the addition of hydrochloric acid, and after purification forms a colourless crystalline powder, $[\alpha]_D +59.1^\circ$: it is almost insoluble in water, and has a bitter taste. Alcoholic hydrogen chloride hydrolyses it to quinoic acid $C_{22}H_{30}O_4$, and a methyl pentose, quinovose (v. CARBOHYDRATES), which, however, under these conditions, is converted into the glucoside ethylquinovoside (quinovite) $C_8H_{11}O_4 \cdot OC_2H_5$. β -Quinovin is found in the *Remijia* species, and crystallises in plates, m.p. 235° , $[\alpha]_D +27.9^\circ$: it yields the same products on hydrolysis (compare Hlasiwetz, Ann. 1859, 111, 183; Rochleder, Zeitsch. Chem. 1867, 357).

Robinin $C_{33}H_{40}O_{19}$, the glucoside of the white azalea, *Robinia pseud-acacia* (Linn.), yields, on hydrolysis, galactose, rhamnose (2 mols.), and a yellow colouring matter robenigin $C_{15}H_{10}O_6$, closely related to quercetin (Schmidt, Arch. Pharm. 1904, 242, 210; Perkin, Chem. Soc. Trans. 1902, 81, 473).

Ruberythrinic acid $C_{26}H_{28}O_{14}$, m.p. 258° , is the constituent of madder root, *Rubia tinctorum* (Linn.), which, on hydrolysis, yields alizarin. It crystallises in citron-yellow needles, sparingly soluble in cold water. It dissolves in concentrated sulphuric acid, and in alkalis with a bright-red coloration. Acids and the enzymes of madder hydrolyse it to glucose (2 mols.) and alizarin (dihydroxyanthraquinone). Since the glucoside is acid, the two glucose molecules are probably united as a disaccharide, and not attached to both hydroxyl groups. The formula

thus represents the glucoside (Liebermann and Bergami, Ber. 1887, 20, 2241; Schunck and Marchlewski, Chem. Soc. Trans. 1894, 65, 182).

Rubiadin glucoside $C_{21}H_{20}O_9$, m.p. 270° , also present in madder, forms yellow needles, which are hydrolysed to glucose and methylidihydroxyanthraquinone (Schunck and Marchlewski, Chem. Soc. Trans. 1893, 63, 969, 1137).

Rutin $C_{27}H_{30}O_{16}3Aq$, m.p. 184° , originally discovered in rue, *Ruta graveolens* (Linn.); also occurs in *Fagopyrum esculentum* (Moench), *Caparis spinosa* (Linn.), *Globularia alypum* (Linn.), *Colpoen compressum* (Berg.), *Eucalyptus macro-rhyncha* (F. Muell.), *Viola tricolor* (Linn.), *Tephrosia purpurea* (Pers.), &c.; it is identical with glucosides described as violaquercitrin, osytritin, myrticlorin. It forms pale-yellow lustrous needles sparingly soluble in cold water and alcohol, more soluble on heating. It is hydrolysed with some difficulty to glucose, rhamnose, and quercitin (compare Schmidt, Arch. Pharm. 1904,

212, 210; 1908, 246, 214; Wunderlich, *ibid.* 1908, 246, 224, 241).

Sakuranin $C_{22}H_{24}O_{10}$, 4Aq, m.p. 210° – 212° , the glucoside of *Prunus paniculata* (Thunb.), the Japanese cherry tree, forms colourless bitter needles, and yields glucose and sakuranetin $C_{16}H_{14}O_5$, m.p. 150° on hydrolysis. It is physiologically inert. Sakuranetin contains one methoxyl group, absorbs bromine, and yields phloroglucinol, acetic, and *p*-hydroxybenzoic acids when fused with potash (Asahina, Arch. Pharm. 1908, 246, 259).

Salicin $C_{13}H_{15}O_7$, m.p. 201° , $[\alpha]_D -65^{\circ}$, is the bitter stuff of willow bark, and was formerly used as a remedy against fever. It is found in many but not all *Salix* species, and besides the bark it occurs also in the leaves and female flowers. The amount varies according to the time of year. It occurs also in poplars and in the flower buds of meadow-sweet, *Spiræa Ulmaria* (Linn.). It crystallises in needles, plates, or rhombic prisms. It dissolves in about 30 parts of cold water, easily in hot water. The solutions taste bitter and are lævo-rotatory. It dissolves in concentrated sulphuric acid with an intense red coloration: this is the so-called 'rutilin' reaction. Emulsin readily hydrolyses it to glucose and saligenin (o-hydroxybenzyl alcohol). It is also hydrolysed by a specific enzyme salicase present in willow leaves and twigs.

Benzoyl salicin is the natural glucoside *populin*. Mild oxidation with dilute nitric acid converts the primary alcohol group of salicin into aldehyde, forming *helicin* $C_{13}H_{14}O_7$; e.g.

This forms bunches of slender needles, m.p. 174° . Emulsin hydrolyses it to glucose and salicylaldehyde. Helicin was synthesised by Michael by the interaction of acetochloroglucose and potassium salicylaldehyde.

Salinigrin $C_{13}H_{14}O_7$, m.p. 195° , $[\alpha]_D -87.3^{\circ}$, found only in *Salix discolor* (Muhl.) (Jowett and Potter, Pharm. J. Aug. 16, 1902), is the glucoside of *m*-hydroxybenzaldehyde, an isomeride of helicin. It gives no colour with sulphuric acid.

Sambunigrin $C_{14}H_{17}O_6N$, m.p. 151° , $[\alpha]_D -76^{\circ}$, is present in the leaves of the elder, *Sambucus nigra* (Linn.). It is isomeric with amygdonitrile glucoside, although, like this, it is hydrolysed by emulsin, the products being glucose and *l*-mandelonitrile, i.e. the nitrile of *d*-mandelic acid (Bourquelot and Danjou, Compt. rend. 1905, 141, 59, 598).

Saponins $C_nH_{2n-8}O_{10}$ are a class of closely analogous glucosides, very widely distributed in plants, having the property of dissolving in water, giving clear solutions which froth strongly on agitation, form emulsions with oils and resinous substances, and prevent the deposition of finely divided precipitates. They have a bitter acid taste, and the dust is very irritating and sternutatory; they are colloids and not dialysable. The more poisonous are distinguished as sapotoxins. They are hydrolysed by dilute acids to glucose, galactose, and active substances termed sapogenins: the different saponins give different proportions of sapogenin and sugar.

The sapogenins from many saponins, such as *Guaiacum*, *Saponaria*, *Senegin*, and *Digitonin*

saponins, have been distilled with zinc dust in an atmosphere of hydrogen, and found to yield a mixture of terpenes including sesquiterpenes (van der Haar, Arch. Pharm. 1913, 251, 217).

Saponins are prepared by extraction with water and precipitation with neutral lead acetate, if acid saponins are present: basic lead acetate is then added to the filtrate to precipitate the neutral saponins. The precipitates are decomposed and the saponin solutions evaporated, the residue being purified by solution in chloroform and precipitation by ether. For further purification, the saponin is precipitated by barium hydroxide, and the barium compound decomposed by carbon dioxide.

Saponins form double compounds with cholesterol (*v. Digitonin*). The best-known saponins are:

Quillaic acid $C_{13}H_{30}O_{10}$, the acid glucoside obtained from the bark of *Quillaja Saponaria* (Molina), is a constituent of commercial saponin. The pure glucoside is non-poisonous: it forms white flakes, which become red on treatment with strong sulphuric acid.

Quillaja sapotoxin $C_{17}H_{26}O_{10}$, derived from the same source, is a colourless amorphous powder possessing poisonous properties.

Saporubrin ($C_{15}H_{28}O_{10}$), the sapotoxin from the root of the soapwort, *Saponaria officinalis* (Linn.), has $[\alpha]_D -54^{\circ}$. It yields a series of sapogenins on hydrolysis, each giving up a further molecule of sugar as the treatment with dilute acid is continued. The final product has the formula $C_{14}H_{22}O_5$.

Levant sapotoxin ($C_{17}H_{26}O_{10} \cdot H_2O$), from the root of *Gypsophila Arrostii* (Guss.) or *G. paniculata* (Linn.), is very similar to saporubrin. On hydrolysis, 4 mols. sugar (56 p.c.), probably a mixture of glucose and galactose, and a sapogenin $C_{10}H_{16}O_2$ (23 p.c.), are formed.

Agrostemma sapotoxin ($C_{17}H_{26}O_{10}$), from the corncockle, *Lychnis* (*Agrostemma*) *Githago* (Scop.), is a yellowish-white amorphous powder yielding 4 mols. sugar and a sapogenin $C_{10}H_{16}O_2$ on hydrolysis. It is absorbed by both the subcutaneous tissue and the intestines, and is therefore a dangerous poison.

Parillin $C_{26}H_{44}O_{10}$, one of the saponin glucosides of sarsaparilla, the dried root of various *Smilax* species, has m.p. 177° , $[\alpha]_D -42^{\circ}$. It is hydrolysed to a mixture of two sugars and parigenin $C_{28}H_{46}O_4$. The other glucosides of sarsaparilla are *smilasaponin* ($C_{20}H_{32}O_{10}$)₅ and *sarasaponin* ($C_{22}H_{36}O_{10}$)₁₂, m.p. 223° .

Sarsaparilla saponin, from *Smilax ornata* (Hooker), contains a *phytosterolin*, crystalline needles, m.p. 280° , $C_{33}H_{56}O_8$, and hydrolysing to glucose and *sitosterol*; and *sarsasaponin* $C_{44}H_{76}O_{20}$, 7Aq, crystals, m.p. 248° . The latter yields on hydrolysis 3 mols. of glucose and 1 mol. of *sarsasapogenin* $C_{26}H_{41}O_5(OH)$, 1½Aq, m.p. 183° , $[\alpha]_D -60^{\circ}$.

The *smilacin* or *smilasaponin* of v. Schulz is not a homogeneous substance (Power and Salway, Chem. Soc. Trans. 1914, 105, 201).

Carlophyllsaponin $C_{66}H_{104}O_{17}$, m.p. 250° – 260° , $[\alpha]_D +32^{\circ}$, is a crystalline saponin found in *Carlophyllum thalictroides* (Linn.), which yields 2 mols. *l*-arabinose and 1 mol. *carlophyllsapogenin* $C_{56}H_{82}O_8(OH)_8$ (Power and Salway, Chem. Soc. Trans. 1913, 103, 191).

Caulosaponin $C_{54}H_{88}O_{17}$, m.p. 250° – 255° , is a crystalline saponin found in *Caulophyllum thalictroides*, and gives 2 mols. glucose and 1 mol. *Caulosapogenin* $C_{42}H_{66}O_5(OH)_4$ upon hydrolysis (Power and Salway, Chem. Soc. Trans. 1913, 103, 191).

Digitosaponin is a colourless amorphous substance present with gitalin in *Digitalis* leaves, which gives *digitosapogenin* and a pentose on hydrolysis (Kraft, Arch. Pharm. 1912, 250, 118). It is apparently identical with Schmiedeburg's *digitonin*.

Hederins. The following saponins have been isolated from ivy (*Hedera helix*):—

α -*Hederin* $C_{42}H_{66}O_{11}$ (?), crystalline needles, m.p. 256° – 257° , insoluble in water, and giving on hydrolysis arabinose, rhamnose, and α -hederogenin $C_{31}H_{50}O_4$, a dihydroxylactone melting at 325° – 326° ;

β -*Hederin*, a crystalline saponin insoluble in water;

γ -*Hederin*, an amorphous saponin insoluble in water; and

Δ -*Hederins*, a mixture of saponins soluble in water (van der Haar, Biochem. Zeitsch. 1916, 76, 335).

Polysciasaponins, from *Polyscias nodosa*, are white amorphous products, carbonising at about 325° .

On hydrolysis with 5 p.c. sulphuric acid, equimolecular amounts of arabinose, glucose, and a *sapogenin* $C_{26}H_{44}O_4$ are produced; the latter forms rhombic crystals, m.p. 324° , and is a saturated lactone, but contains no carboxyl, hydroxyl, methoxyl, or ethoxyl groups (van der Haar, Biochem. Zeitsch. 1916, 76, 335).

Prosapogenin, from *Gypsophila* saponin and dilute sulphuric acid, melts at 207° , and with 2 p.c. sulphuric acid under pressure gives a *sapogenin* $C_{24}H_{34}O_5$, m.p. 267° , a monobasic ketonic acid (Rosenthaler and Ström, Arch. Pharm. 1912, 250, 290).

Saponarin from *Saponaria officinalis*. The aqueous solution of the crystalline saponin is not coloured by iodine, but the colloidal aqueous solution gives a blue adsorption compound with this reagent (Barger and Field, Chem. Soc. Trans. 1912, 101, 1394).

Saponin from *Sapindus Makurosi*, an amorphous white powder, $[\alpha]_D^{+13}$, hydrolysing to *d*-arabinose and a crystalline *sapogenin*, m.p. 319° (Asahina and Shimidzu, J. Pharm. Chim. 1916, [vii.] 14, 188).

Saponin from *Styrax japonica*, a crystalline calcium salt, m.p. 254° – 257° . Treatment with 0.5 p.c. hydrochloric acid gives the free saponin, *jegosaponin* $C_{55}H_{88}O_{26}$, m.p. 238° , $[\alpha]_D^{-39}$. This hydrolyses to glucose, glycuronic and tiglic acids, and a mixture of *sapogenins* (α - $C_{33}H_{52}O_6$, m.p. 150° , and β - $C_{33}H_{52}O_7$, m.p. 225° – 228°) (Asahina and Momoya, Arch. Pharm. 1914, 252, 56).

Saponin from *Yucca angustifolia* (root-stock) $C_{38}H_{58}O_{20}$, gives galactose on hydrolysis (Viehoever, Chernoff, and Johns, J. Biol. Chem. 1916, 24).

Saponin from *Yucca radiosa* (root-stem) $C_{37}H_{58}O_{20}$, gives glucose or mannose on hydrolysis (Johns, Geiger, and Viehoever, J. Biol. Chem. 1916, 24).

Scopolin $C_{22}H_{38}O_{14}$, 2Aq, m.p. 218° , occurs in *Scopolia japonica* (Maxim.) and *S. carniolica*

(Jacq.). It is hydrolysed to glucose (2 mols.) and scopoletin, which is identical with *æsculin* methyl ether (Eykmann, Rec. trav. chim. 1884, 3, 177).

Serotin $C_{27}H_{26}O_{12}$, 3Aq, m.p. 245° , found in the leaves of *Prunus serotina* (Ehrr.), commonly known as the wild black cherry, crystallises in golden yellow leaflets. It is more soluble in water and more readily hydrolysed than quercimeritrin. Acids convert it into glucose and quercitin (Power and Moore, Chem. Soc. Trans. 1910, 97, 1099).

Sinalbin $C_{30}H_{42}O_{15}N_2S_2$, 5Aq, m.p. 138° – 140° , found in white mustard *Sinapis alba* (Linn.), crystallises in faintly yellow-coloured needles which are slightly soluble in cold, easily soluble in hot water, and lævo-rotatory. It is hydrolysed by the myrosin present in the seeds to glucose, sinalbin mustard oil $C_7H_7O \cdot NCS$, and acid sinapin sulphate $C_8H_{12}O_5N \cdot HSO_4$. Sinapin $C_{16}H_{25}O_6N$ is only known in the form of its salts, barium hydroxide converts it into choline $C_2H_4(OH)N(OH)Me_3$ and sinapinic acid $C_6H_2(OH)(OMe)_2CH : CH \cdot CO_2H$.

The alcohol corresponding to this acid is syringenin obtained from the glucoside syringin. Sinapin is accordingly

Sinalbin mustard oil has the composition

Sinigrin $C_{16}H_{16}O_9NS_2K$, Aq, m.p. 126° , is the active principle of black mustard, *Brassica nigra* (Koch). It crystallises in lustrous colourless needles, very soluble in water, sparingly soluble in cold alcohol. It is lævo-rotatory. Myrosin or a water extract of the seeds hydrolyses it to glucose, allylthiocyanate and potassium hydrogen sulphate. Emulsin is without action. As hydrolysis by myrosin proceeds, the increasing quantity of acid potassium sulphate formed renders the ferment less active and ultimately stops its action. Gadamer has proposed the formula, $C_8H_5N : C(SC_6H_{11}O_5)(SO_2K)$. This is supported by Schneider and Wrede (Ber. 1914, 47, 2225), who found that the silver salt of thioglucose was produced by treatment of sinigrin with potassium methoxide followed by the action of ammoniacal silver nitrate.

Skimmin $C_{15}H_{16}O_8$, m.p. 210° , occurs in *Skimmia japonica* (Thunb.). It crystallises in colourless needles, sparingly soluble in water, and dissolves in alkalis with a blue fluorescence. Acids hydrolyse it to glucose (?) and skimmetin ($C_9H_{10}O_3$), m.p. 223° , which is perhaps identical with umbelliferone (monohydroxycoumarin) (Eykmann, Rec. trav. chim. 1884, 3, 208).

Solacein, a nitrogenous glucoside occurring in *Dulcamara* species, m.p. 236° – 237° , hydrolyses to solanidine and a sugar (G. Masson, Bull. Sci. Pharm. 1912, 19, 283).

Solanine ($C_{27}H_{49}O_9N$) $_2 \cdot H_2O$, found in *Solanum sodomæum*, yields on hydrolysis galactose, a methylpentose, and the base solanidine $C_{18}H_{31}ON$, the constitution of which has not been determined, except that it is known to contain hydroxyl and imino groups.

Several different glucosides appear to have received the same name (Oddo and Cesaris, Gazz. chim. ital. 1911, 41, 490, 534; 1914, 44, [ii.] 181), e.g. *Solanine*, occurring in *Solanum angustifolium*, isolated by Tutin and Clewer (Trans. Chem. Soc. 1914, 105, 559); and *Solanine-s* $C_{54}H_{96}O_{18}N_2 \cdot H_2O$, occurring in *Solanum sodomæum*, which is hydrolysed to 1 mol. glucose, 1 mol. *d*-aldomethylpentose, 1 mol. *d*-galactose, and 2 mols. of solanidine- s $C_{15}H_{31}ON$, a base containing hydroxyl and imino groups (Oddo and Cesaris, Gazz. chim. ital. 1914, 44, [ii.] 181).

Strophanthin $C_{40}H_{66}O_{19}$, m.p. 170° – 172° , is obtained from the seeds of *Strophanthus Kombe* (Oliver) and other species. It occurs as a pale-yellow amorphous or a colourless microcrystalline powder, having an intensely bitter taste and a faintly acid reaction. It is freely soluble in water and very poisonous. With concentrated sulphuric acid it is coloured green or orange, then red, and, on warming, dark-brown and finally green. Acids hydrolyse it to strophantidine $C_{27}H_{33}O_7$, and methyl strophantobioside $C_{13}H_{24}O_{10}$, which is in turn broken down to rhamnose, mannose, and methyl alcohol. Strophanthin is similar to digitalis in its action on the heart.

Syringin $C_{17}H_{24}O_9 \cdot 1Aq$, m.p. 191° , $[\alpha]_D -17^{\circ}$, is found in the syringa, *Syringa vulgaris* (Linn.), and also in the bark of lilac and privet. It crystallises in slender needles, gives a reddish-violet coloration with sulphuric acid, and is readily soluble in warm water. It is hydrolysed by emulsin and by acids to glucose and syringenin, i.e. dimethoxyconi-

Trifolin $C_{22}H_{22}O_{11} \cdot 1Aq$, m.p. 260° , found in the flowers of the common red clover, *Trifolium pratense* (Linn.), forms slender pale-yellow needles. It gives intense yellow solutions with alkalis, gives a yellow solution which develops a green fluorescence in concentrated sulphuric acid. It is hydrolysed by acids to rhamnose and trifolitin $C_{16}H_{10}O_6$, a yellow colouring matter (Power and Salway, Chem. Soc. Trans. 1910, 97, 231).

Turpethin $C_{34}H_{56}O_{16}$, m.p. 149° , from the dried sap or root of *Ipomæa Turpethum* (R. Br.), is very similar to jalapin, but differs in being insoluble in ether. It is an amorphous powder. Acids hydrolyse it to glucose (3 mols.), turpethol $C_{16}H_{30}O_5$, isobutyric acid, and a viscid acid, $C_{15}H_{28}O_5$ (see Spigatis, Annalen, 1866, 139, 41; and Kromer, Chem. Soc. Abstr. 1893, i. 482). Votoček and Kastner (Chem. Soc. Abstr. 1907, i. 330) have isolated two other glucosides, α - and β -turpethin from *I. turpethum*. The α -isomeride gives rhamnose, the β -isomeride rhodose, and glucose when hydrolysed.

Vicianin $C_{19}H_{25}O_{10}N$, m.p. 160° , $[\alpha]_D -20^{\circ}$, occurs in the seeds of *Vicia angustifolia* (Bertrand and Weisweiler, Compt. rend. 1908, 147, 252; 1910, 151, 325, 884). It is hydrolysed by an enzyme present in many *Vicia* species to *d*-mandelonitrile and a C_{11} disaccharide (vicianose), which is composed of glucose and

arabinose. Vicianin therefore represents an amygdalin in which arabinose is substituted for glucose.

Violaquercitrin v. Rutin.

Xanthorhamnin $C_{34}H_{42}O_{20}$ is found in the fruits of *Rhamnus infectoria* (Linn.), *Rh. tinctoria* (Wald. and Kit.), and in various parts of other species of *Rhamnus*. It crystallises from alcohol in golden-yellow microscopic needles, is readily soluble in water and dissolves in alkalis with a yellow coloration. It is hydrolysed by an enzyme *rhamninase* to a trisaccharide (rhamnose) and rhamnetin $C_{16}H_{12}O_7$. Rhamnose is further hydrolysed by acids to rhamnose (2 mols.) and galactose. Rhamnetin is: quercitin monomethyl ether

(see Tanret, Compt. rend. 1899, 129, 725).

E. F. A.

GLUCURONIC ACID v CARBOHYDRATES.

GLUE AND GLUE TESTING. The term *glue* comprises preparations obtained by the action of water from certain portions of animals and fishes, which have the power of gelatinising in aqueous solution and drying up to a hard strongly adhesive layer.

Other preparations which possess this adhesive property are also loosely termed glues; e.g. marine glue, a resinous composition; gluten and casein glues, mineral and vegetable glues, &c., but, strictly speaking, they have no claim to that name, as they contain no gelatin.

The term *gelatin* is applied to glues made from specially selected stock, and so gelatin may be considered a purer form of glue.

Glue or gelatin is probably not contained as such in the animal, but is the product of the hydrolysis of various nitrogenous tissues, brought about by boiling with water.

These tissues have been classed as follows:—

(1) *Osseine*, of bones and skin, *Chondrigen*, of cartilage; *Isinglass*, from the bladders of fish; these are classed under the general name of *Collagens*.

(2) *Elastin*, from certain ligaments.

(3) *Chitin*, from beetles, locusts, shrimps, crabs, &c. It can be converted into a gelatinous form by treatment with acids, but is of no utility.

(4) *Keratin*, from hair, horns, hoofs, and feathers. These yield products which have little power of gelatinising, and are not used in the glue manufacture.

For convenience the products obtained from collagens by the action of water may be classed into Glutin and Chondrin, the properties of which will be described later.

Manufacture.—(a) **Bone glue.** For this purpose, bones of all kinds are used, and vary, therefore, so much in composition that it is useless to give any detailed analysis. In addition to calcium phosphate and carbonate, the main ingredients of the ash, they contain fat and gelatin-forming substances, ossein and chondrin. Before the gelatin can be obtained, it is necessary to remove the fat of which fresh bones such as ribs, heads, shoulder blades, contain from 12 to 13 p.c., while large thigh bones may contain 17 to 18 p.c. Marine store bones,

such as have been used for soup, Indian and South American bones rarely contain more than 12 p.c. of fat.

There are in use three chief methods of extracting the fat:—

(1) By simply heating the bones in a tank provided with a steam coil; (2) by heating with steam in a digester under pressure; (3) extraction of the fat by volatile solvents.

By the first of these processes, the yield is only about 10 p.c., by the second up to 12 p.c., whilst by the third almost all the fat can be obtained.

The solvent extraction process is the one now used in most modern factories. The solvents are mainly those portions of Scotch shale naphtha or American or Russian petroleum boiling from 90° to 105°, and coal-tar naphtha of similar boiling-point. In this country, Scotch shale naphtha, boiling between 100° and 115°, is usually employed. A modern extracting plant consists of, say, 6 cylindrical vertical boilers of a capacity of 5 tons of bones, worked in sets of three, one lot extracting while the other set is being emptied. As the bones are delivered at the works, they are sorted and then crushed in a mill and filled into the extractors, which are provided with perforated false bottoms, under which are placed wet and dry steam coils. At the top of each is a pipe for conveying off the vapour of the solvent to a set of condensers usually placed outside the building. When the extractors have been filled and the manholes closed, the solvent is run in and heat applied by the dry coils until the solvent begins to distil over, carrying with it the moisture present in the bones. When it begins to pass over free from moisture, the dry coils are shut off, and the first charge of the extracted fat run off from below the bones into the *mont-jus* or 'distiller.' This operation is repeated three or four times, when the bones are free from fat, but retain a considerable amount of the solvent, which is blown over by high-pressure steam from the wet coils into the condenser. The whole operation takes about 12 hours. The bones are then raked out through the lower manhole and conveyed to the cleanser. When dry, they should be free from smell, and contain not more than $\frac{1}{2}$ p.c. of fat. The fat held in solution in the solvent is then heated in the distiller to expel the solvent which is condensed and used again. The fat is freed from dirt by heating with hot water and settling, and is then run into barrels. It contains about 98 p.c. of pure fat and is used in soap, candle, glycerol, and in the case of fresh bones for margarine making.

The cleansing of the bones is done by passing them through a rotating cylindrical wire gauze sifter, and they are then ready for the boiling operation.

The extraction or 'cooking' is carried out in one of two ways: (1) By the alternate action of steam and water playing on the bones contained in a large iron boiler of from 3 to 5 tons capacity. As this method yields weak glue solutions, costly to concentrate, modern manufacturers prefer the second plan (2) i.e. to 'cook' in autoclaves under, say, 15 lbs. steam pressure, reduced later to 4 to 5 lbs., this being done to allow the glue contained in the interior of the bones to exude, so that it may be washed

down by the spray of water. This action is repeated until the solution contains about 20 p.c. of glue.

The glue liquors are then clarified by standing in tanks, kept warm by steam coils, when the dirt settles, and any grease rising is skimmed off. To assist in the clarification, many substances have been suggested, such as blood, basic lead acetate, milk of lime, sodium phosphate, oxalic acid, albumen, but they are rarely used, as $\frac{1}{2}$ p.c. of potash alum fulfils the purpose better than any of them. After adding the dissolved alum, the whole mass is agitated and heated to 80°, and then strained through fine wire gauze or canvas.

The glue solution, thus clarified, is then introduced into the concentrators, where excess of water is removed under reduced pressure, so as to avoid injury to the glue by heating to too high a temperature.

The principle of these concentrators is that of the vacuum pan, and the Yaryan type is one of the most modern forms.

This consists of an iron vessel, globular or cylindrical in shape, steam jacketed and provided internally with steam coils immersed in the glue solution. The dome, which is provided with baffle plates, is connected with a vacuum pump and condenser. In order to save fuel, the steam from the glue of one pan is led on the multiple-effect principle, into the coils and jacket of another, and so on to a third. (V. EVAPORATION.)

After concentration, the glue liquors, before settling, are usually bleached by the action of sulphur dioxide, produced in any suitable way, which is led through the liquors by perforated pipes while they are contained in lead-lined tanks and kept liquid by steam coils. When the required shade has been reached, the liquors are ready for jelling, and are run out into galvanised iron troughs, 2 feet \times 6 inches, to the depth of 5 inches, and allowed to cool. When set, the mass is removed and cut by a 'wire knife' into sheets of suitable thickness. Or the troughs may be dispensed with and the liquid jellied on water-cooled glass slabs placed in rows on tables.

The drying operation, which follows, is one of the most important parts of the manufacture of glue. Since the jelly melts at a temperature of about 25° in summer, the air entering the drying rooms must be cooled, while in winter it is usually so charged with moisture that, in order to effect any desiccation of the jelly it must be warmed. These operations are carried out by suitable refrigerators and steam pipes.

The cakes of glue are placed on frames covered with nets, which may be of cotton or wire. These are supported on suitable trollies and placed in chambers through which air, of the proper temperature and humidity, as indicated by wet-and-dry bulb thermometers, is circulated by fans. In 4 or 5 days, the cakes are removed from the racks and packed; they then contain 10 to 13 p.c. of water.

Osseine is a French preparation obtained by treating the fat-freed bones with dilute mineral acids, when the phosphates and other soluble salts are removed.

The residue consists of the glue-forming

ingredients of the bones, and may be made into glue by treatment with water under heat, but in the writer's experience, the change is very slow, and the preparation, although useful to the manufacturer of glue, is not to be recommended to the ordinary consumer of size.

Hide or Skin glue. While the *epidermis* of the hide yields little or no glue, the *corium*, or inner skin, consisting mainly of connective tissue, gives a good percentage on treatment with hot water.

The raw materials for skin glue are the various clippings of hides, the ears and tails of oxen and sheep, rabbit and hare skins, old parchment, old gloves, pigs' skins, and all waste leather which has not been tanned.

The first process in the manufacture of glue from these is to subject them to the action of milk of lime in shallow pans or pits for several days, the skins being constantly stirred with forks.

These operations loosen the hair. From the pits, the skins are taken to the unhairing room, where the still adhering hair is scraped off by a blunt knife, and any fleshy parts, &c., removed. The hair thus obtained finds use in plastering work and felt making, &c.

Tanned leather cannot be used, but tannery waste trimmings, after the liming or depilatory process, form the raw material for good glue.

In modern practice, besides milk of lime, other substances, such as sodium sulphide, soda, and a mixture of soda and lime are used. The first is said to be good, but in presence of iron causes blackening of the hides.

After liming, the skins, when firm and free from greasy feel, are washed, first with water, then with dilute hydrochloric acid, and finally again with water. The excess of water is removed from the wet stock by drying and pressing.

The dried material is then heated, enclosed in sacks in a boiler with water until the liquors contain about 32 p.c. of glue. It may then be run in a Yaryan concentrator, or direct into coolers, or on to glass slabs for jellifying and cutting and dried as before.

Fish glue. The raw materials for this are chiefly the skins (especially those of soles and plaice), the bladders of various fish and all varieties of fish offal. These yield, by processes similar to the above, a very adhesive but evil-smelling glue, which it is said may be deodorised by treatment with 1 p.c. of sodium phosphate and 0.25 p.c. of saccharine (Lambert).

Isinglass is a valuable product obtained from the swimming bladders of various fish, of which the sturgeon of the Volga yields the best quality, but Brazilian, Penang, Indian, and Hudson's Bay isinglass are also on the market. It arrives in this country either as the unopened bladders, known as pipe isinglass, or as purse, lump, or leaf. In preparing the last two, the bladders are cleansed by washing with hot water, and then cut open and dried.

Before solution in water, the crude isinglass is moistened, cut into strips, rolled out into ribbons and dried. When dry they are shredded by suitable machines. Isinglass is mainly used in clarifying wines, ciders, and beers, by the cook for making jellies, and in the preparation of plasters.

Glue size may be considered as a by-product, since it usually consists of the crude glue liquors which are the product of the third or fourth extraction of the raw material, which, if dried, would yield a glue of inferior quality. In small works and in some factories, where size is used, it is often made direct from bones or such leather waste as 'pickers' by treatment with lime, heating and straining.

Size is usually treated with sulphur dioxide to improve its colour and its keeping power. Zinc sulphate or boracic acid is often added as a preservative, and when sold it usually contains about from 25 to 38 p.c. of glue.

Concentrated size consists of ground glue, such cakes as are off shade and quality being used.

Coloured or Opaque glues are made by the addition of a small quantity of some pigment such as finely ground chalk or whitening.

CHEMISTRY AND PROPERTIES OF GLUE.

The products yielded by the hydrolysis of collagens may be divided into three groups:

(1) **Glutin (gelatin).** This is a colourless, yellowish, transparent, odourless, and tasteless body. It has the following composition:—

GELATINS FROM CONNECTIVE TISSUE.

(Chittenden, 1908.)

	1	2
Carbon	50.12	50.00
Hydrogen	6.68	6.52
Nitrogen	17.84	17.88
Sulphur	0.32	0.23
Oxygen	25.10	25.35
Ash	0.32	0.36

The quantity of sulphur varies considerably, and appears to be largely a constituent of the ash, which, in commercial glue, is often as high as 1.75 p.c. By precipitation with alcohol from aqueous solution, gelatin may be obtained almost ash- and sulphur-free. When immersed in water, glutin, while insoluble in the cold, swells up and greatly increases (5 or 6 times) in weight. It dissolves in hot water, and the solution, on cooling, sets to a jelly. Prolonged heating with water lessens its gelatinising power. Solutions of glutin on exposure to air rapidly putrefy, evolving, among other products, ammonia. It is insoluble in ether and alcohol, but soluble in glacial acetic acid (such solutions being made use of in the familiar 'Diamond cement' and 'Secotine'). Solutions of glutin are not precipitated by gold, silver, or copper salts, but the two former are reduced to the metallic state on heating. Platinum salts give brown precipitates and form a delicate test for glutin. The various tannic acids precipitate glutin, with the production of leather-like substances. This precipitate is insoluble in organic solvents, such as ether and alcohol, but soluble in warm alkalis. Iron, aluminium, potassium, and lead salts cause no precipitate, but mercuric chloride renders its solution turbid. Chromium salts, especially potassium dichromate and chrome alum, have the power of rendering gelatin insoluble in water after exposure to light, which property is made use of in photography and other industries.

Dry distillation of glutin yields water and a dark thick oil, similar to Dippel's oil, containing pyridene bases, aniline, &c. Formaldehyde,

when added to a glutin solution, solidifies it and renders it no longer soluble even in hot water. 8 p.c. of formaldehyde on the dry glue gives maximum effect. This property has been utilised in waterproofing and in the production of Vandura silk.

(2) **Chondrin.** This horny substance, very similar to glutin, is contained in most glues, but differs in being precipitated from its solutions by nearly all acids, though usually soluble in excess. Many salts, such as alum, lead acetate, and iron salts, also precipitate it. Its composition is given as :

Carbon	49.92
Hydrogen	6.76
Nitrogen	15.65
Oxygen	27.67

Its gelatinising and adhesive powers are weaker than those of glutin.

(3) **Mucin.** This name covers a number of bodies which are usually removed in the liming operation. If left in the glue, they give rise to 'foaming,' and have little or no adhesive property.

Uses of glue.—A great variety of industries employ glue in some form or other. It is employed in sizing textiles, papers, walls, canvas, &c. It is also largely employed in joiners' work, veneering, box making, the making of matches, &c.

Mixed with glycerin, treacle, or glucose, it forms the compositions used as substitutes for rubber and for printing rollers, stamps, &c. Mixed with treacle or glycerin, it is employed in making the familiar 'jellygraph.'

It is also used in photography, and as gelatin it forms part of the raw materials of cookery.

GLUE TESTING.

The testing of glue has relation to the properties required for the particular purpose to which the glue is to be put. General requirements are tenacity, adhesiveness, and keeping power.

Chemical tests. (1) *Moisture determination.*—The sample of glue is reduced to shavings by means of a 'spoke-shave,' and these are ground to powder in a mortar. Five grams are weighed out on to a clock-glass and dried, first in the water-oven and then in a toluene bath to constant weight. Glues in this way yield 12 to 18 p.c. of moisture. A very low result is not desirable, as it shows the glue has been over-dried and has little tenacity, while a high result throws doubts on its keeping quality.

(2) *Ash.*—A portion of the glue is incinerated in a platinum crucible, and the ash weighed. That from bone glue fuses and gives, when taken up in dilute nitric acid, the phosphoric acid reaction with ammonium molybdate, whereas the ash from hide glue does neither, and is usually alkaline from the lime used in the preparation. The ash content of good glues varies from 1.5 to 3.0 p.c. Glues weighted with barytes, &c., and 'coloured glues,' of course, yield more.

(3) *Acidity* may be determined directly by titrating a measured quantity of, say, a 10 p.c. solution with standard alkali, using phenolphthalein as indicator. Should the glue solu-

tion be highly coloured, as is the case with some Scotch glues, fluorescein may be used in its place. The volatile acids of glue may be determined by dissolving 50 grams of the sample in water, and subjecting the solution to steam distillation. The steam and vapour are led through a condenser and received in a vessel containing a known volume of standard alkali. After some 300 c.c. have been condensed, the amount of acid absorbed by the alkali is determined by titration. It is expressed as H_2SO_4 , and a good glue should not yield more than 0.2 p.c. (Lambert).

(4) *Fatty matters* are determined by extracting 5 grams of the finely powdered sample, contained in a capsule in the Soxhlet apparatus with ether.

(5) *Determination of the gelatin content by yield of nitrogen.* Trotman and Hackford (J. Soc. Chem. Ind. 1904, 1072) give a process for the determination of the gelatin present in glue. They point out that a direct determination of nitrogen by Kjeldahl's method or soda lime distillation gives misleading results—owing to the presence of peptones, &c. (the decomposition products of gelatin) when it is multiplied by the factor 5.33. They consequently precipitate the gelatin with zinc sulphate crystals, wash the precipitate with concentrated zinc sulphate solution, and treat the product by the Kjeldahl process. The amount of nitrogen, multiplied by 5.33, gives the gelatin content. This method has been criticised by H. J. Wilson, but it appears to differentiate between gelatin and the other nitrogenous ingredients of glue.

Estimation by precipitation with tannic acid. Standard solutions of pure gelatin (10 grams per litre) and of tannic acid (10 grams per litre) are made. The two are then titrated together until no further precipitate is produced. A weighed quantity of the sample is then titrated against the tannic acid, and thus its gelatin content determined.

Stelling's method of determining gelatin consists in precipitating the solution by 96 p.c. alcohol, but owing to the partial solubility of gelatin in that menstruum, Rideal considers it untrustworthy.

(6) *Water absorption.* A very general method of testing glue consists in determining the amount of water which it will absorb. A weighed quantity of glue is covered with water at 60°F. (15.5°C.) and allowed to soak for from 24 to 48 hours, according to the thickness of the cake, or until the cake is thoroughly saturated by the water, which can be judged by its colour and appearance.

The cake is then removed, dried superficially with filter paper, and the increase of weight determined. Generally speaking, the greater the increase the better the glue, provided that the cake remains firm. Fine bone and skin glues will increase in weight 8 to 11 times, common glues 5 times, but some of the very common fish glues may liquefy completely under these conditions. In making this test, the smell of the glue and the colour of the water should be noted, when valuable information as to the keeping qualities and probable sources of the glue may be gleaned.

Jelly tests. 10 grams of glue are soaked for

24 hours in water, and then melted and the solution made up to 100 c.c. The solution is cooled, and the strength of the jelly tested with the finger. It is quite possible to grade the various samples of glue with considerable accuracy by this method.

Lipowitz shot test. If it is desired to have a quantitative expression of the strengths of the jellies yielded by a number of samples of glue, the samples containing 10 p.c. of glue may be run into cylinders of uniform width and allowed to set. The cylinders are then in turn covered with a lid, through which, in a guide tube, passes a stout wire, to the lower end of which is soldered a convex disc, while the upper end carries a pan to carry weights or shot. The convex surface of the disc rests on the surface of the jelly, and weights or shot are added to the upper pan until the lower disc penetrates. The greater the amount of weight the jelly will carry, the greater is its consistency.

This method is largely employed, but its value is only comparative.

Strength of jelly. The writer has used a method for some years which he claims to give more reliable results. 30 grams of glue are soaked in water and, after melting, the solution is made up to 100 c.c. and transferred to a vessel so that the depth of the layer is $1\frac{1}{2}$ to 2 inches. This, of course, may be varied according to the vessels at command, but it should be the same for all the samples. While the solution is still warm, a circular disc of metal 1 inch in diameter, to the centre of which is fixed a stout wire, is inserted. Halfpennies form convenient discs. The wire is kept in a vertical position until the solution has jellied. The vessel is clamped down and the wire attached to one arm of a stout balance. Weights are then placed in the other pan until the disc is torn through the jelly. The greater this weight, the tougher the jelly and stronger the glue. The test should be repeated several times, and the mean taken. A good glue under these conditions requires over 10 lbs. to tear the disc through the jelly. It is claimed that by this method the variations due to the surfaces of the glue jellies are obviated.

Hulbert (*J. Ind. Eng. Chem.* 1913, 5, 235) has described a simple apparatus for testing the jelly-strength of glues (*cf.* Clark and Du Bois, *J. Ind. Eng. Chem.* 1918, 10, 707).

Melting-point of jelly. 15 grams of the sample are soaked in 30 c.c. of water for 12 hours, heated on the water-bath, and the solution poured into a wide test-tube in which a thermometer is inserted. In a similar tube, a solution of a good hide glue (1 : 1) is poured, and both tubes are immersed in water at 15°. When set, the two tubes are placed in a horizontal position on a shelf over a water-bath. Their melting-point is taken to be the temperature at which the surfaces of the glue solutions leave their vertical positions (Kissling).

According to Sammet (*J. Ind. Eng. Chem.* 1918, 10, 595), comparison with standard glues shows that the melting-point may be taken as a measure of the jelly-strength.

Viscosity of jelly. Fels (*J. Soc. Chem. Ind.* 1901, 139) recommends that the viscosity of a 15 p.c. solution of glue at 30° should be tested in the Engler viscosimeter, on the assumption that

the greater the viscosity the stronger is the glue.

Rideal uses a modified form of the Slotte instrument (*J. Soc. Chem. Ind.* 1891, 615), and uses 1 p.c. solutions at 18°.

A simple way of carrying it out is to run the solution from a burette; the time taken for 50 c.c. to flow is taken as a measure of its viscosity. Supposing 25 secs. are taken by water at that temperature, a 1 p.c. solution of a strong glue will take 32-34 secs.; a medium glue, 28-30 secs.; weak glues, 26-27 secs.

Tensile strength of glue. Many methods have been suggested such as Bauschinger's, Kissling's, and Rideal's. Rideal has devised the following method:—

Two plane surfaces of biscuit porcelain, ground so as to fit, 1 square inch in area, are soaked with a solution made up of 1 part of glue in 2 parts of water at 70° for 30 minutes; they are placed together, weighted with 5 lbs., and kept for 5 days in a cool room. They are then fixed in a testing machine, and the weight necessary to tear them asunder is determined (*cf.* Gill, *J. Soc. Chem. Ind.* 1915, 292).

The writer has used with success a slightly modified form of a method originally suggested by Millar (*J. Soc. Chem. Ind.* 1899, 16). 10 p.c. solutions of the glues to be tested are made up. Strips of filter or other paper are cut, 1 inch in width and about 18 inches in length. These are dipped in the solution at about 50°, and then hung up to dry. When the first coat has dried, they are again immersed in the solution and allowed to dry, the portion that was lowest being placed at the top, so that as far as possible a uniform layer of glue is produced on their surfaces. After air-drying, the strips are heated for 1 hour in the water-oven. Two or three lengths of 3 inches are cut out of the central portion of the strips. These are then separately tested by fixing between two indiarubber-covered clamps, one of which is fixed to the table and the other attached to the beam of a strong balance, the balance with the clamp, of course, being first counterpoised. Weights are added to the other pan until the paper breaks. A blank test is then made with the unsized paper, and this is deducted. Several experiments should be made, and the mean taken. A good glue should require some 9 or 10 lbs. when tested in this way to break the sized paper (*cf.* Gill, *J. Ind. Eng. Chem.* 1915, 7, 102; Rudeloff, *Mitt. K. M. Materialproof*, 1918, 36, 2; *J. Soc. Chem. Ind.* 1918, 37, 743, A).

Foam test. Trotman and Hackford (*J. Soc. Chem. Ind.* 1906, 104) recommend the following procedure: A graduated tube, 70 cm. in length and of such a diameter that each 1 cm. in length has a capacity of 1 c.c., is half filled with a 10 p.c. solution of glue and placed in a water-bath. The temperature of the bath is maintained as nearly as possible at 60°. The tube is then corked, vigorously shaken for 1 min., and the top of the foam layer read off. The line of demarcation between the lower level of the foam and the liquid is too undefined to allow of reading, but that of the upper layer is constant. The peptones present in glue increase its tendency to foam.

The test is of importance for certain uses of glue, such as its application in veneering.

General remarks on the testing of glue.—Of course in each case, as already stated, the tests applied should refer directly to the uses to which the glue is to be put. For veneering and general joiner's work, for bookbinding and the like, a glue should have good tensile strength, little foaming power and good keeping qualities. It should also show a good jelly test and be free from grease, or it may give uneven joints. The glue for use in the sizing of canvas and the like should show a good strength of jelly and good tensile strength: foaming power and grease are of less importance. For the preparation of distempers, the grease content should be low, as it may give rise to 'fleck'; the keeping power should be high, but the tensile strength and strength of jelly are of less importance.

The specifications and tests of glue adopted by the American Society for Testing Materials, 1914, are as follows: Specifications for checking the quality of cabinet glue, should be based upon the viscosity, jelly-strength, odour, reaction, grease, foaming, ash, moisture, and appearance. The glue should be clean and free from an excessive number of air bubbles, the presence of the latter indicating decomposition during manufacture. About 6 p.c. of ash is the permissible maximum; the quantity usually found lies between 2.3 and 4.5 p.c. The glue should be neutral, or practically so to litmus paper. The jelly-strength is best ascertained by steeping the glue in cold water for 16 hours and then melting it at 160°F. (71°C.), the proportions of glue to water being such that the resulting jelly will contain from 7 to 10 p.c. of glue (7 p.c. in the case of higher-grade glues and 10 p.c. for lower qualities). The jelly is then cooled to about 45°F. (7°C.) and its firmness, judged by pressing with the fingers, is compared with that of a jelly prepared from a standard sample. Viscosity is determined at 30°C. in an Engler's viscometer, using a 15 p.c. glue solution; the time of flow for a high-grade glue is about 350 seconds. Glue should not contain any fatty substance, as determined by heating the glue solution with hydrochloric acid and extracting the cooled mixture with ether. Excessive foaming is undesirable; 300 c.c. of a 10 p.c. glue solution are heated for 1 minute to 150°F. (65°C.) in a beaker of about 2.5 inches diameter, when the layer of foam produced should not exceed 0.25 inch in depth (J. Soc. Chem. Ind. 1914, 33, 1021).

Hy. I.

GLUTOL *v.* SYNTHETIC DRUGS.

GLUTAMIC ACID, α -Aminoglutaric acid

was discovered by Ritthausen in 1866 (J. pr. Chem. [1] 99, 6, 454) among the products of the hydrolysis of wheat gluten by sulphuric acid, and hence called by him *glutaminic acid*. Subsequently, Ritthausen and Kreusler (J. pr. Chem. 1871, [2] 3, 214), Gorup-Besanez (Ber. 1877, 10, 780), Schulze (Zeitsch. physiol. Chem. 1892, 9, 253), and Wroblewski (Ber. 1898, 31, 3218) showed that it was formed by the hydrolysis of other vegetable proteids; and Hlasiwetz and Habermann (J. pr. Chem. 1873, [2] 7, 397), Panzer (Zeitsch. physiol. Chem. 1897, 24, 138), Abderhalden and Fuchs (*ibid.* 1908, 57, 339) isolated it from the products of hydrolysis of

animal proteids. Abderhalden (*ibid.* 1913, 88, 478) found it in blood; Monti (Chem. Zentr. 1912, 1, 501) in tomato conserve; Kossel and Edlbacker (Zeitsch. physiol. Chem. 1915, 94, 264) in echinoderm; Meisenheimer in yeast (Chem. Zentr. 1915, ii. 1259). Osborne and Gilbert (Amer. J. Physiol. 1906, 15, 333) showed that the yield of glutamic acid from animal proteid matter varies from 7 to 10 p.c., whilst in vegetable proteids (with the exception of leucosine of wheat, 5.7 p.c.), the yield is larger, 12 to 37 p.c. A fruitful source of glutamic acid is beet-root molasses; Habermann (Annalen, 1875, 179, 248; Scheibler, Ber. 1884, 17, 1725; Andrlík, Zeitsch. Zuckerind. Böhm, 1903, 27, 665) obtained it to the extent of 7 p.c. on the dry solids of the molasses lye.

Kutscher (Zeitsch. physiol. Chem. 1899, 28, 123) isolated glutamic acid from the products of hydrolysis of casein by sulphuric acid, by precipitating the larger part of the organic bases with phosphotungstic acid, and removing the excess of sulphuric and phosphotungstic acids from the filtrate by means of barium hydroxide; the leucine and tyrosine crystallised out of the filtrate, and from the mother liquor the aspartic and glutamic acids were separated by the difference in solubility of their copper salts. Glutamic acid may be prepared from its hydrochloride by passing ammonia through the solution and evaporating to dryness; the greater part of the acid may be separated by fractional crystallisation, the remainder precipitated by alcohol (Abderhalden, Zeitsch. physiol. Chem. 1912, 77, 75).

For its isolation from molasses, see Stoltzenberg (Ber. 1913, 46, 557), who obtained the hydrochloride; Andrlík (Zeitsch. Zuckerind. Böhm, 1915, 39, 387), who obtained the acid from aqueous solution by means of tartaric sulphuric or phosphoric acid.

Siegfried and Schmidt (Zeitsch. physiol. Chem. 1912, 81, 261) prepared the acid by means of the insoluble normal barium salt.

Ikeda and Suzuki (U.S. Pat. 1015891) separate glutamic acid from other hydrolysis products of albuminous substances by electrolysis; see, also, Scheermesser (Pharm. Zeit. 60, 487); Corti (J. Soc. Chem. Ind. 1917, 36, 979; Eng. Pat. 106081, 1916).

For the quantitative estimation of glutamic acid in the products of protein hydrolysis, see Foreman (Bio-Chem. J. 1914, 8, 465).

Glutamic acid contains an asymmetric carbon atom, and the dextro- and lævo-rotatory and the racemic variety of the acid are all known.

d-Glutamic acid, the naturally occurring compound, crystallises in the rhombic system $a:b:c=0.6868:1:0.8548$ (Oebbecke, Ber. 1884, 17, 1725); m.p. 208° (213° corr.) with decomposition (Fischer, Ber. 1889, 32, 2451); 224°-225° (corr.) decomposes (Abderhalden, Zeitsch. physiol. Chem. 1910, 64, 450); 211° when heated rapidly (Skola, Zeitsch. Zuckerind. Cechoslov. 1920, 44, 347), is sparingly soluble in water (the solubility is raised in presence of alkali and alkaline earth salts (Pfeiffer, Ber. 1915, 48, 1938), insoluble in alcohol or ether, and is practically insoluble in cold glacial acetic acid. It is dextro-rotatory in aqueous solution, $[\alpha]_D^{20}+12.04^\circ$. According to Abderhalden and Kautzsch, $[\alpha]_D^{20}=+31.2^\circ$

(Zeitsch. physiol. Chem. 1910, 64, 450). Fischer (Ber. 1899, 32, 2470) gives 30°-85°. Increasing amounts of strong acid cause a continuous increase of the specific rotation, which tends towards a maximum. The addition of bases first changes the dextro- into laevo-rotation, which attains its highest numerical value with the formation of the acid salt, further quantities of base convert the laevo-rotation again into a dextro-rotation. With lead hydroxide, no change in sign of the rotation takes place (Andrlík, Zeitsch. verein. deut. Zuckerind., 1903, 572, 948; see, also, Pellet, Chem. Zentr. 1911, 1, 1766). Glutamic acid is converted into *l*-pyrrolidonecarboxylic acid to a large extent when its aqueous solution is boiled also to some extent at the temperature of the water-bath. After boiling a 2 p.c. aqueous solution for 100 hours, 90-95 p.c. of glutamic acid (pyrrolidone-2-carboxylic acid) is formed (Skola, Zeitsch. Zuckerind. Cechoslov. 1920, 44, 347). About 8 p.c. sulphuric acid and about 3 p.c. hydrochloric acid present in the solution inhibit the change; the reverse change occurs on boiling *l*-pyrrolidonecarboxylic acid with strong hydrochloric acid (Foreman, Bio-Chem. J. 1914, 8, 492); see, also, Fischer and Böhner (Ber. 1911, 2, 1332). Staněk (Zeitsch. Zuckerind. Böhm., 1912, 371), on heating the aqueous solution above 200°, obtained *dl*-glutamic acid, below that temperature *l*-glutamic was the chief product.

A solution of *α*-glutamic acid (1:22,000) gives a characteristic colour reaction with triketohydrindene (Abderhalden and Schmidt, Zeitsch. physiol. Chem. 1913, 85, 143).

When glutamic acid is administered as a food, 96 p.c. is absorbed, a portion being used up in proteid synthesis, and the rest oxidised to urea (Andrlík and Velich, Zeitsch. Zuckerind. Böhm., 1908, 32, 313); its administration to phloridzinised dogs leads to increased elimination of dextrose in the urine (Warkalla, Beitr. Phys., 1914, 1, 91).

For its catabolism in the animal organism, see Ringer, Frankel (J. Biol. Chem. 1913, 14, 541). According to Roxas (J. Biol. Chem. 1916, 27, 77), it retards the action of tyrosinase on polypeptides.

Glutamic acid is decomposed by the action of bacteria, yielding *n*-butyric acid, together with small quantities of succinic and formic acids (Brasch and Neuberg, Biochem. Zeitsch. 1908, 13, 299, also under the action of certain micro-organisms, yielding γ -aminobutyric acid (Acker-mann, Zeitsch. physiol. Chem. 1910, 69, 273; Abderhalden, *ibid.* 1913, 85, 131). It breaks down under the action of sunlight to propaldehyde, ammonia, and carbon dioxide (Ganassini, Giorn. Farm. Chim. 1912, 81, 226). When oxidised by hydrogen peroxide, it yields succinic acid (Dakin, J. Biol. Chem. 1909, 5, 409); and yields γ -hydroxyglutaric acid (glutamic acid, *q.v.*), when treated with nitrous acid (Ritt-hausen, J. pr. Chem., [1] 103, 239). Natural *d*-glutamic acid is converted by nitrous acid into *l*- α -hydroxyglutaric acid, and by nitrosyl chloride or hydrochloric acid and nitrous acid into *l*- α -chloroglutamic acid, which in turn yields *d*- α -hydroxyglutaric (Fischer and Moreschi, Ber. 1912, 45, 2447).

For electrolytic diazotisation of the acid,

see Krauss (J. Amer. Chem. Soc. 1917, 39, 1427).

d-Glutamic acid forms normal and acid salts, the latter being the more general. Of these, the sodium $C_5H_8O_4NNa$, potassium $C_5H_8O_4NK$, calcium $(C_5H_8O_4N)_2Ca$, barium $(C_5H_8O_4N)_2Ba$, lead $(C_5H_8O_4N)_2Pb$, are crystalline and hygroscopic. The calcium salt is converted to calcium pyrrolidone carboxylate on heating to 180°-185° (Abderhalden, Zeitsch. physiol. Chem. 1910, 64, 447); it is precipitated quantitatively from aqueous solution if sufficiently concentrated (Foreman, Bio-Chem. J. 1914, 8, 479). The normal barium salt is almost insoluble in water (Siegfried and Schmidt, Zeitsch. physiol. Chem. 1912, 81, 261). The glutamates of general formula $C_5H_8O_4NM'$ are largely soluble in water and have a characteristic taste. The manufacture and consumption of the sodium salt is general in Japan. Japanese seaweed, which is used for its flavour, has this taste (Ikeda, Olig. Com. 8th Intern. Cong. Appl. Chem. 18, 147). The normal ammonium salt $(NH_4)_2C_5H_8O_4N$ loses NH_3 at 110°-115°, and forms the acid salt $(NH_4)C_5H_8O_4N$; $[a]_D$ about -3°-6° (Schulze and Trier, Ber. 1912, 45, 257). The blue copper derivative

is crystalline; zinc, and cadmium salts, and cobalt and nickel derivatives have been prepared (Hugouenq and Florence, Bull. Soc. Chim. 1920 [iv], 27, 750). The copper salt $C_5H_8O_4NCu, \frac{1}{2}H_2O$ is amorphous and greenish-blue, and dissolves in 400 parts boiling water (Wolff, Annalen, 1890, 260, 79); the silver salts $C_5H_8O_4NAg_2$ and $C_5H_8O_4NAg$ are white insoluble powders; the ferrous salt is obtained when glutamic acid is boiled with an excess of iron powder in an oxygen-free atmosphere (Hoffmann, D. R. P. 264390); the zinc salt is basic $(C_5H_8O_4N)_2Zn, ZnO$; the mercuric salt a heavy crystalline powder decomposing 208°-209° (Habermann, Annalen, 1871, 179, 248; Abderhalden and Kautzsch, Zeitsch. physiol. Chem. 1910, 64, 447; 68, 487; and *ibid.* 1912, 78, 333). The hydrochloride has m.p. 202° (decomp.), or heated quickly, m.p. 210° (Abderhalden, Zeitsch. physiol. Chem. 1910, 64, 450); $[a]_D^{20} + 25^\circ$ (*ibid.*); or 24°-5° (Fischer and Böhner, Ber. 1911, 44, 1334). For crystallography of hydrochloride, see Kaplanova (Abh. Böh. Akad. 1915, No. 23, 8 pp.; from Jahrb. Min. 1917, 1, 123). The strychnine salt has m.p. 225°-230° $[a]_D^{20} - 25^\circ$; the brucine salt has m.p. 240° $[a]_D^{20} - 23^\circ$ (Dakin, Biochem. J. 1919, 13, 398). For the imido-orthophosphoric ester $C_7H_{14}O_7NP$ of glutamic acid, see Langheld (Ber. 1911, 44, 2076). *dl*-Glutamic-picolonate crystallises in fine short spindles which decompose 184°, *d*-glutamic picolonate has $[a]_D^{20} + 85^\circ$ (Levene and van Slyke, J. Biol. Chem. 1912, 12, 127). The ethyl ester $C_5H_8(C_2H_5)O_4N$ is crystalline, and melts at 188° (Menozzi and Appiani, Gazz. chim. ital. 1894, 24, i. 384); the diethyl ester has b.p. 139°-140°/10 mm., sp.gr. 1.0737 at 17°, and $[a]_D^{20} + 7.34$ (Fischer, Sitzungsber. Akad. Wiss. Berlin, 1900, 48, 1062).

Glutamic acid forms a soluble benzene sulphonyl derivative, $\text{SO}_2\text{Ph}\cdot\text{NH}(\text{C}_2\text{H}_5)(\text{CO}_2\text{H})_2$ (Hedin, Ber. 1890, 23, 3196); and the following acyl derivatives are described by Fischer (Ber. 1907, 40, 3704), Fischer, Kropp and Stahl-schmidt (Annalen, 1909, 365, 181): *l*-leucyl-*d*-glutamic acid

$\text{CHMe}_2\cdot\text{CH}_2\cdot\text{CH}(\text{NH}_2)\cdot\text{CO}\cdot\text{NH}\cdot\text{CH}(\text{CO}_2\text{H})\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$,
m.p. 232° (decomp. corr.), has $[\alpha]_D^{20} + 10.5^\circ$ in $\text{N}/1\text{-HCl}$, forms soluble sodium and barium salts, the silver salt being sparingly soluble; *chloracetyl-d-glutamic acid*

$\text{CH}_2\text{Cl}\cdot\text{CO}\cdot\text{NH}\cdot\text{CH}(\text{CO}_2\text{H})\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$,
m.p. 143° (corr.), $[\alpha]_D^{20} - 13.5^\circ (\pm 0.2^\circ)$ in aqueous solution, yields *glycyl-d-glutamic acid*

$\text{NH}_2\cdot\text{CH}_2\cdot\text{CO}\cdot\text{NH}\cdot\text{CH}(\text{CO}_2\text{H})[\text{CH}_2]_2\text{CO}_2\text{H}$,
m.p. 178° (corr.), $[\alpha]_D^{20} - 6.3^\circ$; *chloracetylglutamylglycinediethyl ester*

$\text{CH}_2\text{Cl}\cdot\text{CO}\cdot\text{NH}\cdot\text{CH}(\text{CO}\cdot\text{NH}\cdot\text{CH}_2\cdot\text{CO}_2\text{Et})\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}\cdot\text{NH}\cdot\text{CH}_2\cdot\text{CO}_2\text{Et}$
m.p. 146° (corr.), yields on hydrolysis *chloracetylglutamylglycine* $\text{C}_{11}\text{H}_{16}\text{O}_7\text{N}_3\text{Cl}$, m.p. 173° (decomp. corr.), and yields on treatment with aqueous ammonia *glycylglutamylglycine* $\text{C}_{11}\text{H}_{18}\text{O}_7\text{N}_4$, m.p. 248° (corr.). *Phenylacetylglutamic acid* $\text{C}_{13}\text{H}_{15}\text{O}_5\text{N}$, microscopic needles, has m.p. 123°, $[\alpha]_D^{20} = -19^\circ$ in 3–10 p.c. aqueous solution; the brucine salt

$\text{C}_{13}\text{H}_{15}\text{O}_5\text{N}\cdot 2\text{C}_{23}\text{H}_{26}\text{O}_4\text{N}_2$
has $[\alpha]_D - 1.37^\circ$ (Thierfelder, Sherwin, Zeitsch. physiol. Chem. 1915, 94, 1; Ber. 1915, 47, 2630).

r-Glutamic acid has been synthesised by Wolff (Annalen, 1890, 260, 79) from lævulinic acid. Glyoxylpropionic acid

$\text{OHC}\cdot\text{CO}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$
obtained by boiling dibromolævulinic acid with water, reacts with hydroxylamine to form γ -diisotonitrosovaleric acid

$\text{CH}(\text{NOH})\text{C}(\text{NOH})\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$,
from which *isonitrosocyanobutyric acid*
 $\text{CN}\cdot\text{C}(\text{NOH})\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$

is obtained by hydrolysis with sulphuric acid and subsequent treatment with cold sodium hydroxide. When *isonitrosocyanobutyric acid* is hydrolysed with boiling alkali, it yields *isonitroglutamic acid*

$\text{CO}_2\text{H}\cdot\text{C}(\text{NOH})\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$,
and this is reduced to inactive glutamic acid
 $\text{CO}_2\text{H}\cdot\text{CH}(\text{NH}_2)\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$

by tin and hydrochloric acid. *r*-Glutamic acid can be prepared from the dextro- isomeride by heating it with barium hydroxide (Schulze and Bosshard, Ber. 1885, 18, 388; Schulze, Zeitsch. physiol. Chem. 1892, 9, 253).

r-Glutamic acid crystallises from hot water in rhombic plates, $a:b:c=0.7454:1:1.2367$, m.p. 199° (decomp. corr.), dissolves in 66.7 parts water at 20°, and is sparingly soluble in ether, alcohol, carbon disulphide, or light petroleum. The *copper salt* $\text{C}_5\text{H}_7\text{O}_4\text{NCu}\cdot 2\frac{1}{2}\text{H}_2\text{O}$ forms blue needles, becomes anhydrous at 135°, and is not soluble in less than 1000 parts of boiling water. The *hydrochloride* crystallises in needles, m.p.

193° (decomp.) (Wolff), 200° (Abderhalden and Kautzsch, Zeitsch. physiol. Chem. 1910, 68, 487), and is crystallographically identical with the hydrochloride of the *d*-acid, $a:b:c=0.8873:1:0.3865$ (Wolff, l.c.).

When *r*-glutamic acid is heated at its melting-point, it decomposes, yielding *pyrrolidonecarboxylic acid*

This compound has m.p. 182°–183°, and is identical with the pyrrolutamic acid obtained by Haitinger (Monatsh. 3, 228) by heating *d*-glutamic acid, and also with the glutimic acid of Schutzenberger (Ann. Chim. [5] 16, 372), obtained by decomposing albumin with barium hydroxide at 180° (compare also Abderhalden and Kautzsch, Zeitsch. physiol. Chem. 1910, 68, 487). *r*-Benzoylglutamic acid crystallises with H_2O , m.p. 152°–153° (155°–157° corr.), and is soluble in 124 parts of water at 20° (Fischer, Ber. 1899, 32, 2451). *Chloracetyl-r-glutamic acid* has m.p. 123°; *glycyl-r-glutamic acid* is a hygroscopic powder, and forms a *copper salt* crystallising with $3\frac{1}{2}\text{H}_2\text{O}$ that decomposes at 223° (corr.) (Fischer, Kropp and Stahlschmidt, Annalen, 1909, 365, 181).

l-Glutamic acid. When *r*-glutamic acid is crystallised from water, right- and left-handed enantiomorphous crystals are deposited, but this fact cannot conveniently be utilised for the preparation of the *l*-isomeride; this was, however, effected by the cultivation of *Penicillium glaucum* in a solution of the *r*-acid, whereby the *d*-acid is destroyed and the *l*-acid remains in solution (Menozzi and Appiani, Gazz. chim. ital. 1894, 24, i. 370). Fischer (Ber. 1899, 32, 2451) resolved *r*-benzoylglutamic acid by the fractional crystallisation of the strychnine salt; *benzoyl-l-glutamic acid* has m.p. 130°–132° (corr.), dissolves in less than two parts of water at 100°, or 21 parts at 20°, and has $[\alpha]_D + 13.81^\circ$ in 5 p.c. aqueous solution, and the potassium salt has $[\alpha]_D - 18.7^\circ$; it yields *l*-glutamic acid on hydrolysis, and this is identical with the *d*-isomeride, except that it has $[\alpha]_D^{20} - 30.05^\circ$, whilst the *d*-acid has $+30.45^\circ$.

l-Pyrrolidonecarboxylic acid, obtained by heating *d*-glutamic acid at 150°–160°, forms large colourless orthorhombic crystals, m.p. 162°, $a:b:c=1.5034:1:1.6292$, and has $[\alpha]_D - 11.5^\circ$ (Menozzi and Appiani, Gazz. chim. ital. 1894, 24, i. 370; Abderhalden and Kautzsch, Zeitsch. physiol. Chem. 1910, 68, 487). For the conversion of glutamic acid or pyrrolidonecarboxylic acid into proline, see Fischer and Bochner (Ber. 1911, 44, 1332).

β -Hydroxyglutamic acid

$\text{CO}_2\text{H}\cdot\text{CH}(\text{NH}_2)\text{CH}(\text{OH})\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$
has been isolated from the products of acid hydrolysis of caseinogen; it crystallises in stout prisms, has $[\alpha]_D^{20}$ about $+0.8^\circ$ in 4 p.c. aqueous solution, and $[\alpha]_D^{20} + 16.3^\circ$ in 2 p.c. hydrochloric acid solution. On prolonged heating at 100°–110° over phosphorous pentoxide it yields hydroxypyrrolidonecarboxylic acid. It yields *silver, copper, mercury, lead, cadmium, zinc, calcium, and barium salts*, and

gives a diethyl ester. The *strychnine* salt has m.p. 245° , $[\alpha]_D^{20} = -26.3^{\circ}$. The *brucine* salt has $[\alpha]_D^{20} = -25.0^{\circ}$ and decomposes at about 200° .

The synthesis of the compound from glutamic acid has been effected (Dakin, Biochem. J. 1918, 12, 290; 1919, 13, 398). M. A. W.

GLUTAMINE $\text{CO}_2\text{H}\cdot\text{C}_3\text{H}_5(\text{NH}_2)\text{CONH}_2$ is the half amide of glutamic acid. It was discovered in 1877 by Schulze and Urich (Ber. 10, 85) in the juice of young pumpkin plants, and isolated from beet-root sap by Schulze and Bosshard (*ibid.* 1883, 16, 312), one litre yielding 0.7 to 0.9 gram of glutamine; see, also, Smolenski (Chem. Zentr. 1911, 1, 518, from Zeitsch. Ver. Dtsch. Zuckerind. 1910, 1215). It appears to replace its homologue asparagine in some natural organs, e.g. *Carophyllaceae*, *Cruciferae*, and *Filices*, where it occurs in the leaves, seedlings, roots, and tubers. The greatest amount of glutamine found in seedlings is only 2.5 p.c. of the dry matter which is much less than the amount of asparagine found in leguminous seedlings, but it is probable that, owing to the difficulties of separating glutamine, the plant contains at least twice as much as is actually isolated (Schulze, Zeitsch. physiol. Chem. 1894, 20, 327; 1897, 24, 18; Ber. 1896, 29, 1882; Landw. Versuchs.-Stat. 1898, 49, 442; Deleano, Zeitsch. physiol. Chem. 1912, 80, 79). Glutamine occurs with asparagine in the juice of ripening oranges (Scurti and De Plato, Chem. Zentr. 1908, ii. 16, 1370); for distribution in plants, see, also, Stieger (Zeitsch. physiol. Chem. 1913, 86, 245). According to Thierfelder and von Cramm, glutamine is a component of the protein molecule (Zeitsch. physiol. Chem. 1919, 105, 58).

Glutamine crystallises in needles; it dissolves in about 25.7 parts of water at 16° (Schulze and Godet, Landw. Versuchs.-Stat. 1907, 67, 313), and is sparingly soluble in alcohol. It behaves as a very weak acid towards indicators (Sellier, Chem.-Zentr. 1904, i. 789). Glutamine is dextro-rotatory in aqueous solution, seven specimens from various vegetable sources were found to have $[\alpha]_D$ between $+1.9^{\circ}$ and $+9.5^{\circ}$, the differences being probably due to the presence of the two stereoisomerides in varying proportions (Schulze and Bosshard, Ber. 1885, 18, 390; Sellier, Chem. Zentr. 1904, i. 789; Schulze, Ber. 1906, 39, 2932; Landw. Versuchs.-Stat. 1906, 65, 237). Schulze and Trier (Ber. 1912, 45, 257) found that a 4 p.c. aqueous solution of glutamine, obtained from its purified copper salt, has $[\alpha]_D^{20} +6^{\circ}$ to $+7^{\circ}$; a 7-8 p.c. acid solution (5 p.c. hydrochloric acid) has $[\alpha]_D^{20} +31^{\circ}$ to $+32^{\circ}$; compare Pellet (Chem. Zentr. 1911, 1, 1766, from Zeitsch. Zuckerind. Böhm. 35, 437), who recommends estimating the rotation in hydrochloric acid solution.

The estimation of glutamine is best effected by Schlösing's method (Schulze, J. pr. Chem. 1885, [2] 31, 233), as the $-\text{CO}\cdot\text{NH}_2$ group is completely hydrolysed when distilled with magnesia under the ordinary pressure, but if the pressure be reduced sufficiently to cause the solution to boil at 40° , hydrolysis does not take place, and under these conditions ammonium salts may be completely removed (Sellier, Bull. Soc. chim. Sucr. Dist. 1907, 25, 124; Schulze, Landw.

Versuchs.-Stat. 1906, 65, 237). For the catalysis of glutamine in the organism, see Thierfelder and Sherwin (Zeitsch. physiol. Chem. 1915, 94, 1); also Sherwin, Wolf and Wolf (J. Biol. Chem. 1919, 37, 113).

Owing to the feebly acidic character of glutamine, very few salts have been isolated: the *copper* derivative, $\text{Cu}(\text{C}_5\text{H}_9\text{O}_3\text{N}_2)_2$, forms bluish violet crystals, the *cadmium* derivative, $\text{Cd}(\text{C}_5\text{H}_9\text{O}_3\text{N}_2)_2$, forms fine prisms; and is decomposed by boiling water. Glutamine forms a compound with tartaric acid, that separates in large transparent crystals (Schulze and Godet, Landw. Versuchs.-Stat. 1907, 67, 313). Phenylacetylglutamine has $[\alpha]_D -18^{\circ}$ in 2-4 p.c. aqueous solution; the specific rotation decreases in hydrochloric acid solution (Thierfelder and Sherwin, *l.c.*). For a description of dipeptides and tripeptides containing glutamine, see Thierfelder and von Cramm (Zeitsch. physiol. Chem. 1919, 105, 58); also Abderhalden and Spinner (Zeitsch. physiol. Chem. 1919, 107, 1).

By the action of alcoholic ammonia on the ester of *d*- or *l*-glutamic acid, the amide of the corresponding pyrrolidonecarboxylic acid is formed; these are called *glutimides* by Menozzi and Appiani, and the dextro- and laevo-rotatory and the racemic variety are described.

crystallises in needles belonging to the anorthic system, $a:b:c = 1.403:1:1.421$, $\beta = 86.55^{\circ}$; it has m.p. 165° , and $[\alpha]_D +41.29^{\circ}$. *l*-Glutimide has $[\alpha]_D -40^{\circ}$, and has the same melting-point and other properties as its dextro-isomeride. *r*-Glutimide is formed when *l*-glutimide is heated with alcoholic ammonia at 140° - 150° , or alone at 200° ; it has m.p. 214° , and crystallises in the orthorhombic system, $a:b:c = 0.8853:1:0.3866$ (Menozzi and Appiani, Atti. R. Accad. Linc. 7, i. 33; Gazz. chim. ital. 1894, 24, i. 370).

M. A. W.

GLUTANIC ACID, α -hydroxyglutaric acid, is formed when nitrous acid reacts with glutamic acid (Markownikoff, Annalen, 1876, 182, 347); it occurs in molasses, and was isolated in the form of the zinc salt from the ethereal extract of the product of the action of dilute nitric acid at 70° on casein (Habermann and Ehrenfeld, Zeitsch. physiol. Chem. 1902, 35, 231). The zinc salt $\text{C}_5\text{H}_6\text{O}_5\text{Zn}\cdot 3\text{H}_2\text{O}$ and the magnesium salt $\text{C}_5\text{H}_6\text{O}_5\text{Mg}\cdot 4\text{H}_2\text{O}$ are well defined (Markownikoff, *l.c.*). The free acid has not been isolated, but forms *butyrolactone- γ -carboxylic acid*

when an aqueous solution is evaporated at 100° , and the resulting syrup allowed to crystallise over sulphuric acid.

Ethylbutyrolactonecarboxylate

prepared by the action of epichlorhydrin on ethylsodiummalonate, is a colourless oil, b.p. $175^{\circ}/25$ mm. (Traube and Lehmann, Ber. 1901, 34, 1971).

Natural *d*-glutamic acid is converted by

nitrous acid into *l*- α -hydroxyglutaric acid, which has a very small lævo-rotation. The sodium salt has $[\alpha]_D^{19} = -8.65^\circ$. Nitrosyl chloride transforms *l*- α -hydroxyglutaric acid into *l*- α -chloroglutaric acid, m.p. 99° (corr.), $[\alpha]_D^{18} = -12.5^\circ$, and this yields *d*- α -hydroxyglutaric acid $[\alpha]_D^{25} = +8.58^\circ$. (Fischer and Moersch, Ber. 1912, 45, 2447). The Walden inversion in the case of α -hydroxyglutaric acid and its derivatives, has been examined by Karrer and Kaase (Helv. Chim. Acta, 1919, 2, 436). M. A. W.

GLUTARIC ACID $C_5H_8O_4$. Glutaric acid and its alkyl derivatives, when heated, break down into anhydrides and water. The anhydrides readily yield anilic acids, from which anils can be obtained by the withdrawal of water (Auwers, Oswald, and Thorpe, Annalen, 285, 229). The glutaric acids resemble the succinic acids in their reactions, but they are not so volatile in steam, and not so readily changed to anhydrides by acetylchloride.

Glutaric acid. Normal Pyrotartaric acid.

Found in Caucasian naphtha (Markownikow, Ber. 1897, 947), in beet-root (Lippmann, *ibid.* 1891, 3299), and in the wash-water from raw sheep wool. Prepared by oxidising fats (Bouveault, Bull. Soc. chim. 19, [3] 562), stearic and oleic acids (Carette, *ibid.* 46, 65) or sebaccic acid (Carette, *ibid.* 45, 270), with nitric acid; by treating 1:3-dicyanopropane with hydrochloric acid (Reboul, Ann. Chim. 14, [5] 14, 501; Markownikow, Annalen, 182, 341); by treating β -hydroxyglutaric acid with hydriodic acid at 180° (Pechmann and Jenisch, Ber. 1891, 3252); by the action of baryta on ethyl pentanehexacarboxylate (Bottomley and Perkin, Chem. Soc. Trans. 1900, 300); by treating ethyl malonate with methylene chloride, hydrolysing the product with caustic potash and heating the dicarboxylglutaric acid thus formed to 200° (Conrad and Guthzeit, Annalen, 222, 257; Perkin, Ber. 1886, 1055); by condensing ethylsodiummalonate with formaldehyde in the presence of a small quantity of piperidine or diethylamine, and heating the methylene dimalononic acid thus formed with hydrochloric acid (Knoevenagel, Ber. 1894, 2346); by the electrolysis of equal quantities of the potassium salts of the methyl hydrogen succinate and malonate (Vanzetti and Coppadro, Chem. Zentr. 1904, i. 1254; 1903, ii. 1053); by treating hydroresorcin with sodium hypobromite (Vörländer and Kohlmann, Ber. 1899, 1878); by treating cyclopentanone with nitric acid (Wislicenus, Annalen, 275, 318) or with acetic anhydride, and subsequently with potassium permanganate (Mannich and Hancu, Ber. 1908, 572); by the action of nitric acid on methylcyclopentane (Markownikow, *ibid.* 1900, 1908), or on cyclopentane (Markownikow, *ibid.* 1897, 975); by treating α -acetoglutamic ester with concentrated potash (Vörländer and Knötzsch, Annalen, 294, 31ä; Wislicenus and Limpach, *ibid.* 192, 128); by treating glutaconic acid with sodium amalgam (Conrad and Guthzeit, *ibid.* 222, 254); by the oxidation of piperidine with hydrogen peroxide (Wolfenstein, Ber. 1892, 2777).

Glutaric acid crystallises in large monoclinic

plates, m.p. 97.5° ; 100 c.c. of water dissolve 42.9 parts of acid at 0° , 63.9 at 20° , and 95.7° at 50° (Lamouroux, Compt. rend. 128, 998); readily soluble in alcohol and ether. It condenses with aldehydes to form substituted glutaric acids (Fittig and Roedel, Annalen, 282, 334, 338, 344; Knoevenagel, Ber. 1894, 2346); electrolysis of the potassium salt of the monoethyl ester gives rise to the diethyl ester of suberic acid (Brown and Walker, Annalen, 261, 119). By heating glutaric acid at 230° – 280° , or by treating the silver salt with acetyl chloride, *glutaric anhydride*, m.p. 56° – 57° , is produced (Fichter and Herbrand, Ber. 1896, 1193). When treated with aluminium amalgam, the anhydride is converted into a mixture of glutaric and δ -hydroxyvaleric acids, the latter of which readily changes into δ -hydroxyvalerolactone (Fichter and Beisswenger, Ber. 1903, 1200).

The *dimethyl ester of glutaric acid* is a colourless liquid, b.p. 213.5° – 214° (751 mm.), sp.gr. 1.09337 $15^\circ/4^\circ$ (Meerburg, Rec. trav. chim. 1899, 367); the *diethyl ester* boils at 236.5° – 237° (corr.), and has sp.gr. 1.0284 at 15° (Perkin, Chem. Soc. Trans. 1888, 567).

The three possible isomerides of glutaric acid are all known and are described below.

Pyrotartaric acid. Methylsuccinic acid (Ger. Brenzweinsäure; Methylbernsteinsäure)

Obtained from suint (Buisine, Compt. rend. 107, 789). Prepared by the dry distillation of tartaric, racemic, or pyruvic acids (Fourcroy and Vauquelin, Ann. Chim. 35, (i.) 161; 64, 42; Wolff, Annalen, 317, 22; Réchamp, Zeitsch. Chem. 1870, 371; Bourgoin, Ann. Chim. 12, [5] 419); by heating pyruvic acid with hydrochloric acid (Wolf, *l.c.*; Jong, Rec. trav. chim. 21, 191); by the reduction of citra-, ita-, or mesaconic acids with sodium amalgam (Kekulé, Annalen, Spl. 1, 338; Spl. 2, 95); by the reduction of the anhydride of citraconic acid with hydrogen in the presence of nickel, when pyrotartaric acid and its anhydride are produced (Eijkman, Chem. Zentr. 1907, i. 1617); by treating β -cyanobutyric acid with caustic potash (Wislicenus, Annalen, 165, 93; Breddt and Kallen, *ibid.* 293, 350); by fusing gamboge with caustic alkali (Hlasiwetz and Barth, *ibid.* 138, 73); by treating aldehydeisobutyric acid with nitric acid (Perkin and Sprankling, Chem. Soc. Trans. 1899, 19; Bischoff and Kuhlberg, Ber. 1890, 634); by the interaction of ethylsodiummalonate with ethylbromopropionate and subsequent boiling with hydrochloric acid (Bone and Sprankling, Chem. Soc. Trans. 1899, 348); by the interaction of ethylsodiomethylmalonate and ethylchloracetate or of ethylsodioethenyltricarboxylate and methyl iodide, and subsequently hydrolysing the ester of methylethenyltricarboxylic acid thus formed (Bischoff and Kuhlberg, *l.c.*); by treating ethyldibromomethylacetacetate with concentrated potash and subsequently with sulphuric acid (Cloeze, Compt. rend. 110, 583); by treating calcium lactate with potassium permanganate, when calcium pyrotartrate is produced (Wiegand, Ber. 1884, 840).

Pyrotartaric acid crystallises in triclinic prisms, m.p. 117° – 118° (Ladenburg), 112° (Perkin). Soluble in water, alcohol, and ether.

By heating pyrotartaric acid with dilute sulphuric acid at 150°, acetaldehyde and formic acid are produced (Wiegand, *l.c.*); by condensation with acetaldehyde, benzaldehyde, &c., substituted paraconic acids are produced (Fittig, *Annalen*, 255; 108, 126, 257); with salicaldehyde coumarinpropionic acid is produced (Fittig and Brown, *ibid.*, 255, 285). Methylthiophen is produced by the distillation of the sodium salt with phosphorus pentasulphide. Pyrotartaric acid contains an asymmetric carbon atom, and it has been resolved into its two optically active antipodes by means of the fractional crystallisation of its strychnine salt (Ladenburg, *Ber.* 1895, 1170; 1896, 1254; *Annalen*, 364, 227).

Pyrotartaric anhydride is obtained by heating the acid above 200°, or by treating the acid with acetylchloride (Perkin, *Chem. Soc. Trans.* 1888, 564; Fichter and Herbrand, *Ber.* 1896, 1193); m.p. 31°5'-32°; b.p. 247°4' (corr.), sp.gr. 15°/15°, 1.2378. By reduction with hydrogen in the presence of nickel, the anhydride yields butyrolactone (Eijkman, *Chem. Zentr.* 1907, i. 1617), and with sodium amalgam and hydrochloric acid, α -methylbutyrolactone (Fichter and Herbrand, *l.c.*).

The *dimethyl ester of pyrotartaric acid* is a colourless oil, b.p. 197°; and the *diethyl ester* boils at 217°5'-218°5'.

Dimethylmalonic acid, β -Isopyrotartaric acid $(CH_3)_2C(CO_2H)_2$. Obtained by the oxidation of fenchone with nitric acid (Gardner and Cockburn, *Chem. Soc. Trans.* 1898, 708); by the oxidation of phoronic acid with nitric acid or with potassium permanganate in alkaline solution (Pinner, *Ber.* 1882, 585; Anschütz, *ibid.* 1893, 827; Anschütz and Walter, *Annalen*, 368, 95); by the oxidation of filicinic acid, obtained from filicin, which is extracted from *Filix mas* (male fern) (Boehm, *Chem. Zentr.* 1896, ii. 1036; Dacomo, *Gazz. chim. ital.* 24, 1, 517); by the oxidation of camphor with nitric acid (Bredt, *Ber.* 1894, 2093). Prepared by treating α -cyanisobutyric acid with hydrochloric acid (Markownikow, *Annalen*, 182, 336); by heating 5:5-dimethylbarbituric acid with caustic potash (Conrad and Guthzeit, *Ber.* 1881, 1644); by the oxidation of $\alpha\alpha$ -dimethylglutaconic acid with potassium permanganate (Henrich, *Ber.* 1899, 670; Perkin, *Chem. Soc. Trans.* 1902, 255).

Dimethylmalonic acid is best obtained pure from its zinc salt; m.p. 190° (Perkin, *Chem. Soc. Trans.* 1903, 1237), 192°-193° (Königs and Hörlin, *Ber.* 1893, 2049); sparingly soluble in water and alcohol, readily soluble in ether; decomposes on heating into carbon dioxide and isobutyric acid. Dimethylmalonylchloride yields a duodecimolecular anhydride on treatment with aqueous pyridine; it is an amorphous white powder, m.p. 145°-148° (Einhorn, *Annalen*, 359, 169). *Dimethylmalononitrile* is prepared by treating dimethylcyanacetamide with phosphoric oxide or phosphorus pentachloride (Hesse, *Annalen*, 18, 723; Errera and Berti, *Gazz. chim. ital.* 26, ii. 224), m.p. 32°, b.p. 162°5'. *Dimethylmalonamide* is prepared from the methyl ester and concentrated aqueous ammonia (Perkin, *Chem. Soc. Trans.* 1903, 1242; Thorne, *ibid.* 1881, 545); from the ethyl ester and alcoholic ammonia (Fischer and Dilthey, *Ber.* 1902,

851, 855); from dimethylmalonylchloride and concentrated aqueous ammonia (Meyer, *Ber.* 1906, 198), m.p. 269° (corr.) (Perkin). The *dimethyl ester* is a colourless liquid, b.p. 177°-178° (753 mm.); the *diethyl ester* boils at 194°5'. The latter may be obtained by treating the ester of dimethylcyanacetic acid with sulphuric acid: on treatment with alkali and urea, dimethylbarbituric acid is obtained (Merck, *Chem. Zentr.* 1905, ii. 1141; D. R. P. 163200). The diethyl ester of dimethylmalonic acid condenses with bromisobutyric ester in the presence of zinc to form the ester of tetramethylacetonedicarboxylic acid (Shdanowitsch, *Chem. Zentr.* 1907, i. 519). The potassium salt of the monoethyl ester is converted by electrolysis into the diethyl ester of tetramethylsuccinic acid (Brown and Walker, *Annalen*, 274, 48).

Ethylmalonic acid. Isopyrotartaric acid

Prepared by boiling the ethyl ester of α -cyanobutyric acid with potash (Wislicenus and Urech, *Annalen*, 165, 93; Tuoplew, *ibid.* 171, 243; Markownikow, *ibid.* 182, 329); the diethyl ester is produced by treating ethyl malonate with sodium or zinc and ethyl iodide (Daimler, *ibid.* 249, 174; Schukowsky, *Chem. Soc. Abstr.* 1888, 1179; Schee, *Rec. trav. chim.* 16, 356; Michael, *J. pr. Chem.* 72, [2] 537). Crystallises in rhombic prisms, m.p. 111°5'; readily soluble in water, alcohol, and ether; decomposes on heating into butyric acid and carbon dioxide.

Ethylmalononitrile is prepared from ethylcyanacetamide and phosphorus pentachloride; it is a colourless oil, b.p. 200° (Hessler, *Annalen*, 1899, 169; Henry, *J.* 1889, 637). *Ethylmalonamide* is prepared by the action of sodium ethoxide and ethyl iodide on malonamide (Meyer, *Monatsh.* 28, 1; Conrad and Schulze, *Ber.* 1909, 730); by treating the diethyl ester with concentrated aqueous ammonia (Freund and Goldsmith, *ibid.* 1888, 1245); m.p. 214°. The *diethyl ester* boils at 207°; when the sodium derivative of this ester is condensed with ethylbrommalonate in alcoholic solution, the ethyl ester of ethylenetetracarboxylic acid is produced (Bischoff, *Ber.* 1896, 1514).

GLUTEN. Wheat flour differs from that of all other cereals in that after it has been made into a dough with a little water, it is possible to wash out the starch, leaving a sticky adhesive brown or greyish-brown residue which consists mainly of protein. This is crude gluten: on drying it in a water-oven, a hard, brittle horny mass, not unlike glue, results, which has lost its power of becoming plastic when wetted, and strongly adheres to the substance on which it rests. At a higher temperature, the wet gluten expands greatly until the expansive force ruptures its vesicles.

The flour of other cereals when washed in a similar way entirely disintegrates, leaving no protein residue. The physical properties of wheat flour depend almost entirely on the gluten, which acts as a mechanical agency for binding the particles of starch and for entangling the carbon dioxide gas produced by the fermentation: in the oven, this gas expands, causing the dough to rise and the gluten to remain distended until the heat fixes it.

Crude gluten varies in colour from grey to

brown. Besides protein, it contains traces of starch, fibre, cholesterol, fat, and a small proportion of mineral matter. It is insoluble in tap water, strong alcohol, and ether, but dissolves partly in distilled water, in dilute alkalis and more slowly in dilute acids.

Gluten, after treatment with dilute acids or salts, has some diastatic action, which the freshly prepared gluten lacks (Reychler, Ber. 1889, 22, 414; see also Baker, J. Soc. Chem. Ind. 1908, 27).

The quantity of gluten in wheaten flour varies considerably according to its race and the country in which it was grown. Further, the best patent flour, milled from the centre of the grain, contains slightly less gluten than the households flour from the outer layers of the same grain.

Speaking very generally, the proportion of gluten varies from 8 to 15 p.c., though exceptional flours may have either less or more than this amount. English flours as a class have about 10 p.c. or less gluten, Canadian and American spring wheat flours, e.g. the so-called No. 1 Manitoba, contain 13 p.c. and upwards. The strength of a flour depends, however, not so much on the quantity of gluten present as on its quality. A gluten, though present in satisfactory quantity, may be too tough, or hard and brittle, or it may be too elastic and have no power of retaining the gas in its pores.

Gluten consists mainly of two proteins, *gliadin* and *glutenin*, both of which are essential for its formation. The gliadin forms a sticky network which entangles the glutenin to make a compact mass. The presence of soluble salts, i.e. electrolytes, is also essential, but the mineral constituents of the flour are sufficient for this purpose. In distilled water, gluten partly dissolves, the semi-fluid residue having no tenacity. Pure gluten has of itself neither ductility nor tenacity, and the physical properties like those of other colloidal substances depend upon the electrolytes present in the dough.

The researches of Wood and Hardy (Wood, J. Agric. Sci. 1907, 2, 139, 267; Wood and Hardy, Proc. Roy. Soc. 1909, B, 81, 38; Summary by Hardy, Brit. Assoc. Report, Winnipeg, 1909) have shown that any salt confers cohesion upon gluten; any acid or alkali, when sufficiently dilute, lessens or destroys it. Gluten which has

concentration of the acid and the amount of salt required to undo its action. As the concentration of the acid is increased, the amount of salt needed to maintain cohesion rises to a maximum, and thence falls until a point is reached when the acid alone is sufficient. The curve shows the concentration of salt and acid needed just to preserve cohesion: it encloses an area of no cohesion, whilst outside it is a region of cohesion. The areas represent continuous changes as is characteristic of colloidal matter: a line inclined upwards follows a system in which there is continual separation of water and gluten; in consequence the water-holding power of the protein becomes less and less, the tenacity grows, and the ductility diminishes.

Upson and Calvin (J. Amer. Chem. Soc. 1915, 37, 1295-1304) have shown that moist gluten absorbs water from acid solutions in quantity varying with the nature and concentration of the acid. The presence of neutral salts retards the absorption of water, and in high concentrations may even cause a loss of water from moist gluten. If gluten which has absorbed water in an acid solution be transferred to a salt solution it loses water and regains its original physical properties. Non-electrolytes are much less effective than electrolytes in inhibiting the swelling of gluten in acid solutions.

In practice, the water-holding capacity, or *hydration ratio*, of gluten is of considerable significance. It is measured by the ratio of the weight of the wet gluten immediately after extraction under carefully standardised conditions to its weight after drying. On the average, it is about 3 : 1; that is, gluten carries about twice its weight of water. It varies from 2.5 in strong flours to above 3 in very weak flours.

The ratio of gliadin to glutenin in different wheats is not constant. It appears to be about 50 p.c. According to Shutt (J. Soc. Chem. Ind. 1909, 28, 336), there is a relationship between the maturity of the grain and the gliadin content, the more fully ripened wheat containing the higher proportion.

Gluten may be estimated in flour as follows: 30 grams of flour are made into a dough with from 12 to 15 c.c. of water, and set aside for an hour. The dough is then worked between the fingers in a stream of running water to wash out the starch, being held over a muslin screen, so that any particles which are dropped can be recovered. Finally the gluten is worked vigorously between the fingers to remove the last traces of starch. With practice the washing can be carried out so as to occupy always the same time. The ball of gluten is then placed under water for an hour. It is next freed from excess of moisture by working between the hands and wiping off excess of water until the moment when the ball begins to stick: it is then removed to a little square of parchment paper, weighed, and dried for at least 24 hours at 100°. The ratio of the wet and dry weights gives the hydration ratio. Considerable information as to the strength of the gluten is gained by the feel both of the dough and of the gluten between the fingers. The method, though empirical, gives with practice very trustworthy results.

Marchadier and Goujon (J. Pharm. Chim.

lost cohesion owing to the action of an acid, may be rendered coherent again by the addition of salt. There is a definite relation between the

1914, vii. 10, 191-202) have shown that the abnormal diminution in the percentage of coagulable gluten in wheat flour produced by mixing it with flour from buckwheat, barley, rice, maize, &c., is also produced by the admixture of inorganic substances, such as powdered talc, magnesia, or silica. This is not due to a variation in the ratio gliadin to glutenin, but to a variation in the sum of these two.

Germination, milling, preservation of the flour either in a moist state or in a humid atmosphere, and unfavourable meteorological conditions during the growth of the corn, produce a similar diminution in the percentage of coagulable gluten, due in this case to the conversion of glutenin into gliadin or *vice versa*. It is suggested that the diminution in all these cases is due to a rise in the acidity of the flour under the conditions named, the coagulation of gluten being materially hindered by a very slight rise in the acidity.

It was at one time customary to test the quality of the gluten in an aluerometer. The wet gluten was placed in a tube provided with a piston, heated to a definite temperature (150°), and the amount of expansion read off. This test is of very little value.

As a check on the gluten estimation, the total nitrogen may be determined by Kjeldahl's method in the flour and in the crude dry gluten, and multiplied by 5.7 to express it as protein.

Gluten in the form of a light-brown powder, dried at a low temperature, is a commercial product, being used for the manufacture of bread and biscuits for diabetic patients: it usually contains from 3 to 5 p.c. of starch, and sometimes a great deal more, and should yield a very tough elastic dough when wetted.

In the commercial process the flour is made into a stiff dough, placed in open kneading machines, and kneaded with water. The starch goes into suspension, the starch milk being strained off periodically until gluten alone remains in the machine.

The open kneading machine most used for the process consists of a trough in which two kneading arms work in opposite directions.

In Germany wheaten starch factories are often run directly in connection with a bakery.

The flour is kneaded out as described and 60-75 p.c. pure starch obtained. The glutinous residues are then used for baking.

Westrup (Eng. Pats. 4028, 1908; 8337, 1909) proposes to test the strength of flours by making a ball of 15 grams flour and 7.5 grams of water, and placing this under a disc of plate glass, 3½ inches in diameter. A 200-gram weight is put on the glass for 30 minutes. The dough is pressed out, and, after hardening for 24 hours, the circumference of the flattened cake is measured by rolling it along a scale. Different flours are flattened to different extents.

Baine (Eng. Pat. 14770, 1909) puts a dough of standard proportions into a cylinder provided with a piston. As the dough rises, the piston is pushed up, an arresting mechanism prevents it dropping from the highest point reached, which can be read off later.

Neither of these methods appears to be of much practical value.

Gliadin. Wheat gluten was first separated into two constituents in 1819 by Taddei, who termed the alcohol soluble protein gliadin. Subsequently, Ritthausen thought gliadin to consist of three different proteins, but the researches of Osborne and others have made it clear that only one alcohol-soluble protein is present in wheat.

The alcohol-soluble protein of rye is apparently identical with that of wheat, and is therefore also termed gliadin. Other alcohol-soluble cereal proteins are the hordein of barley and zein of maize; these, however, are quite different from gliadin. Osborne has proposed to call this group *prolamins*.

The solubility of gliadin is a maximum in 70 p.c. ethyl alcohol—it is nearly insoluble in water and in absolute alcohol. When dehydrated with absolute alcohol and dried over sulphuric acid, gliadin is obtained as a colourless friable substance. As precipitated from dilute alcohol or water and dried, it is amorphous and transparent, somewhat resembling gelatin, but it is more brittle. It turns sticky with distilled water, and part dissolves, still more being dissolved on boiling. The addition of the smallest quantity of a mineral salt immediately precipitates it completely, either from aqueous or dilute alcoholic solution. The salts with acids or alkalis are freely soluble in water. They are precipitated unchanged on neutralisation.

Gliadin may be extracted both from gluten and from flour with 70 p.c. alcohol. The residue will no longer form a dough when wetted with water.

Gliadin has the composition C=52.72 p.c., H=6.86 p.c., N=17.66 p.c., S=1.03 p.c., O=21.73 p.c., and gives 5738 calories per gram on combustion (Benedict and Osborne, J. Biol. Chem. 1907, 3, 119). The specific rotation in 70 p.c. alcohol is -92° (Mathewson, J. Amer. Chem. Soc. 1906, 28, 1482): the same author has determined the rotatory power in a number of solvents.

The total nitrogen, 17.66 p.c., is distributed as follows: as ammonia 4.33 p.c., basic 1.09 p.c., non-basic 12.17 p.c.

Osborne and Clapp (Amer. J. Physiol. 1906, 17, 231) have made a very careful determination of the products of hydrolysis of gliadin (*see also* Abderhalden and Samuely, Zeitsch. physiol. Chem. 1905, 44, 276). Their figures are as follows:—

	p.c.		p.c.
Glycine	absent	Tyrosine	1.20
Alanine	2.00	Cystine	0.45
Valine	0.21	Lysine	absent
Leucine	5.61	Histidine	0.61
Proline	7.06	Arginine	3.16
Phenylalanine	2.35	Ammonia	5.11
Aspartic acid	0.58	Tryptophan	present
Glutamic acid	37.33		
Serine	0.13	Total	65.80

The striking points in the composition are the absence of glycine and lysine and the small proportion of basic amino acids, the very large quantity of glutamic acid and the high proportion of ammonia and proline.

About 60 p.c. of the total sulphur in gliadin is converted into sulphide on boiling with sodium hydroxide.

Glutenin. The second protein of gluten is characterised by being insoluble in water, saline solutions, and alcohol, and remains after exhaustive treatment of gluten with these three solvents. When freshly prepared, it is soluble in 0.1 p.c. potassium hydroxide and 0.2 p.c. hydrochloric acid, and also in very dilute sodium carbonate and ammonia. After drying over sulphuric acid, it forms an amorphous greyish-brown powder somewhat less soluble in these reagents. It is precipitated on neutralisation. The only other cereal protein described, similar to glutenin, is the oryzenin of rice (Rosenheim and Kajiura, J. Physiol. 1908, 36, liv.), although it is probable that other seeds contain similar proteins. Osborne groups these as *glutelins*.

Glutenin has the composition, C=52.34 p.c. H=6.83 p.c., N=17.49 p.c., S=1.08 p.c.; O=22.26 p.c.; heat of combustion 5704 calories (Benedict and Osborne, J. Biol. Chem. 1907, 3, 119). The nitrogen is distributed as follows: ammonia, 3.30 p.c.; basic, 2.05 p.c.; non-basic, 11.95 p.c.

According to Osborne and Clapp, the products of hydrolysis are:

	p.c.		p.c.
Glycine	0.89	Tyrosine	4.25
Alanine	4.65	Cystine	0.02
Valine	0.24	Histidine	1.76
Leucine	5.95	Arginine	4.72
Proline	4.23	Lysine	1.92
Phenylalanine	1.97	Ammonia	4.01
Aspartic acid	0.91	Tryptophan	present
Glutamic acid	23.42		
Serine	0.74		59.68

[See the Discussion on Wheat, Brit. Assoc. Report, Winnipeg, 1909, Supplement to J. Board of Agric. 1910, vol. 17, No. 3; see also T. B. Osborne, Pflanzenproteine, Wiesbaden, 1910; Jago, Science and Art of Bread-making, London, 1911.]

GLYCARBIN. Syn. for glyceryl carbonate.

GLYCERIN (*Glycerol*, *Glycyl alcohol*, *Propenyl alcohol* $C_3H_8O_3$ or $C_3H_5(OH)_3$) occurs in

combination with fatty acids in all fatty oils and fats. Glycerin was discovered by Scheele, when preparing lead plaster from olive oil, and was termed by him '*principium dulce*.' The fatty oils and fats may be regarded as salts formed by the combination of fatty acids and glycerol, with the loss of three molecules of water. Glycerol being a trihydric alcohol, and consequently behaving like a trihydric base, is able to combine with three radicles of fatty acids, as is expressed by the following equation, in which R represents the acid radicle of any fatty acid:

This equation, when read from right to left, symbolises the process of saponification of fats, and expresses the fact, that by the addition of water (under suitable conditions) to the neutral glycerides, the latter are resolved into three molecules of fatty acids and one molecule of glycerol (see SAPONIFICATION). From the right side of the equation it follows that glycerol does not exist as such in the fatty oils and fats, but that it is formed by the assimilation of three molecules of water. Hence the sum of the weight of the fatty acids and glycerol is always greater than the weight of the original fat employed. The excess over 100 p.c. may be gathered from the following table by adding up the numbers given in column 4, and deducting 100 from that sum (see column 5).

Owing to this complete analogy between the formation of a tribasic salt and a triglyceride, the natural triglycerides are also termed 'neutral glyceryl esters.'

The triglycerides of the most frequently occurring fatty acids are collated in the following table, in which their chemical formulæ and molecular weights are given, as also the quantities in p.c. of fatty acids and glycerol resulting from saponification of 100 parts of the glycerides:—

1 Glyceride	2 Formula	3 Molecular weight	4 Products obtained on saponification of 100 parts		5 Excess over 100 parts	6 Chief sources
			Fatty acids	Glycerin		
Glyceryl tributyrate (Butyrin)	$C_3H_5(O \cdot C_4H_7O)_3$	302	p.c. 87.44	p.c. 30.46	p.c. 17.90	Milk fats
„ tricaproate (Caproin)	$C_3H_5(O \cdot C_8H_{17}O)_3$	386	90.15	23.96	14.11	Milk fats, cocoa-nut oil, palm-nut oil
„ tricaprylate (Caprylin)	$C_3H_5(O \cdot C_8H_{15}O)_3$	470	91.91	19.58	11.49	„ „ „
„ tricaprate (Caprin)	$C_3H_5(O \cdot C_{10}H_{19}O)_3$	554	93.14	16.67	9.81	„ „ „
„ trilaurate (Laurin)	$C_3H_5(O \cdot C_{12}H_{23}O)_3$	638	94.04	14.42	8.46	Laurel oil, cocoa-nut oil, palm-nut oil, dika fat
„ trimyristate (Myristin)	$C_3H_5(O \cdot C_{14}H_{27}O)_3$	722	94.75	12.74	7.49	Myristica fats
„ tripalmitate (Palmitin)	$C_3H_5(O \cdot C_{16}H_{31}O)_3$	806	95.29	11.42	6.71	Palm oil, Chinese vegetable tallow, Japan wax
„ tristearate (Stearin)	$C_3H_5(O \cdot C_{18}H_{35}O)_3$	890	95.73	10.34	7.07	Cacao butter, tallow
„ trioleate (Olein)	$C_3H_5(O \cdot C_{18}H_{33}O)_3$	884	95.70	10.41	6.11	Olive oil, lard oil, tallow oil
„ trilinolate (Linolin)	$C_3H_5(O \cdot C_{18}H_{31}O)_3$	878	95.67	10.48	6.15	Drying and semi-drying oils
„ trilipolenate (Linolenin)	$C_3H_5(O \cdot C_{18}H_{29}O)_3$	872	95.63	10.55	6.18	Drying oils
„ trichupanodionate (Clupanodonin)	$C_3H_5(O \cdot C_{19}H_{27}O)_3$	866	95.61	10.62	6.23	Marine animal oils
„ triricinoleate (Ricinolein)	$C_3H_5(O \cdot C_{19}H_{33}O)_3$	932	95.93	9.87	5.80	Castor oil
„ triarachidate (Arachin)	$C_3H_5(O \cdot C_{20}H_{39}O)_3$	974	96.09	9.45	5.54	Earth-nut oil
„ trierucate (Erucin)	$C_3H_5(O \cdot C_{22}H_{41}O)_3$	1052	96.39	8.74	5.13	Rape oils

From the above formulæ it appears that glycerol is regarded as a trivalent, or triatomic alcohol, containing the radicle C_3H_5 in combination with three OH groups. Hence, glycerol bears the same relation to ordinary ethyl alcohol as orthophosphoric acid bears to nitric acid. Just as tribasic phosphoric acid forms three distinct classes of salts, with three different proportions of the same base, so does glycerol form three distinct classes of esters, viz. mono-glycerides, diglycerides, and triglycerides (see OILS, FIXED, and FATS). And just as phosphoric acid may combine with two or three different bases to form two different classes of tribasic salts, so does glycerol lead to different classes of triglycerides. Each triglyceride enumerated in the foregoing table must be considered as glycerol in which all three hydrogen atoms of the three OH groups are replaced by one and the same radicle of fatty acid. Such glycerides are termed *simple triglycerides*. If, however, the three hydrogen atoms are replaced by two or three different fatty acid radicles, *mixed glycerides* are obtained.

Should a triglyceride contain two different fatty acid radicles, two isomeric triglycerides may be expected; and in the case of a triglyceride containing three different acid radicles, three isomerides may be expected. This is explained by the following formulæ:—

It was formerly assumed that the natural fats consisted of simple triglycerides; modern researches, however, have made it extremely likely that simple triglycerides occur in nature, as a rule, in small quantities only, and that natural oils and fats are composed chiefly of mixed glycerides. Thus, for instance, in tallow, only a few p.c. of tristearin have been found; hence tallow must be assumed to consist mainly of mixed glycerides.

A considerable number of mixed glycerides have been already isolated from such natural oils and fats as tallow, cacao butter, Borneo tallow, &c. The mixed glycerides of most frequent occurrence which have been isolated hitherto are *oleodipalmitin*, *stearodipalmitin*, *oleopalmitostearin*, *palmitodistearin*, *oleodistearin*, and *dioleostearin*.

Glycerin has also been found, in the free state, in the blood and in fermented alcoholic liquors. Pasteur has shown that glycerin is a constant product of the alcoholic fermentation of sugar; hence it is a natural constituent of beer, wine, &c. 100 parts of sugar produce 3.5 parts of glycerin. Until a few years ago these latter sources of glycerin were of no commercial importance, but the increasing value of glycerin has made it profitable to recover even this small proportion, and several processes have been devised for treating the *vinasses* from distilleries. For example, in Barbet's process (Fr. Pat. 449961 of 1912) the material is concentrated, mixed with calcined plaster and kieselguhr, and the glycerin distilled under reduced pressure, while caramelisation is prevented by the action

of scrapers within the retort. In another process (Eng. Pat. 27300 of 1912) the *vinasses* are dried, treated with acid, and the glycerin extracted by means of solvents such as alcohol. Increased quantities of glycerin are obtained from molasses by fermentation with *Saccharomyces ellipsoideus* (var. Steinberg) in presence of sodium carbonate and ammonium chloride at a temperature of 30°–32°, when from 20 to 25 p.c. of the sugar is converted into glycerin, and the greater part of the remainder into alcohol and carbon dioxide. The investigations of Lüdecke on the production of glycerin on an industrial scale from the fermentation of sugar led to a practical process worked out by Connstein and Lüdecke, which was employed to a considerable extent in Germany during the great war. The process is based upon the fact that the percentage of glycerin is increased if the fermentation proceeds in presence of alkaline substances, particularly sodium sulphite, whereby it was possible to obtain 20 parts of purified glycerin, 27 parts of alcohol, and 3 parts of aldehyde from 100 parts of sugar. After removal of the yeast by filtration and of the alcohol and aldehyde by distillation, the bulk of the salts present are precipitated by calcium chloride and then by sodium carbonate, the liquid being afterwards neutralised with hydrochloric acid and filtered from the sludge; concentration and distillation yield a glycerin suitable for technical purposes (J. Soc. Chem. Ind. 1919, 38, 287; R. Schweizer, Chim. et Ind. 1921, 6, 149).

The synthetic preparation of glycerin, although it has been made the subject of several patents, has as yet hardly passed beyond the theoretical stage.

Glycerin is obtained on a large scale in the several saponification processes which are practised in candle and soap works (see SAPONIFICATION). According to the process by which the commercial product 'crude glycerin' is obtained, we differentiate in commerce the following five qualities of crude glycerin, viz.: (1) crude saponification glycerin; (2) crude distillation glycerin; (3) Twitchell crude glycerin; (4) fermentation crude glycerin; (5) soap lye glycerin, or soap crude glycerin.

In the stearine candle and soap industries, glycerin is obtained as a dilute aqueous solution, which contains various impurities, the nature and quantity of which depend on the manufacturing processes themselves. The purest raw material results from saponification by means of lime in open vessels; hardly inferior to this is the glycerin obtained by 'autoclaving.' Less pure is the raw material recovered from the 'acid saponification process,' 'Twitchell's process,' and the 'ferment process.' The crude glycerin obtained from soap lyes, notwithstanding its high proportion of inorganic salts, may, on the one hand, surpass in purity (*i.e.* as regards the amount of organic impurities) the crude material from the last-named processes; but, on the other hand, it may be very impure if fats and oils of low quality have been saponified by means of black-ash lyes, as was done until a few years ago in Lancashire and in Marseilles. Modern processes of refining have, however, overcome a number of difficulties caused by the several impurities, so that *e.g.* chemically pure

glycerol from good soap lyes cannot be distinguished from chemically pure glycerol obtained by lime saponification. Crude glycerins further vary as regards quality in accordance with the care exercised in the manufacture. Crude glycerins obtained from the acid saponification, the Twitchell, and the fermentation processes, retain very tenaciously some organic impurities which hitherto seem to have defied all attempts to remove them, as the writer has ascertained in

FIG. 1.

the case of a number of 'chemically pure' glycerols originating from these processes.

1. Crude saponification glycerin. This glycerin represents the best quality of crude glycerin. It is obtained from the 'sweet water' of the autoclave process (*see SAPONIFICATION*) and as a by-product in the process of soap making by double decomposition.

The proportion of glycerol in the 'sweet waters' varies from 6 to 16 p.c. The metallic

FIG. 2.

oxides contained in the 'sweet waters' are neutralised, and the filtered solution is concentrated by means of steam, either in a Wetzel pan (Fig. 1) or, as is done in modern works, in a vacuum evaporator of a type identical with or similar to those shown in Figs. 2, 3. According to the quantity of salts which separate when the bulk of water has been driven off, a vacuum evaporator either of the type A or type B (Fig. 4) is used. The evaporation is carried on until the crude glycerin contains about 85-90 p.c. of

glycerol. Its sp.gr. is then from 1.240 to 1.242, corresponding with the commercial brand of '28°Bé saponification crude' or 'candle crude glycerin.' The colour of this glycerin varies from yellow to dark-brown; its taste is sweet. With basic lead acetate, it gives but a slight precipitate. By refining this crude glycerin with charcoal, a 'refined' glycerin (used for a number of commercial purposes) is obtained. This crude glycerin contains up to 0.3 p.c. of ash, chiefly calcium (or magnesium or zinc) sulphate, and only small quantities of organic impurities.

This crude glycerin is valued on the percentage of pure glycerol, of ash, and of organic impurities.

The 'sweet water' obtained in the process of soap making by double decomposition is treated in the same manner as described above, and yields a good 'saponification crude,' which is equal in quality to a 'candle crude glycerin,' provided that the original fatty matter was of good quality. Since this process is used in small works only, where chiefly low-quality greases are worked up, the crude glycerin thus obtained is apt to contain a considerable amount of organic impurities, so that it is liable to ferment when stored. Within the author's experience, such crude glycerins did ferment, thus showing that the organic substances in low-class grease are not destroyed by treatment with lime. In the course of the fermentation, trimethyleneglycol is formed. This crude glycerin is also high in proportion of ash (the author found even as much as 1.77 to 5 p.c. of ash), whereas the respective proportions of glycerol were 84.3 and 77.1 p.c.

A typical sample of high quality examined by Grimwood (1918) had: sp.gr. 1.2455; glycerol, 89.7 p.c.; ash, 0.55 p.c.; and organic residue, 0.57 p.c.

2. Crude distillation glycerin. This kind of crude glycerin is obtained from the acid water resulting in the so-called acid saponification processes (*see SAPONIFICATION*). It is termed in commerce 'crude distillation glycerin' for the reason that the fatty acids obtained by this process must be distilled to yield candle material. The dilute glycerin waters ('sweet waters') are worked up in the same manner as described under 'crude saponification glycerin,' but owing to the large amount of sulphuric acid used in the process, a considerable quantity of salts remain in solution after the mineral acid has been neutralised with lime. As the concentration of the solution proceeds, especially when the thickened liquor approaches the sp.gr. of 1.240, calcium sulphate, which is no longer held in solution, separates out, and is deposited on the heating surface of the evaporating apparatus in the form of a hard crust, which rapidly diminishes the evaporative power of the steam, unless the calcium sulphate is removed.

Hence, such tube evaporators as are represented by vessel B (Fig. 4) are useless for concentrating the dilute solution, and a type of evaporator must be employed which permits the heating surface to be continuously scraped so as to keep it clean. An evaporator of this kind, designed by the author, is shown in Fig. 2, the inner construction of which is exemplified by Fig. 3.

The finished crude distillation glycerin contains considerable proportions of calcium sulphate, inasmuch as the solvent power of glycerol for calcium sulphate (*see below*) is still further increased by the organic impurities which the crude glycerin retains. The ash of this kind of crude glycerin rises to as much as 2 and even 3.5 p.c. The amount of organic impurities is greater than in crude saponification glycerin,

FIG. 3.

and it may rise to even 2 p.c., the amount depending on the lack of care exercised in the manufacturing process. The colour of this crude glycerin is usually pale-yellow; its taste is sharp and astringent, and when rubbed between the hands it emits an unpleasant smell. On adding basic lead acetate, a voluminous precipitate is obtained; hydrochloric acid produces a turbidity, due to the presence of fatty acids.

This crude glycerin has the sp.gr. 1.240–1.242. As a rule, it contains from 84 to 86 p.c. of glycerol. The trade term for this kind of glycerin is 'crude distillation glycerin, 28°Bé.'

3. Crude glycerin from the Twitchell process. This kind of crude glycerin is obtained from the acid water resulting in Twitchell's saponification process (*see SAPONIFICATION*). The sweet waters are treated with lime or barium hydroxide or barium carbonate, so as to precipitate the dissolved sulphuric acid as completely as possible. The purified liquors are concentrated up to a sp.gr. of about 1.24 or more, in the same manner as described under the two preceding headings. The quality of this crude glycerin varies considerably with the quality of the fatty material from which it has been obtained. If the raw material is of good quality, the glycerin is fairly good; but even in that case, owing to the high amount of ash it contains, and owing to its unpleasant taste, it is valued at a somewhat lower price than is crude candle glycerin. By way of example, the following analysis made by the author, may be given: sp.gr. 1.239; glycerol,

84.8 p.c.; ash, 0.52 p.c. A typical sample analysed by Grimwood (1918) had: sp.gr. 1.2453; glycerol, 87.0 p.c.; ash, 1.1 p.c.; and organic residue, 1.4 p.c. Since the Twitchell saponification process is best adapted to low-class material (such as greases), the glycerin obtained from such material contains so considerable an amount of organic impurities that it cannot be refined by itself, even for the production of dynamite glycerin. Each special make of such glycerin must therefore be valued on the basis of the impurities it contains.

4. Fermentation crude glycerin (*see SAPONIFICATION*). The sweet water from the process of hydrolysis by means of enzymes is rich in proteins and other organic impurities. In addition to the usual treatment described above, it must be filtered over char, which retains the bulk of the proteins and other organic impurities. Nevertheless, a certain amount is still retained; consequently, the finished crude is not only dark in colour, but has also a very unpleasant smell and taste, even if the glycerin be made from good raw material, such as refined cotton-seed oil or refined linseed oil. In the infancy of the process, the crude glycerin obtained thereby was practically unusable. In consequence of improvements, the amount of impurities has been considerably reduced, so that a sample examined in the author's laboratory gave the following somewhat favourable results: sp.gr. 1.2369; ash, 0.49 p.c.; organic impurities (proteins, &c.), 1.54 p.c. But the difficulties have not yet been sufficiently surmounted to make the process satisfactory, and it is still but little used. The last two kinds of crude glycerin are difficult to refine (by the usual process of distillation) and must be mixed in the glycerin still with better kinds of crude glycerin.

5. Soap lye glycerin, Soap crude glycerin, Soap crude. Since Chevreul established the constitution of fats and oils, it has been known that the spent soap lyes, resulting in the manufacture of soap, contain, if not the whole, a very large proportion of the glycerol, combined originally with fatty acids in the oils and fats which had been converted into soap in the soap pan. During the first half of last century, no attempt had been made to recover the glycerol from those lyes, not only on account of the difficulty attending this operation, but also for the reason that the small demand for glycerin then ruling in the market could be readily satisfied by the candle makers' crude glycerin. When, at the end of the seventies of the last century, a great demand for nitroglycerin ('dynamite') sprang up, attention was drawn forcibly to this source of glycerin, and serious endeavours were made to recover the hitherto wasted product. Although as early as 1858, H. Reynolds had patented the main features of a process of recovery, features which essentially reappeared in all subsequent processes, yet serious failure at first attended all attempts at the recovery of glycerin, on account of the considerable amount of impurities in the spent lyes, and most prominently on account of the large amount of dissolved salts. Modern processes, especially improvements in apparatus on the one hand, and the rapidly growing employment in the soap industry of

caustic soda of the highest purity, tended to evolve a process which is now worked with more or less success in all the large soap works, not only of Europe and America, but also of Australia, Africa, India, and New Zealand. The earliest successful attempts to recover glycerin from soap lyes were made in English soap works, where the largest quantities of oils and fats were worked up in the largest soaperies of the world; the working up of the soap lyes for crude glycerin may be said to have established its success in Great Britain towards the middle of the 'eighties of the last century. Since that time, crude glycerin recovered from soap lyes, 'soap crude glycerin,' has established its great importance in the world's commerce.

The lyes obtained in the soap-making process by boiling oils and fats in an open pan with caustic soda contain practically all the glycerol which the natural oils and fats are capable of yielding. According to the manner in which the 'changes' are worked up (*see SOAP*), the spent lyes contain from 5 to 8 p.c. of pure glycerol. In addition to glycerol, the spent lyes hold in solution the common salt used in 'cutting' the soap, and also small amounts of free caustic soda, sodium carbonate, soap, and organic impurities. The less free caustic soda, sodium carbonate, and organic impurities the lyes contain, the more readily can the process of recovery and purification be carried out. In case impure caustic soda lyes have been used (*see above*), the spent soap lyes contain, in addition to the substances enumerated above, thiocyanates, sulphides, thiosulphates, cyanides, and ferrocyanides. These impurities were present in the crude (black-ash) lyes, which were used up to a few years ago to a large extent in the Marseilles district. The difficulties caused thereby in the recovery of crude glycerin have led, favoured by the establishment of Solvay's soda works in that neighbourhood, to the almost complete abandonment of black-ash lyes, so that even in Marseilles the vast majority of soaps are prepared with pure caustic lyes. The exact treatment of the lyes in a soap works depends on the state of purity of these lyes, and has, as its object, the removal or destruction of the albuminous, resinous, and soapy matters present in the lyes. This is done by various additions, such as lime or hydrochloric acid, or salts of aluminium and iron, which precipitate foreign substances, so that they can be filtered off, whereupon the purified lyes are neutralised and become ready for concentration. The purified lyes are boiled down in fire-heated vessels, which are of a conical shape, so that the salt, as it separates, slides down into a vessel fixed to the bottom of the pan, whilst rotating gear keeps the heating surface free from incrustation. Such vessels, although in large works considered antiquated, are still being used and even introduced in smaller works, where the amount of water available is limited or where water is very dear. In the case of large works, the lyes are usually evaporated *in vacuo*. The first concentration of the lyes to the 'salting-point' (at which salt commences to separate) is considered to have been completed when the lyes have reached a sp.gr. of 44°Tw. at 15.5°C. The percentage of glycerol in these lyes then usually amounts to 10-16 p.c. If

evaporation were carried on beyond this 'salting-point' in a tube evaporator, the separated salts would deposit on the tubes, and thus soon prevent the evaporation from proceeding to the desired stage. The author has frequently seen tube evaporators which, after a couple of days' working, had become so heavily encrusted with salts that the evaporator had to be stopped and 'laid off' for cleaning. A large number of patents has been taken out, with a view to preventing the settling down of the salts on the evaporator tubes. Lewkowitsch overcomes this difficulty by providing the evaporator with suitable stirring and scraping arrangements, which remove the salts as they separate, the salts falling down into a vessel (of any desired shape) which can be shut off from the vacuum evaporator, and emptied at will under ordinary pressure. After removal of the salt, the vessel is exhausted and again connected with the evaporator. An evaporator of this type is shown in Fig. 2. The construction of the rotating heating surface is typified by Fig. 3. In these evaporators, the soap lyes can be evaporated from their dilute stage beyond the 'salting-point', the salt which falls out being removed by using, at given intervals, the vessel fixed to the outlet of the evaporating pan. This vessel, as has been pointed out already, can be emptied while the contents are kept continuously boiling. In large installations, the lyes are concentrated in double, or triple, or quadruple effect vacuum apparatus. A double effect, designed by Lewkowitsch on the same principle as Fig. 2, is illustrated by Fig. 4.

FIG. 4.

This figure shows a combination of a tube evaporator, B, with an evaporator as illustrated by Fig. 2. The first preliminary concentration up to the 'salting-point' is carried out in vessel B, whilst the further concentration takes place in vessel A. The salt which separates out during the process of concentration is collected in the vessel shown underneath A, and is removed at fixed times, and washed in the washing

machine shown in the illustration. The salt is washed first with purified lyes of low percentage of glycerol, and finally with water to remove the glycerin from the salt. The salt itself is recovered in such purity that it can be used immediately in the soapery in place of fresh salt (see SOAP).

The glycerin solutions are boiled *in vacuo* until the crude glycerin has reached a sp.gr. of 1.3. The progress of concentration is controlled by the sp.gr. test, or, equally well, by taking out samples and ascertaining the boiling-point in a porcelain dish, by means of a thermometer, while the contents of the dish are kept stirred, so that the salt may not cause bumping of the contents or cracking of the dish. The glycerin has reached the sp.gr. of 1.3 and the percentage required by commerce, if the boiling-point is 150°. The crude glycerin then contains 80 p.c. of pure glycerol, and about 10 p.c. of salts, the remainder consisting of water and a small amount of organic impurities. If the concentration is carried a little further, crude glycerin, containing as much as 86 p.c. of glycerol, can readily be obtained.

The proportion of organic impurities in soap-lye glycerin varies considerably, depending on the process of purification and the care of the operator. Some commercial soap crude glycerins contain less than 1 p.c. of organic impurities (thus representing a better quality glycerin than 'crude distillation glycerin,' crude glycerin from the 'Twitchell process,' and crude glycerin from the 'fermentation process'). Other specimens of crude glycerin, again, contain large quantities of impurities, consisting of fatty acids, rosin acids, and of albuminoid substances, gelatin, and hydrocarbons (from bone fat), and also trimethyleneglycol in the lyes resulting from bone fat which has been allowed to ferment. In the distillates from such impure glycerins, the author even found organic bases, amongst which he identified picoline and lutidine.

The following analyses by Grimwood show the composition of typical samples of crude glycerin in 1917-1918:—

	Sp.gr.	Glycerol	Ash	Organic residue
		p.c.	p.c.	p.c.
High quality	1.3097	85.8	9.33	1.68
Low quality	1.2980	77.2	10.63	3.61

The colour of 'salt crude glycerin' is pale-yellow to brown, or almost black, according to its purity. The taste of good 'soap crude' is sweet, qualified, of course, by that of the common salt contained therein. Impure samples have a most unpleasant garlic-like taste, even if sulphides be absent. This is specially characteristic of the lyes obtained in the Marseilles district (due to the use of 'sulphur' olive oil).

Soap-lye glycerin can be rapidly distinguished from the crude glycerins described above by the large proportion of common salt which it contains (heavy precipitate with silver nitrate solution) and by its high sp.gr.

soap-lye glycerin containing considerable quantities of sulphides, thiosulphates, or sulphites, is almost valueless to the refiner of crude glycerin.

Considerable quantities of crude glycerin, especially crude saponification glycerin, are used

in the arts for various purposes, *e.g.* in the manufacture of inks. By far the largest quantities of crude glycerin are, however, purified by distillation, and thereby converted into 'distilled glycerin.' In commerce, two kinds of distilled glycerin are differentiated, distilled glycerin for making nitroglycerin (dynamite), 'dynamite glycerin,' and chemically pure glycerin, sometimes termed 'twice-' or 'treble-distilled glycerin.'

Distilled glycerins are obtained, as the name implies, from crude glycerin by distillation. The distillation is carried out, either under ordinary pressure or in a vacuum. In either case the distillation is supported and accelerated by the aid of steam. At present vacuum distillation, coupled with superheated steam, is the combination mostly in vogue. Some manufacturers work off a certain amount (depending on the size of the still) of crude glycerin in one batch. Other manufacturers resort to continuous distillation, the still being fed as the glycerin distils off.

The successful distillation of crude glycerin does not so much depend on the kind of still and condensers used as on the skill and care of the operator. A considerable number of special apparatus have been patented, and are still being patented, but owing to the fact pointed out, *viz.* that success depends more on attention to details than on the particular apparatus employed, the details of the *modus operandi* in conducting the distillation are considered valuable secrets.

Space does not permit a complete reference to the patent literature or to the illustrations accompanying it. It may therefore be generally stated that some inventors introduce details which neither contribute to cheapening the process nor permit the realisation of the refinements claimed. Some of the apparatus embody a faulty principle, inasmuch as not only is complete purification not effected, but even partly purified distillates are contaminated with the impurities driven off from a partially purified batch. Here it may suffice to illustrate in Fig. 5 a glycerin distillation plant which the author designed for the distillation of crude glycerins, both of 'saponification crude' and 'soap crude.' The still shown is provided with an arrangement for withdrawing the salts as they separate out. The contents of the still are heated by means of open superheated steam, which carries off the vapours of glycerin into a battery of condensing columns. Between the latter and the still itself is inserted a catch box in which the heaviest portions are condensed, while small amounts of sodium chloride, which is carried over mechanically with the steam, are simultaneously deposited. From the end of the battery of columns a connection leads to a vacuum pump, the distillation being carried out *in vacuo*. The glycerin vapours, with varying amounts of water, condense in the several columns. In the first columns little water condenses; thus the strongest glycerin, of sp.gr. 1.25, is obtained therein. The following columns yield weaker glycerin liquors which, in the end column, are so dilute that the then escaping vapours are practically free from volatilised glycerin. The distillates are drawn off *in vacuo*, sampled and graded according to

their sp.gr. In the figure, the vessels into which the glycerin is drawn off are partly shown.

It depends solely on the mode of working—especially in the case of soap-lye glycerin—as to whether one distillation will suffice to obtain a satisfactory product for nitrating purposes, or whether the once distilled glycerin must be re-distilled. In case the distillation has not been conducted carefully, the once-distilled glycerin is so strongly contaminated with sodium chloride and organic impurities (volatile fatty acids and even polyglycerols), that a second distillation becomes imperative.

The distilled glycerin liquors collected from the columns are treated with char, if required, in order to remove some organic impurities, and, at the same time, to clarify the glycerin and

improve its colour. The collected and filtered glycerin liquors are finally concentrated in a vacuum evaporator, up to the desired sp.gr. For the purposes of dynamite glycerin, the sp.gr. must be at least 1.261 at 15°. Other commercial qualities of distilled glycerin need only be concentrated to a sp.gr. of 1.250 or 1.240, as the case may be. The dynamite glycerin quality is used exclusively for purposes of making nitroglycerin. Other qualities of distilled glycerin, especially those of sp.gr. 1.250 and 1.240, are used for various purposes in the arts, such as for filling gas meters and hydraulic jacks, in the manufacture of ink, waterproof paper, toilet soaps, 'sizes' for textiles, and for the production of plastic masses, such as printing rollers, hectograph mass, &c. The bulk of the

Fig. 5.

distilled glycerin is, however, employed in the manufacture of high explosives, such as dynamite, blasting gelatine, cordite, &c.

The yield obtainable from crude glycerin depends, just like the distillation itself, on the care of the operator. The losses incurred by faulty methods are large, and range, within the knowledge of the author, from as-much as 15 to even 40 p.c. A large proportion of the loss is due to destruction of glycerol with the formation of volatile acids and acrolein on the one hand, and to the formation of polyglycerols on the other hand. The polyglycerols which are formed in the course of distillation should remain in the still itself, and are found with the still residue (see below, *Glycerin foots*).

The commercial 'distilled glycerins' vary in colour from yellow to white; they also vary in their content of glycerol according to their sp.grs., which range, as a rule, between 1.220 and 1.260. Glycerin, purified by distillation, should contain a very small amount of ash only;

thereby distilled glycerins are easily distinguished from crude glycerins.

The residues ('*glycerin foots*') remaining in the still, in the case of those crude glycerins which contain small proportions of ash (see above, *Crude glycerins*, 1, 2, 3, 4), consist chiefly of polyglycerols and of notable amounts of salts, as the mineral matters originally contained in the crude material naturally accumulate in the residues. These residues are used in the manufacture of shoe blacking. Claessen proposed to employ them also in the production of plastic masses, such as printing rollers, hectograph masses, sizes for textiles, and for waterproofing paper.

The still residues from soap lye crude contain much larger amounts of salts than those described above. The residues obtained in the course of distillation retain such considerable amounts of glycerol in addition to polyglycerols, salt, sodium carbonate, sodium acetate, and sodium salts of other organic non-volatile acids,

that the accumulated residues are worked up for the recovery of glycerin. They are boiled up with water, and dilute hydrochloric or sulphuric acid is added to decompose the sodium carbonate and the organic salts. The organic non-volatile acids collect on the surface of the liquid as a resinous mass, which is removed in any suitable manner. The liquor is then filtered and concentrated separately, or is mixed with the ordinary soap lyes. As during the concentration of these liquors, acetic acid is volatilised, it is advisable to concentrate the lyes and distil the recovered crude glycerin separately.

The distilled glycerins described above contain, as a rule, amounts of impurities, which although small, are yet sufficiently large to forbid the employment of those distilled glycerins for pharmaceutical and dietetic purposes. The 'distilled glycerins' must therefore, as a rule, be subjected to a second distillation. If this distillation be carried out with sufficient care, the distillates give, after concentration and treatment with char, the chemically pure glycerin of commerce.

At a time when the art of preparing chemically pure glycerin was not so far advanced as it is at present, some chemically pure glycerin was manufactured by allowing glycerin to crystallise, and centrifuging the crystals, whereby the impurities were removed with that portion of glycerin which melted in the centrifugal machine. This process has, however, been abandoned, not only on account of its costliness, but also on account of the inferiority of the product as compared with the best brands of chemically pure glycerin obtained by careful distillation, as it was found that the crystals were apt to occlude impurities.

The statements found in chemical literature that glycerin only crystallises at -40° , must be corrected, in so far as glycerin, exposed for a long time to a low temperature (-5° or -10°), will gradually crystallise. Thus the author frequently found in very cold winters that glycerin, even glycerin of 'dynamite quality' which had been left undisturbed for some prolonged time, had crystallised.

Electro-osmotic processes of decolorising and purifying glycerin have been patented (Eng. Pats., 144,727, 145,046, 146,865, 1920).

Chemically pure glycerin is obtainable in commerce in the following 'strengths' (concentrations): chemically pure glycerin of 1.24 sp.gr., chemically pure glycerin of 1.25 sp.gr., and chemically pure glycerin of 1.26 sp.gr.

The chemically pure glycerin of the highest sp.gr. approaches, as nearly as is possible for a product made on a large scale, the chemical substance glycerol.

Glycerol (pure glycerin) is an odourless, colourless, viscid liquid, having an intensely sweet taste. The preparation demanded by the Pharmacopœias of different countries is the purest commercial article, which consists practically of glycerol, containing a very small amount of water. Glycerol is optically inactive, and is neutral to indicators. On exposure to an intense cold for a prolonged time, it crystallises in rhombic crystals, melting at 20° . With the help of a few crystals, large quantities of glycerol can easily be solidified at the temperature of the freezing-point of water,

Glycerin is oily to the touch, and produces on the skin, especially on the mucous membrane, the sensation of heat, due to its absorbing moisture from the tissues. The water-absorbing power of glycerin is so great that, on exposure to the atmosphere, it takes up as much as 50 p.c. of its own weight of water.

The sp.gr. of pure glycerin has been determined by several observers, whose statements do not agree, owing, no doubt, to the difficulty of removing the last traces of water. The most trustworthy values are the following:—

$$\begin{aligned}\text{sp.gr. } 15^{\circ}/15^{\circ} &= 1.26468; \\ \text{sp.gr. } 17.5^{\circ}/17.5^{\circ} &= 1.2620.\end{aligned}$$

Kailan (Zeitsch. anal. Chem. 1912, 51, 81) obtained values of 1.26414 at $15^{\circ}/4^{\circ}$, and 1.26082 at $20^{\circ}/4^{\circ}$, which are in close agreement with those recorded by other chemists. The relationship between the sp.gr. and temperature is shown in the following formula (Kailan):—

$$\text{Sp.gr. at } t^{\circ}/4^{\circ} = 1.26413 + (15 - t)0.000632.$$

Provided a specimen of chemically pure glycerin satisfies the qualitative tests described below, the proportion of glycerol in it can be found by merely determining the sp.gr. of the sample. The percentage can also be obtained, approximately, from the refractive index of the glycerin. The table (p. 438) by Skalweit (Repertor. d. Analyt. Chemie, 5, 18) gives the sp.gr.s and refractive indices, for the sodium ray, at 15° , of mixtures of glycerol and water in various proportions.

Other tables for the sp.gr. and the refractive indices of glycerol solution are given in Lewkowitsch's Chem. Technology of Oils, &c. Lenz states that the observations of the several observers agree amongst each other within a few units of the fourth decimal, whilst the differences in the refractive indices, corresponding to 1 p.c. of glycerol, amount to 13.5 units of the fourth decimal. By reference to the above table, the percentage of glycerol in a sample can therefore only be determined accurately to 0.5 p.c. (cf. Grün and Wirth, Zeitsch. angew. Chem. 1919, 32, 59). Bosart (J. Ind. Eng. Chem. 1921, 13, 944) has shown that Gerlach's table of sp. gr. at 15° is sufficiently accurate for technical purposes, but that his table of values at 20° is inaccurate.

Where the volume of glycerin is not enough to permit the accurate determination of its sp.gr., the refractive index can be ascertained with the aid of Abbe's refractometer. Zeiss's immersion refractometer has also been applied to the determination of dilute glycerin solutions; but it should be noted that the immersion refractometer (which is used extensively for the determination of alcohol in beer and other fermented liquors) does not permit more concentrated solutions to be tested than those containing 26 p.c. It is not permissible to dilute concentrated glycerin with a known amount of water to a lower percentage, and then determine the refractive index, inasmuch as contraction takes place on mixing glycerin with water.

Glycerin boils under 760 mm. pressure at 290° , when it undergoes only slight decomposition. Under considerably reduced pressure,

glycerin distils unchanged. The viscosity of crude distilled glycerin is reduced during the refining process, and viscosity measurement is therefore a rapid means of determining the degree of purity (Kellner, Chem. Zentr. 1921, 92, [ii] 834).

The following table contains the most trustworthy observations made under reduced pressures (cf. also Richardson, Chem. Soc.

Glycerol is miscible with water in all proportions. On mixing glycerol with water, a contraction of volume and an increase of temperature take place. The greatest increase of temperature, viz. 5°, is observed when 58 parts of glycerol (by weight) are mixed with 42 parts of water: the greatest contraction equals 1.1 p.c. (Gerlach). Glycerin can be completely freed from water by allowing it to stand *in vacuo* over sulphuric acid for some prolonged time.

At the ordinary temperature, glycerol does not volatilise; at the boiling-point of water, however, appreciable quantities escape with the water vapour. If glycerol be heated in an open dish on a water-bath, a slight loss is incurred, such loss depending on the shape of the vessel (whether deep or shallow), the area of the surface exposed, and the frequency with which the air over its surface is renewed.

The vapour pressure of a dilute solution of glycerol rises with the rise of temperature of the boiling solution, so that considerable amounts of glycerol volatilise with the water vapour. Theoretically, a mixture of saturated water and glycerol vapour, under the ordinary atmospheric pressure, cannot contain more than 0.2 to 0.3 p.c. of glycerol, provided that the two vapours are not miscible. Since, however, glycerol and water are miscible in every proportion, the composition of the escaping vapours cannot be calculated according to Dalton's law, but must be derived from actual observations. Gerlach determined, with the aid of a vaporimeter, in which the pressure of the vapour was measured by a column of mercury, the vapour pressures given in the table on p. 439.

Up to a concentration of about 50 p.c., no glycerol escapes with the water vapours, even if the dilute solutions be kept boiling for a prolonged time. At a concentration of about 70 p.c., traces of glycerol escape from the boiling solution (Hehner). The boiling-point of such a solution is 113.6° (see table). Above this concentration, noticeable amounts of glycerol escape, so that the quantitative determination of glycerol in an aqueous solution by evaporating it down on the water-bath leads to faulty results. Even if the concentration of glycerol solutions be carried out *in vacuo*, considerable proportions of glycerol escape with the water vapour when the concentration of the solution exceeds 80 p.c. (Lewkowitsch).

Glycerol is miscible with alcohol in all proportions. It dissolves easily in a mixture of alcohol and ether, but is sparingly soluble in ether alone, one part of glycerol, sp.gr. 1.23, requiring about 500 parts of ether. It is therefore impossible to extract glycerol from its aqueous solution by means of ether. Glycerol is soluble in acetone. Nine parts of glycerol dissolve in 100 parts of ethyl acetate. It is, however, insoluble in chloroform, light petroleum, carbon disulphide, or benzene; it is also insoluble in oils and fats (Lewkowitsch).

On heating glycerol slowly in a platinum dish to 150°–160°, it evaporates gradually without leaving a residue; at 150° it will burn with a bluish non-luminous flame without emitting any odour. If, however, glycerol is heated rapidly in a platinum dish, it burns with formation of acrolein, and yields a residue consisting of polyglycerols.

The penetrating smell of acrolein (which is

also noticeable when glycerides are burnt, *e.g.* when an oil lamp or a tallow candle has been blown out) serves as the most characteristic reaction for the detection of the smallest quantities of glycerol. For this purpose, it is best to mix the substance under examination with dehydrating substances, such as potassium hydrogen sulphate, and heat rapidly, when acrolein is readily formed. The most delicate reagent for detecting acrolein in an aqueous solution is an ammoniacal solution of silver nitrate (reduction to metallic silver with production of a mirror). With Schiff's reagent, a solution of rosaniline which has been previously decolorised by sulphur dioxide, the pink colour is restored. The latter reaction, however, is less delicate than the silver test.

Glycerol has powerful solvent properties; it combines in this respect the properties of water and of ordinary alcohol; many substances dissolve even more easily in it than in either of these two latter liquids. The following table of solubilities will serve to illustrate this:—

100 parts of glycerol dissolve at 15° 98 parts of crystal soda; 60 parts of borax; 50.5 parts of potassium arsenate; 50 parts of sodium arsenate; 50 parts of zinc chloride; 48.8 parts of tannic acid; 40 parts of alum; 40 parts of zinc iodide; 40 parts of potassium iodide; 35.2 parts of zinc sulphate; 32 parts of potassium cyanide; 30 parts of copper sulphate; 25 parts of ferrous sulphate; 25 parts of potassium bromide; 20 parts of lead acetate; 20 parts of ammonium carbonate; 20 parts of arsenious acid; 20 parts of arsenic acid; 20 parts of ammonium chloride; 15 parts of oxalic acid; 11 parts of boric acid; 10 parts of barium chloride; 10 parts of copper acetate; 10 parts of benzoic acid; 8 parts of sodium bicarbonate; 7.5 parts of mercuric chloride; 5 parts of calcium sulphide; 3.7 parts of potassium chloride; 3.5 parts of potassium chlorate; 1.9 parts of iodine; about 1 part of calcium sulphate; 0.1 part of sulphur; 0.25 part of phosphorus.

An aqueous glycerol solution, of the sp.gr. 1.114, dissolves 0.957 p.c. of calcium sulphate. Metallic soaps (which are insoluble in water) are to some extent dissolved by glycerol; thus: 100 parts of glycerol, sp.gr. 1.114, dissolve 0.71 part of iron oleate, 0.94 part of magnesium oleate, and 1.18 parts of calcium oleate.

Glycerol is completely oxidised to carbon dioxide and water by potassium dichromate in an acid solution. In a dilute aqueous solution, and in the presence of caustic alkali, potassium permanganate oxidises glycerol so definitely to oxalic acid and carbonic acid (under the conditions stated below) that this reaction may be used for its quantitative determination (provided no other organic substance yielding oxalic acid be present).

Dry potassium permanganate reacts violently with concentrated glycerol. If finely powdered potassium permanganate be heaped up to form a small truncated cone and concentrated glycerol be poured into a hole made on the top, fumes escape; after a very short time the glycerol commences to froth and ignites spontaneously with violent evolution of gases.

Glycerol treated with hydrogen peroxide in presence of a ferrous salt yields glyceric aldehyde $\text{CH}_2\text{OH}\cdot\text{CHOH}\cdot\text{CHO}$.

By gentle oxidation with nitric acid, glycerol yields glyceric and oxalic acids, together with formic, glycollic, glyoxylic, and racemic acids. The glyceric acid so obtained is a racemic compound which can be resolved into optically active enantiomorphous glyceric acids (Lewkowsch, Ber. 1883, 2720).

A strong aqueous solution of glycerol reduces Barreswil's (Fehling's) solution only slightly. On boiling the solution for 10 minutes, and allowing it to stand for 24 to 48 hours, a red or a yellow precipitate is obtained. If, however, the glycerol be diluted previously with 10 times its bulk of water, no reduction occurs.

A mixture of glycerol and silver nitrate solution heated at the temperature of boiling water with a few drops of ammonia, gives a precipitate of metallic silver. If ammonia solution be added to glycerol in the cold, and heat be then applied, as a rule no reduction takes place on adding silver nitrate, because the ammonia escapes before the glycerol has been heated sufficiently; the addition of caustic soda or potash, however, causes metallic silver to separate slowly. According to Bullheimer, 1 part of metallic silver corresponds with 11.3 parts of glycerol.

Glycerol dissolves caustic alkalis, alkaline earths, and lead oxide, to form chemical compounds with them. The compounds so formed are termed metallic glyceroxides. Lime, strontia, and baryta are precipitated nearly completely from such solutions by carbon dioxide, a small quantity only of the earths escaping precipitation. In the presence of caustic alkalis, glycerol also dissolves ferric oxide, cupric oxide, and bismuth oxide, no doubt in consequence of the formation of soluble compounds (metallic glyceroxides), such as are represented by monosodiumcuproglyceroxide (see below). The oxides enumerated above are not reduced to metals, or at most only to their lower oxides. The following oxides: silver oxide (*cp.* above), gold oxide, mercury oxide, rhodium oxide, palladium oxide, and platinum oxide (Ag_2O , Au_2O_3 , HgO , RhO_2 , PdO , PtO_2), are reduced to metals when heated with alkaline glycerol solution (Bullheimer).

The great solubility of zinc sulphate, as also of nickel, cobalt and copper sulphates, in glycerol, is explained by the fact that these salts combine with three molecules of glycerol to form compounds (Grün, Ber. 1908, 3465) of the general formula:

For these compounds, the name 'glycerinates' has been proposed by Grün, in order to distinguish them from the metallic glyceroxides described above.

QUANTITATIVE DETERMINATION OF GLYCERIN.

Here only the determination of glycerol in commercial products containing considerable quantities of it can be considered. The determination of glycerol in fermented liquors falls outside the scope of this article (see BEER, WINE, &c.). For a description of its methods for quantitative determination, see Lewkowsch, Chem. Techn. 1. For its determination in fermentation glycerin, v. Fleischer, Z. anal. Chem. 1921, 60, 330.

A direct method for determining glycerol in oils and fats by isolating it, has been worked out by Shukoff and Schestakoff. It is necessary to operate with a solution containing at least 40 p.c. of glycerol. If the solution be more dilute, a quantity corresponding to about 1 gram of glycerol is carefully evaporated on the water-bath, the concentration not being allowed to reach so high a degree that volatilisation of glycerol can take place (*i.e.* a concentration of about 50 p.c. must not be exceeded). Before evaporating, the solution is rendered slightly alkaline with potassium carbonate. The concentrated solution is then mixed with 20 grams of ignited and powdered anhydrous sodium sulphate and exhausted in a Soxhlet extractor with anhydrous acetone (previously well dried over ignited potassium carbonate). As acetone attacks both cork and indiarubber, all connections must be made with ground-glass fittings. The extraction requires several hours, and the results, at best, are only approximately correct.

As a rule, the determination of glycerol in oils and fats is carried out by one of the following indirect methods.

Permanganate process. The glycerol solution is made strongly alkaline and a concentrated solution of potassium permanganate is added at the ordinary temperature, until the solution is blackish. The glycerol is converted quantitatively into oxalic acid, carbon dioxide, and water, according to the following equation:

This reaction, originally suggested by Wanklyn and Fox, has been worked out as a quantitative method by Benedikt and Zsigmondy. The excess of permanganate is destroyed by adding a solution of sodium sulphite, and the oxalic acid is determined by precipitating it as calcium oxalate. It is essential that other substances which form oxalic acid on oxidation must be absent. (For a full description of the details of this method, *cf.* Lewkowsch, Chem. Techn.) Other oxidation methods leading to the complete combustion of glycerol, can only be employed in the complete absence of organic impurities.

Acetin process. In case an impure glycerin be under examination (such as the crude glycerins described above), it is most convenient to determine the proportion of glycerol by the Benedikt-Cantor acetin process, which is based on the quantitative conversion of glycerol into triacetin on heating the solution with acetic anhydride. If the product of this reaction is then dissolved in water, and the free acetic acid carefully neutralised with alkali, the dissolved triacetin can be easily estimated by saponifying it with a known volume of standard alkali, and titrating back the excess.

Details of the method are given in the Report of the International Committee on the Analysis of Glycerin (p. 441).

Chemically pure glycerin. The proportion of glycerol in *chemically pure glycerin* is best ascertained by determining the sp.gr. (see table on p. 438) or by oxidising the glycerol by means of permanganate, provided organic impurities be absent. This is ascertained in the following manner: A somewhat dilute solution is mixed

with a cold ammoniacal silver nitrate solution; the solution should remain colourless even after standing for 24 hours. Any acrolein present in the sample is detected by the test described above. Any polyglycerols, due to faulty distillation, are determined by allowing an accurately weighed quantity of the sample to evaporate gently at 160°. Care should be taken not to heat too rapidly, otherwise even the purest glycerol may become polymerised with the production of the very substances that are to be detected. From the weight of the residue, the weight of ash, subsequently found on incineration, must be deducted. The difference ('the organic residue') is a fair indication of the care with which the glycerol has been manufactured.

The following table gives the 'organic residue' and ash of a number of 'chemically pure glycerins' examined in the author's laboratory; they are arranged according to the amount of organic residue they contain:—

ORGANIC RESIDUE AND ASH IN COMMERCIAL CHEMICALLY PURE GLYCERINS.

(Lewkowitsch.)

No.	Residue at 160° p.c.	Ash p.c.	Organic residue p.c.
1	0.03033	0.00603	0.0243
2	0.0276	0.0030	0.0246
3	0.0377	0.0050	0.0327
4	0.0498	0.0138	0.0360
5	0.0452	0.0081	0.0371
6	0.0509	0.0066	0.0443
7	0.0656	0.0139	0.0517
8	0.0748	0.4000	0.0738
9	0.0905	0.0154	0.0751
10	0.1047	0.0190	0.0857
11	0.1236	0.0305	0.0931
12	0.1621	0.0183	0.1438
13	0.8060	0.2090	0.5970

From this table, rules for the valuation of commercial chemically pure glycerins may be derived. The first six samples certainly deserve the name of chemically pure glycerin, the following four samples represent lower qualities unfit for pharmaceutical purposes, whereas the last two samples are merely glycerins, refined by distillation; the last sample would be rejected as unsuitable even by dynamite makers. Sample No. 2 represents a chemically pure glycerin, manufactured by the author on a large scale from soap-lye glycerin, in 1890 (*cf.* Lewkowitsch, Year-Book of Pharmacy, 1890, 382; *cf.* also Thorpe, J. Soc. Chem. Ind. 1895, 720).

Chemically pure glycerin must further be free from all but the most minute traces of arsenic. This is ascertained by a modification of Gutzeit's test (*cf.* Lewkowitsch, Chem. Techn.) substituting mercuric chloride for silver nitrate.

According to Kebler and Fuller (U.S. Dept. Agric. Bureau of Chem. Bull. 1912, 150), glycerin of the best quality should be neutral to litmus, leave no ash on ignition, and have sp.gr. of about 1.250 at 25°. It should not emit any odour when heated on the water-bath, or any fruity odour when warmed with alcohol and sulphuric acid. It should not contain sulphates, chlorides, oxalates, metals, or sugars, and when mixed with an equal volume of water must not reduce Barreswill's (Fehling's) solution. It

should show at most a yellow coloration in Hager's test, according to which 5 c.c. of the sample are mixed with 5 c.c. of 26 p.c. ammonia solution, and 5 drops of silver nitrate solution, and left in the dark for 15 minutes at the ordinary temperature.

The British Pharmacopœia (1914) requires glycerin to have sp.gr. 1.260, to leave no appreciable ash, to be free from lead and copper, and not to contain more than 2 parts of arsenic per million.

Distilled glycerin (dynamite glycerin). The proportion of glycerol in these products is best determined by the acetin method. 'Dynamite glycerin' is usually sold according to a specification agreed upon between buyer and seller. The following conditions are usually stipulated: sp.gr. not below 1.261; absence of lime, magnesia and alumina; absence of more than traces of chlorine and of arsenic; amount of organic impurities, and total residue not to exceed a fixed quantity. In addition thereto, the 'nitration and separation' tests must be satisfactory.

Crude glycerins. All commercial transactions are now based on the following Report of the International Committee on the Analysis of Crude Glycerin (1911), the importance of which demands that it should be given in full:—

INTERNATIONAL STANDARD METHODS (1911).

'Analysis of Crude Glycerol.' The valuation of crude glycerol has in recent years assumed greater commercial importance owing to the increased value of the commodity. The want of uniformity in the methods and processes of analysis, together with the irregularity of the results obtained, emphasised the desirability for the standardisation of crude glycerol analysis; so with this object in view committees were formed in America, France, Germany, and Great Britain. These committees worked in the first instance independently, but were ultimately brought together, and after a series of conferences the conclusions arrived at by the various committees were summarised, and drawn up in the form in which they are now presented. The methods detailed in this report have the unanimous support of each of the above committees, and are strongly recommended by them as International Standards.

'Sampling.' The most satisfactory method available for sampling crude glycerol liable to contain suspended matter, or which is liable to deposit salt on settling, is to have the glycerol sampled by a mutually approved sampler as soon as possible after it is filled into drums, but in any case before any separation of salts has taken place. In such cases he shall sample with a sectional sampler (a suitable sampling apparatus is described in an appendix to the report), then seal the drums, brand them with a number for identification, and keep a record of the brand number. The presence of any visible salt or other suspended matter is to be noted by the sampler, and a report of same made in his certificate, together with the temperature of the glycerol. Each drum must be sampled. Glycerol which has deposited salt or other matters cannot be accurately sampled from the drums, but an approximate sample can be

obtained by means of the sectional sampler, which will allow a complete vertical section of the glycerol to be taken, including any deposit.

Analysis. (1) *Determination of Free Caustic Alkali.*—Weigh 20 grams of the sample into a 100 c.c. flask, dilute with approximately 50 c.c. of freshly-boiled distilled water, add an excess of neutral barium chloride solution, 1 c.c. of phenolphthalein solution, make up to the mark, and mix. Allow the precipitate to settle, draw off 50 c.c. of the clear liquid, and titrate with normal acid ($\frac{N}{1}$). Calculate to p.c. of Na_2O existing as caustic alkali.

(2) *Determination of Ash and Total Alkalinity.*—Weigh 2 to 5 grams of the sample in a platinum dish, burn off the glycerol over a luminous Argand burner, or other source of heat giving a low-flame temperature, the temperatures being kept low to avoid volatilisation, and the formation of sulphides. When the mass is charred to the point that water will not become coloured by soluble organic matter, lixiviate with hot distilled water, filter, wash, and ignite the residue in the platinum dish. Return the filtrate and washings to the dish, evaporate, and carefully ignite without fusion. Weigh the ash. Dissolve the ash in distilled water, and titrate total alkalinity, using as indicator methyl orange cold or litmus boiling.

(3) *Determination of Alkali present as Carbonate.*—Take 10 grams of the sample, dilute with 50 c.c. distilled water, add sufficient $\frac{N}{1}$ acid to neutralise the total alkali found at (2), boil under a reflux condenser for 15 to 20 minutes, wash down the condenser tube with distilled water free from carbon dioxide, and titrate back with $\frac{N}{1}$ NaOH, using phenolphthalein as indicator. Calculate the p.c. of Na_2O . Deduct the Na_2O found in (1). The difference is the p.c. of Na_2O existing as carbonate.

(4) *Alkali combined with Organic Acids.*—The sum of the p.c. of Na_2O found at (1) and (3) deducted from the p.c. found at (2) is a measure of the Na_2O or other alkali combined with organic acids.

(5) *Determination of Acidity.*—Take 10 grams of the sample, dilute with 50 c.c. of distilled water free from carbon dioxide, and titrate with $\frac{N}{1}$ NaOH and phenolphthalein. Express in terms of Na_2O required to neutralise 100 grams.

(6) *Determination of Total Residue at 160°.*—For this determination the crude glycerol should be slightly alkaline with Na_2CO_3 , not exceeding the equivalent of 0.2 p.c. Na_2O , in order to prevent loss of organic acids. To avoid formation of polyglycerol, this alkalinity must not be exceeded.

Preparation of Glycerol.—Ten grams of the sample are weighed into a 100 c.c. flask, diluted with water, and the calculated quantity of $\frac{N}{1}$ HCl or Na_2CO_3 added to give the required degree of alkalinity. The flask is filled to 100 c.c., the contents mixed, and 10 c.c. measured into a weighed Petri or similar dish 2.5 inches

diameter and 0.5 inch deep, which should have a flat bottom. In the case of crude glycerols abnormally high in organic residue a less quantity is to be evaporated, so that the weight of organic residue does not materially exceed 30 to 40 milligrams.

Evaporation of the Glycerol.—The dish is placed in a water-bath (the top of the 160° oven acts equally well) until most of the water has evaporated. From this point the evaporation is effected in the oven. Satisfactory results are obtained in an oven measuring 12 inches cube, having an iron plate $\frac{3}{4}$ inch thick lying on the bottom to distribute the heat. Strips of asbestos millboard are placed on a shelf half-way up the oven. On these strips the dish containing the glycerol is placed.

If the temperature of the oven has been adjusted to 160° with the door closed, a temperature of 130° to 140° can be readily maintained with the door partially open, and the glycerol, or most of it, should be evaporated off at this temperature. When only a slight vapour is seen to come off, the dish is removed and allowed to cool.

An addition of 0.5 to 1 c.c. of water is made, and by a rotatory motion the residue brought wholly or nearly into solution. The dish is then allowed to remain on a water-bath or top of the oven until the excess water has evaporated and the residue is in such condition that on returning to the oven at 160° it will not spit. The time taken up to this point cannot be definitely given, nor is it of importance. Usually 2 to 3 hours are required. From this point, however, the schedule of time must be strictly adhered to. The dish is allowed to remain in the oven, the temperature of which is carefully maintained at 160° for one hour, when it is removed, cooled, the residue treated with water, and the water evaporated as before. The residue is then subjected to a second baking of one hour, after which the dish is allowed to cool in a desiccator over sulphuric acid, and weighed. The treatment with water, &c., is repeated until a constant loss of 1 to 1.5 milligrams per hour is obtained.

Corrections to be applied to the Weight of Total Residue.—In the case of acid glycerol, a correction must be made for the alkali added.

One c.c. $\frac{N}{1}$ alkali represents an addition of 0.022 gram. In the case of alkaline crudes a correction should be made for the acid added. Deduct the increase in weight due to the conversion of the NaOH and Na_2CO_3 to NaCl. The corrected weight multiplied by 100 gives the percentage of total residue at 160°.

Preserve the total residue for the determination of the non-volatile acetylisable impurities.

(7) *Organic Residue.*—Subtract the ash from the total residue at 160°. (Note.—It should be noted that alkaline salts of organic acids are converted to carbonates on ignition, and that the CO_2 radicle thus derived is not included in the organic residue.)

(8) *Moisture.*—This test is based on the fact that glycerol can be completely freed from water by allowing it to stand *in vacuo* over sulphuric acid or phosphoric anhydride. Two to three grams of very bulky asbestos freed

from acid soluble material, which has previously been dried in a water-oven, are placed in a small stoppered weighing-bottle of about 15 c.c. capacity. The weighing-bottle is kept in a vacuum desiccator furnished with a supply of concentrated sulphuric acid under a pressure equivalent to 1 to 2 mm. of mercury, until constant in weight. From 1 to 1.5 gram of the sample is then carefully dropped on to the asbestos in such a way that it will be all absorbed. The weight is again taken, and the bottle replaced in the desiccator under 1 to 2 mm. pressure until constant in weight. At 15° the weight is constant in about 48 hours. At lower temperatures the test is prolonged.

The sulphuric acid in the desiccators must be frequently renewed.

'Acetin Process for Glycerol Determination.

This process is the one agreed upon at a Conference of Delegates from the American, British, French, and German Committees, and has been confirmed by each of the above Committees as giving results nearer to the truth on crudes in general, and is the process to be used (if applicable) whenever only one method is employed. On pure glycerols the methods are identical with those of the dichromate process. For the application of this process the crude glycerol should not contain over 50 p.c. water.

The following reagents are required:—

'1. *Best Acetic Anhydride*.—This should be carefully selected. A good sample must not require more than 0.1 c.c. normal NaOH for saponification of the impurities when a blank is run on 7.5 c.c. Only a slight colour should develop during digestion of the blank.

'2. *Pure Fused Sodium Acetate*.—The purchased salt is again completely fused in a platinum, silica, or nickel dish, avoiding charring, powdered quickly, and kept in a stoppered bottle or a desiccator. It is most important that the sodium acetate be anhydrous.

'3. *A Solution of Sodium Hydroxide for Neutralising, of about N Strength, free from Carbonate*.—This can be readily made by dissolving pure sodium hydroxide in its own weight of water (preferably water free from carbon dioxide), and allowing to settle until clear, or filtering through an asbestos or paper filter. The clear solution is diluted with water free from carbon dioxide to the strength required.

'4. *Normal Sodium Hydroxide, free from Carbonate*.—Prepared as above, and carefully standardised.

'Some sodium hydroxide solutions show a marked diminution in strength after being boiled; such solutions should be rejected.

'5. *Normal Acid*.—Carefully standardised.

'6. *Phenolphthalein Solution*.—0.5 p.c. phenolphthalein in alcohol and neutralise.

'THE METHOD.—Into a narrow-mouthed flask (preferably round-bottomed), capacity about 120 c.c., which has been thoroughly cleaned and dried, weigh accurately and as rapidly as possible 1.25 to 1.5 grams of the glycerol. Add first about 3 grams of the anhydrous sodium acetate, then 7.5 c.c. of the acetic anhydride, and connect the flask with an upright Liebig condenser. For convenience the inner tube of this condenser should not be over 50 cm. long and 9 to 10 mm. inside.

'The flask is connected to the condenser

by either a ground glass joint (preferably) or a rubber stopper. If a rubber stopper is used, it should have had a preliminary treatment with hot acetic anhydride vapour.

'Heat the contents and keep just boiling for 1 hour, taking precautions to prevent the salts drying on the sides of the flask. Allow the flask to cool somewhat, and through the condenser tube add 50 c.c. of the carbon-dioxide-free distilled water, heated to about 80°, taking care that the flask is not loosened from the condenser. The object of cooling is to avoid any sudden rush of vapours from the flask on adding water, and to avoid breaking the flask. Time is saved by adding the water before the contents of the flask solidify, but the contents may be allowed to solidify, and the test proceeded with the next day without detriment. The contents of the flask may be warmed to, but must not exceed, 80°, until the solution is complete, except a few dark flocks representing organic impurities in the crude. By giving the flask a rotatory motion solution is more quickly effected. Cool the flask and contents without loosening from condenser. When quite cold wash down the inside of the condenser tube, detach the flask, wash off stopper or ground glass connection into the flask, and filter contents of flask through an acid-washed filter into a Jena glass flask of about 1 litre capacity. Wash thoroughly with cold distilled water free from carbon dioxide. Add 2 c.c. of phenolphthalein solution (F), then run in sodium hydroxide solution (C) or (D) until a faint pinkish-yellow colour appears throughout the solution. This neutralisation must be done most carefully. The alkali should be run down the sides of the flask, the contents of which are kept rapidly swirling, with occasional agitation or change of motion, until the solution is nearly neutralised, as indicated by the slower disappearance of the colour developed locally by the alkali running into the mixture. When this point is reached the sides of the flask are washed down with carbon-dioxide-free water, and the alkali subsequently added drop by drop, mixing after each drop until the desired tint is obtained.

'Now run in from a burette 50 c.c. or a calculated excess of NaOH with $\frac{N}{1}$ acid (E) until the pinkish-yellow or chosen end-point colour just remains. A further addition of the indicator at this point will cause a return of the pinkish colour; this must be neglected, and the first end-point taken.

'From the $\frac{N}{1}$ NaOH consumed calculate the percentage of glycerol after making the correction for the blank test described below.

'1 c.c. of $\frac{N}{1}$ NaOH = 0.03069 gram of glycerol.

The coefficient of expansion for normal solutions is approximately 0.00033 per c.c. for each degree C. A correction should be made on this account if necessary.

'Blank Test.—As the acetic anhydride and sodium acetate may contain impurities which affect the result, it is necessary to make a blank test, using the same quantities of acetic anhydride and sodium acetate as in the analysis.

After neutralising the acetic acid it is not necessary to add more than 5 c.c. of the $\frac{N}{1}$ alkali (D), as that represents the excess of alkali usually left after saponification of the triacetin in the glycerol determination.

Determination of the Glycerol Value of the Acetylatable Impurities.—The total residue at 160° is dissolved in 1 or 2 c.c. of water, washed into a clean acetylising flask, 120 c.c. capacity, and the water evaporated. Now add anhydrous sodium acetate and proceed as in the glycerol determinations before described. Calculate the result to glycerol.

Analysis of the Acetic Anhydride.—Into a weighed stoppered vessel, containing 10 to 20 c.c. of water, run about 2 c.c. of the anhydride, replace stopper, and weigh; allow to stand, with occasional shaking for several hours, till all anhydride is hydrolysed; then dilute to about 200 c.c., add phenolphthalein, and titrate with $\frac{N}{1}$ NaOH. This gives the total acidity due to free acetic acid and acid formed from anhydride.

Into a stoppered weighing-bottle containing a known weight of recently distilled aniline (from 10 to 20 c.c.) measure about 2 c.c. of the sample stopper, mix, allow to cool, and weigh. Wash contents into about 200 c.c. of cold water, and titrate acidity as before. This yields the acidity due to the original, preformed, acetic acid plus one half the acid due to anhydride (the other half having formed acetanilide); subtract the second result from the first (both calculated for 100 grams) and double result, obtaining c.c. $\frac{N}{1}$ NaOH per 100 gram sample. One c.c. NaOH equals 0.0510 gram of acetic anhydride.

'DICHROMATE PROCESS FOR GLYCEROL DETERMINATION.

Reagents required. (a) *Pure Potassium Dichromate* powdered and dried in air free from dust or organic vapours at 110° to 120°. This is taken as the standard.

(b) *Dilute Dichromate Solution.*—7.4564 grams of the above dichromate (a) are dissolved in distilled water and the solution made up to a litre at 15.5°.

(c) *Ferrous Ammonium Sulphate.*—Dissolve 3.7282 grams of potassium dichromate (a) in 50 c.c. of water. Add 50 c.c. of 50 p.c. (by volume) sulphuric acid and to the cold undiluted solution add from a weighing-bottle a moderate excess of the ferrous ammonium sulphate, and titrate back with the dilute dichromate (b). Calculate the value of the ferrous salt in terms of dichromate.

(d) *Silver Carbonate.*—This is prepared as required; for each test from 140 c.c. of 0.5 p.c. silver sulphate solution by precipitation with about 4.9 c.c. $\frac{N}{1}$ sodium carbonate solution (a little less than the calculated quantity of $\frac{N}{1}$ sodium carbonate should be used; any excess of alkali carbonate prevents rapid settling), settle, decant, and wash once by decantation.

(e) *Subacetate of Lead.*—Boil a pure 10 p.c. lead acetate solution with an excess of litharge for one hour, keeping the volume constant, and filter while hot. Disregard any precipitate which subsequently forms. Preserve out of contact with carbon dioxide.

(f) *Potassium Ferrocyanide.*—A very dilute solution containing about 0.1 p.c.

THE METHOD.—Weigh 20 grams of the glycerol, dilute to 250 c.c., and take 25 c.c. Add the silver carbonate, allow to stand, with occasional agitation, for about 10 minutes, and then add a slight excess (about 5 c.c. in most cases) of the basic lead acetate (e), allow to stand a few minutes, dilute with distilled water to 100 c.c., and then add 0.15 c.c. to compensate for the volume of the precipitate, mix thoroughly, filter through an air-dry filter into a suitable narrow-mouthed vessel, rejecting the first 10 c.c., and return filtrate if not clear and bright. Test a portion of the filtrate with a little basic lead acetate, which should produce no further precipitate. (In the great majority of cases 5 c.c. is ample.) Occasionally a crude glycerol will be found requiring more, and in this case another aliquot of 25 c.c. of the dilute glycerol should be taken and purified with 6 c.c. of the basic acetate. Care must be taken to avoid a marked excess of basic acetate. Measure off 25 c.c. of the clear filtrate into a glass flask or beaker (previously cleaned with potassium dichromate and sulphuric acid). Add 12 drops of sulphuric acid (1:4) to precipitate the small excess of lead as sulphate. Add 3.7282 grams of the powdered dichromate (a). Rinse down the dichromate with 25 c.c. of water and stand, with occasional shaking, until all the dichromate is dissolved (no reduction will take place).

Now add 50 c.c. of 50 p.c. sulphuric acid (by volume), and immerse the vessel in boiling water for two hours, and keep protected from dust and organic vapours, such as alcohol, until the titration is completed. Add from a weighing-bottle a slight excess of the ferrous ammonium sulphate (c), making spot tests on a porcelain plate with the potassium ferrocyanide (f). Titrate back with the dilute dichromate. From the amount of dichromate reduced calculate the percentage of glycerol.

1 gram glycerol equals 7.4564 grams dichromate.

1 gram dichromate equals 0.13411 gram glycerol.

Notes.—1. It is important that the concentration of acid in the oxidation mixture and the time of oxidation should be strictly adhered to.

2. Before the dichromate is added to the glycerol solution it is essential that the slight excess of lead be precipitated with sulphuric acid as stipulated in the process.

3. For "crudes" practically free from chlorides the quantity of silver carbonate may be reduced to one-fifth and the basic lead acetate to 0.5 c.c.

4. It is sometimes advisable to add a little potassium sulphate to ensure a clear filtrate.

Instructions for calculating Actual Glycerol Content.—1. Determine the apparent amount of glycerol in the sample by the acetin process as

described. The result will include acetylisable impurities if any be present.

'2. Determine the total residue at 160°.

'3. Determine the acetin value of the residue at (2) in terms of glycerol.

'4. Deduct the result found at (3) from the percentage obtained at (1), and report this corrected figure as glycerol. If volatile acetylisable impurities are present, these are included in this figure.

'Notes and Recommendations.—Experience has shown that in crude glycerol of good commercial quality the sum of water, total residue at 160°, and corrected acetin result, comes to within 0.5 of 100. Further, in such "crudes" the dichromate result agrees with the uncorrected result to within 1 p.c.

'In the event of greater differences being found, impurities such as polyglycerols or trimethylene glycol, are present. Trimethylene glycol is more volatile than glycerol; it can therefore be concentrated by fractional distillation. An approximation to the quantity can be obtained from the spread between the acetin and dichromate results of such distillates, trimethyleneglycol showing by the former method 80.69 p.c. and by the latter 138.3 p.c. expressed as glycerol.

'In valuing crude glycerol for certain purposes it is necessary to ascertain the approximate proportion of arsenic, sulphides, sulphites, and thiosulphates. The methods for detecting and determining these impurities have not formed the subject of this investigation.

'Recommendations by Executive Committee.

—If the non-volatile organic residue at 160° in the case of a soap lye "crude" be over 2.5 p.c.—i.e. when not corrected for carbon dioxide in the ash—then the residue shall be examined by the acetin method and any excess of glycerol found over 0.5 p.c. shall be deducted from the acetin figure.

'In the case of saponification, distillation, and similar glycerol the limit of organic residue which should not be passed without further examination shall be fixed at 1 p.c. In the event of the sample containing more than 1 p.c. the organic residue must be acetylated, and any glycerol found (after making the deduction of 0.5 p.c.) shall be deducted from the p.c. of glycerol found by the acetin test.'

With reference to this Report, Grimwood (J. Soc. Chem. Ind. 1913, 32, 1039) has shown that the oven recommended therein does not enable a steady temperature to be maintained. In the case of one oven he found a maximum variation of 45° between the temperatures of two shelves. In place of the standard oven he has devised an electrically heated oven cased with uraltite. He also describes an accelerated method of evaporating the glycerin, in which the vapours are removed by means of an electric fan.

British Standard Specifications for Soap Lye and Saponification Crude Glycerins.—The following standard specifications were drawn up by the British Executive Committee on Crude Glycerin Analysis, and approved at a meeting of glycerin makers, buyers, and brokers held in London on October 3, 1912:—

Soap Lye Crude Glycerin.—Analysis to be made in accordance with the International Standard Methods. **Glycerol.**—The Standard shall be 80 p.c. of glycerol. Any crude glycerin tendered which test 81 p.c. of glycerol or over, shall be paid for at a *pro rata* increase, calculated as from the standard of 80 p.c. Any crude glycerin which tests under 80 p.c. of glycerol, but is 78 p.c. or over shall be subject to a reduction of $1\frac{1}{2}$ times the shortage, calculated at the *pro rata* price as from 80 p.c. If the test falls below 78 p.c. the buyer shall have the right of rejection. **Ash.**—The standard shall be 10 p.c. In the event of the percentage of ash exceeding 10 p.c., but not exceeding 10.5 p.c., a percentage reduction shall be made for the excess calculated as from 10 p.c. at *pro rata* price, and if the percentage of ash exceeds 10.5 p.c., but does not exceed 11 p.c., an additional percentage reduction shall be made equal to double the amount in excess of 10.5 p.c. If the amount exceeds 11 p.c. the buyer shall have the right to reject the parcel.

Organic Residue.—The standard shall be 3 p.c. A percentage deduction shall be made of three times the amount in excess of the standard of 3 p.c., calculated at *pro rata* price. The buyer shall have the right to reject any parcel which tests over 3.75 p.c.

Saponification Crude Glycerin.—Analysis to be made in accordance with the International Standard Methods. **Glycerol.**—The standard shall be 88 p.c. Any crude glycerin which tests 89 p.c. or over shall be paid for at a *pro rata* increase calculated as from the standard of 88 p.c. Any crude glycerin which tests under 88 p.c., but is 86 p.c. or over, shall be subject to a reduction of $1\frac{1}{2}$ times the shortage, calculated at *pro rata* price as from 88 p.c. If the test falls below 86 p.c., the buyer shall have the right of rejection. **Ash.**—The standard shall be 0.5 p.c. In the event of the percentage of ash exceeding 0.5 p.c., but not exceeding 2.0 p.c., a percentage reduction shall be made equal to double the amount in excess of 0.5 p.c. If the amount of ash exceeds 0.2 p.c. the buyer shall have the right to reject the parcel.

Organic Residues.—The standard shall be 1 p.c. A percentage deduction shall be made of twice the amount in excess of the standard of 1 p.c., calculated at *pro rata* price. The buyer shall have the right to reject any parcel which tests over 2 p.c.

Estimation of Trimethylene Glycol.—The proportion of trimethylene glycol in crude glycerin may be approximately estimated by distillation under reduced pressure and determining the sp.gr. and apparent glycerol content (by the acetin method) of the distillate (Salway, J. Soc. Chem. Ind. 1918, 37, 123T). From these data the amount of trimethylene glycol may be calculated by means of the following formula, assuming only glycerol, water, and trimethylene glycol to be present:—

$$\text{Sp.gr.} = 1 + 0.00263x + 0.00053y$$

$$\text{Apparent glycerol content} = x + 0.81y$$

If the amount of trimethylene glycol is less than 1 p.c., it is necessary to fractionate the glycerol, and apply the tests to the fraction boiling at 110°–280°.

ESTERS OF GLYCEROL.

The most important esters of glycerol are those resulting from the combination of one molecule of glycerol with three molecules of fatty acids. These esters occur in largest quantities in the natural oils and fats which represent a mixture of a number of simple and mixed triglycerides (*see* OILS, FIXED, AND FATS).

Glycerol, being a trihydric alcohol, is able to form mono-acid and di-acid esters, which are usually described as monoglycerides and diglycerides (although these terms must be considered incorrect, for the term 'monoglyceride' should more appropriately be applied to a triglyceride containing one and the same acid radicle, and the term 'diglyceride' to a triglyceride containing two different acid radicles). The *monoglycerides* have the general formula :

According to the position which the fatty acid radicle occupies in the molecule, two isomeric glycerides may exist, as is explained by the following two formulæ, in which R denotes the fatty acid radicle :—

Compounds of this composition contain an asymmetric carbon atom, and may therefore represent racemic compounds. Monoglycerides corresponding to the first formula are termed α -monoglycerides, and those corresponding to the second formula are termed β -monoglycerides. If a second acid radicle enters, the so-called diglycerides are obtained. Theoretically, two isomeric diglycerides containing the same fatty acid radicle are possible, as is indicated by the following two formulæ :—

The compounds conforming to the first formula are denoted $\alpha\alpha$ (or symmetric) glycerides; they are prepared from $\alpha\alpha$ -dichlorohydrin and the salts of fatty acids. The compounds corresponding to the latter formula are termed $\alpha\beta$ (or unsymmetric) glycerides; they are prepared in a corresponding manner from β -dibromohydrin. $\alpha\beta$ glycerides contain an asymmetric carbon atom; hence the synthetically prepared $\alpha\beta$ diglycerides are likely to represent racemic compounds. If one or both of the acid radicles were optically active (*e.g.* if derived from ricinoleic, chaulmoogric, or hydnocarpic acid), the diglycerides would be optically active on that account alone.

If the two fatty acid radicles are different, the existence of diglycerides having the following formulæ is theoretically possible :—

These diglycerides may be termed 'mixed diglycerides'. As they all contain an asymmetric carbon atom they may represent racemic com-

pounds. If one or both acid radicles be derived from optically active fatty acids, the diglycerides containing them will exhibit optical activity.

The monoglycerides and diglycerides do not occur in nature, but very strong evidence has been adduced that these esters are formed in the course of slow hydrolysis of the natural triglycerides; hence they may be found in fats and oils which have become rancid by a natural process on exposure to air, light, and moisture.

Glycerol also forms esters with inorganic acids, such as sulphuric, nitric, phosphoric, boric, and arsenious acids.

A mixed triglyceride, containing two acid radicles of fatty acids and one of phosphoric acid, occurs in nature as *Lecithin*, in which two fatty acid radicles and one acid radicle of phosphoric acid are combined with the glycerol rest. In the phosphoric acid radicle, one of the two free OH groups is combined with the base choline. *Lecithin* appears to be a representative of a whole group of mixed triglycerides (occurring in the liver, in the brain, &c.), which have been termed by Thudichum, phosphatides, and more recently by Leathes, phospholipines.

Mixed triglycerides containing, in addition to one or two fatty acid radicles, two or one radicles of inorganic acids other than phosphoric acid have not been met with in nature; they have, however, been prepared synthetically. Representatives of such mixed glycerides are chlorodilaurin, chlorodimyristin, chlorodistearin, and monostearochlorohydrin.

The sulphuric acid esters of glycerol are obtained by dissolving glycerol in concentrated sulphuric acid. On boiling with steam, the esters are easily dissociated into glycerol and sulphuric acid. All three possible glycerol sulphuric acids, glyceroltrisulphuric acid, glyceroldisulphuric acid, and glycerolmonosulphuric acid are known.

Glycerylphosphoric esters are obtained by heating phosphoric acid with glycerol. The most important ester, commercially, is monoglycerolphosphoric acid, which forms a series of salts (sodium, lithium, calcium, strontium, iron, &c.), largely used in pharmaceutical practice (especially in France).

It has been found by Umney and Bennett (*Proc. Brit. Pharm. Conf.* 1914, 22) that the composition of commercial calcium glycerophosphate varies. It should contain at least 15 p.c. of calcium, and may contain added citric acid to increase the solubility. The magnesium salt should contain not less than 10 p.c. of magnesium, and the ferric salt at least 15 p.c. of iron, and be soluble in 2 parts of water. Sodium glycerophosphate crystallises with 5 molecules of water.

For a method of examining glycerylphosphoric esters, *see* Grimbert and Bailly (*Compt. rend.* 1915, 160, 207; Bailly, *idem.* 1915, 161, 677).

Optically active glycerophosphoric acid may be synthesised by adding phosphorylchloride to a solution of *d*- α -bromohydrin in dry pyridine at below -10° . The bromine is removed by lithium hydroxide and the product is isolated as nearly pure lithium *d*-glycerophosphate $\text{HO}\cdot\text{CH}_2\cdot\text{CH}(\text{OH})\cdot\text{CH}_2\cdot\text{O}\cdot\text{PO}(\text{OLi})[\text{a}]_D^{18} = +3.51^\circ$

in aqueous solution. Lithium *l*-glycerophosphate has $[\alpha]_D^{18} = -3.02^\circ$ (Abderhalden and Eichwald, Ber. 1918, 51, 1308).

Of great commercial importance are the nitric esters of which the most important is glyceryl trinitrate, or 'nitroglycerin,' prepared by allowing glycerin to run into a mixture of one part of strongest nitric acid and two parts (by weight) of concentrated sulphuric acid. Nitroglycerin is a heavy oily liquid of sp.gr. 1.60, which volatilises at 160° under a pressure of 15 mm. Its most remarkable property of exploding violently under certain conditions is made use of in high explosives and 'smokeless powders,' such as 'dynamite,' 'blasting gelatin,' 'gelignite,' &c. (*v. EXPLOSIVES*).

The mono- and dinitrates of glycerol and their chlorides and ethers are employed as ingredients of non-freezing nitroglycerin blasting combinations. The dinitrate of monochlorohydrin is used in such explosives as gelatin astralit, gelatin westfalit, &c. The nature and explosive character of α -methylin dinitrate (glyceryl methyl ether dinitrate) have been investigated by Trevor Jones (Chem. Soc. Trans. 1919, 76) (*v. EXPLOSIVES*).

Glyceryl arsenite is formed by dissolving arsenious oxide in glycerol and heating to 250° . Above 250° it decomposes. It is volatile with the vapours of glycerol, hence, when distilling glycerin in a current of superheated steam (*see above*), the arsenite is either volatilised unchanged, or is hydrolysed by the steam; at any rate the distillate contains arsenious acid. Glyceryl arsenite is used in calico printing.

POLYGLYCEROLS.

When glycerol is heated rapidly, polyglycerols are obtained. They are formed by the combination of several molecules of glycerol with loss of water: hence they are formed on a large scale during the distillation of glycerin, when the bulk of the polyglycerols remains behind in the still. The condensation of glycerol to polyglycerol has been effected by Lourenço, by heating glycerol with monochlorohydrin. (For the application of polyglycerols in the arts, *see above*.) J. L.

GLYCERIN-FORMAL. A condensation product of glycerol and formaldehyde.

GLYCEROLPHOSPHORIC ACID and GLYCEROLPHOSPHATES *v. GLYCERIN (GLYCEROL)*.

GLYCIN is the trade name for the chloride of *p*-hydroxyphenylaminoacetic acid. It is used in photography as a developer (also *v. GLYCINE*).

GLYCINE. *Glycin, Glycocine, Glycocol, Aminoacetic acid*

(Sakurai, Chem. Soc. Proc. 1894, 90; 1896, 38; Walker, Chem. Soc. Proc. 1894, 94). Glycine was discovered in 1820 by Braconnot (Ann. Chim. [2] 13, 114) among the products obtained by decomposing glue with sulphuric acid. It is obtained by decomposing various protein substances with sulphuric acid (Spiro, Zeitsch. physiol. Chem. 28, 187), and is present as the chief amino-acid in the sugar cane (Shorey, J. Amer. Chem. Soc. 1897, 881; 1898, 137).

It may be prepared by treating bromacetic or chloracetic acids with ammonia (Perkin and Duppa, Annalen, 108, 112; Kraut, Ber. 1890, 2577; Mauthner and Suida, Monatsh. 11, 374; Goldberg, Kunz and Kraut, Annalen, 266, 295); by treating chloracetic acid with ammonium carbonate (Nencki, Ber. 1883, 2828); by passing cyanogen into boiling hydriodic acid (sp.gr. 1.96) (Emmerling, Ber. 1873, 1361); by heating potassium phthalimide with ethyl chloracetate (Gabriel and Kroseberg, *ibid.* 1889, 427); by treating nitrosomalonic ester with zinc and acetic acid (Conrad and Schulze, *ibid.* 1909, 729); by boiling hippuric acid with strong sulphuric acid (Curtius, J. pr. Chem. [2] 26, 145; Dessaignes, Annalen, 58, 322); by treating glyoxylic acid with ammonium carbonate and subsequently heating to 120° with hydrochloric acid (Erlenmeyer, junr., and Kunlin, Ber. 1902, 2438); by the action of hexamethylene amine on potassium monochloracetate (Bourcet, Bull. Soc. chim. 19, [3] 1005; Auger, *ibid.* 21, [3] 5). In order to obtain the pure acid, the solution containing the acid, prepared by any of the above methods, is freed from ammonia (if present) and freshly precipitated copper hydroxide is added. The copper salt of the acid crystallises out; this is filtered off and decomposed with sulphuretted hydrogen. Another method consists in extracting the acid with glycerol and thus separating it from the impurities present (Farbw. Meister, Lucius and Bruning, D. R. P. 141976; Zeitsch. angew. Chem. 1903, 16, 527). Siegfried (D. R. P. 188005; Chem. Zentr. 1907, ii. 1466) adds barium or strontium hydroxides to the solution, passes in carbon dioxide, filters off the separated solid and heats it with water.

Properties.—Glycine crystallises from water in plates and from dilute alcohol in needles. After drying at 100° the plate form begins to decompose on heating at 212° , whilst the needle form remains unchanged until a temperature of 220° to 230° is reached, when they melt with the evolution of gas at 232° – 236° ; sp.gr. 1.1607 (Curtius, *l.c.*). It is soluble in 4.3 parts of cold water and in 930 parts of ethyl alcohol (sp.gr. 0.828), but is insoluble in absolute alcohol. Hydriodic acid reduces glycine to ammonia and acetic acid (Kwisda, Monatsh. 12, 419), whilst sodium amalgam yields amino-acetaldehyde (Neuberg, Ber. 1908, 956; Fischer, *ibid.* 1019). On electrolysis, the acid or the copper salt yields ethylenediamine (Lilienfeld, D. R. P. 147943; Chem. Zentr. 1904, i. 133; Kühling, Ber. 1905, 1638; 1907, 757). Hydrogen peroxide oxidises glycine to glyoxylic acid and formaldehyde (Dakin, J. Biol. Chem. 1, 171); treatment with nitrosyl chloride results in the formation of chloracetic acid (Tilden and Forster, Chem. Soc. Trans. 1895, 491). Glycine and its derivatives are used in photography as developers, in place of pyrogallol, &c. (Farbw. Meister, Lucius and Bruning, D. R. P. 142489; U.S. Pat. 767815; Eng. Pat. 20377; J. Soc. Chem. Ind. 1903, 380), and also for reducing silver images.

Derivatives.—*Aromatic glycines* are prepared from aromatic amines and monohalogenated acetic acids or dihalogenated vinyl ethers (Imbert and Consortium für Elektrochemische Industrie, Chem. Soc. Abstr. 1908, i. 975;

D. R. P. 199624). *Glycocolamide* is produced when glycocholic and alcoholic ammonia are heated together at 160°. *Glycocolamidide* is prepared from chloro- or bromo- acetanilide and ammonia (Majert, Eng. Pat. 5269; D. R. P. 59121; J. Soc. Chem. Ind. 1892, 369). The *Ethyl ester* is prepared by the action of ammonia on chloroacetic acid, and subsequent treatment of the crude dry product with absolute alcohol and dry hydrogen chloride (Hantzsch and Metcalf, Ber. 1896, 1684; Hantzsch and Silberrad, *ibid.* 1900, 70) or by the interaction of hexamethylene amine and chloroacetic acid and subsequent treatment as above (Auger, Bull. Soc. chim. [3] 21, 5). It boils at 51.5°–52.5° (10 mm.), and has sp.gr. 1.0358 11.8°/4° (Schmidt, Ber. 1905, 200).

Methylglycine v. SARCOSINE.

Trimethylglycine v. BETAINÉ.

Glycine anhydride $\text{CH}_2 \begin{array}{c} \text{NH} \cdot \text{CO} \\ \diagup \quad \diagdown \\ \text{CO} \cdot \text{NH} \end{array} \text{CH}_2$ was

discovered by Curtius (J. pr. Chem. [2] 37, 173). It separates out from an aqueous solution of glycine ester on long standing. It is best prepared by treating the hydrochloride of the ester with caustic soda (Fischer, Ber. 1906, 2893). It is a white crystalline solid, which, on heating, becomes brown at 245° and melts at 275°.

Glycocolaminocarbonylic acid esters (v. Einhorn, Chem. Zentr. 1901, i. 1115; D. R. P. 108027).

GLYCOBROM. Syn. for the glyceryl ester of dibromohydrocinnamic acid.

GLYCOCHOLEIC ACID v. CHOLIC ACID.

GLYCOLL v. GLYCINE.

GLYCOCYAMINE. Syn. for guanidine acetic acid.

GLYCOGEN v. CARBOHYDRATES.

GLYCOL. See Ethylene Glycol, art. ETHYL.

GLYCOLLIC ACID, *Hydroxyacetic acid*

$\text{CH}_2(\text{OH})\text{COOH}$

It is present as the chief acid constituent in the juice from the sugar cane (Shorey, J. Amer. Chem. Soc. 1899, 21, i. 45) and is found in the calcium precipitate formed in the treatment of beet-juice (Lippmann, Ber. 1891, 3299). It is formed by the oxidation of glycol (Wurtz, Annalen, 103, 366); by treating alcohol with nitric acid in the cold (Drechsel, *ibid.* 127, 150); by reducing oxalic acid with zinc (Forcrand, Bull. Soc. chim. [ii.] 39, 310); by the electrolytic reduction of oxalic acid in dilute hydrochloric or sulphuric acids, using lead electrodes (Roessler and Hasslacher Chem. Co., U.S. Pat. 837083; D. R. PP. 194038, 204787; J. Soc. Chem. Ind. 1907, 157; 1909, 108; Rainhold, Fr. Pat. 378276; J. Soc. Chem. Ind. 1907, 1097; Avery and Dales, Ber. 1899, 2236); and by treating formaldehyde with equivalent quantities of potassium cyanide and calcium chloride (Kohn, Monatsh. 1899, 903; Franzen, J. pr. Chem. [2], 1912, 133). Glycollic acid may be prepared by boiling a concentrated solution of potassium chloracetate for 24–30 hours in a flask under a reflux apparatus. The product is then distilled under reduced pressure, the temperature being kept below 70°. The residue is mixed with a large quantity of acetone, the solution filtered from the separated potassium chloride, and after a short time the glycollic acid separates from the acetone solution in colourless crystals. The yield is about 85 p.c.

(Colman, Chem. Soc. Proc. 1892, 72; cf. Witzemann, J. Amer. Chem. Soc. 1917, 39, 109).

Glycollic acid crystallises from water in crystals belonging to the monoclinic system and from acetone in those of the orthorhombic system (Colman, *l.c.*); m.p. 78.9° (Drechsel, *l.c.*). On heating to 100°, glycollic anhydride $\text{C}_4\text{H}_6\text{O}_5$ is formed, and by heating the calcium salt with much sulphuric acid, metaformaldehyde is produced. Oxidation with nitric acid yields oxalic acid, and reduction with zinc and sulphuric acid results in the formation of acetic acid (Claus, Annalen, 145, 256). It may be detected by heating 0.02–0.1 gram of the substance with 0.2 c.c. of water and 2 c.c. of sulphuric acid (sp.gr. 1.34); after gas has ceased to be evolved, the addition of one drop of *p*-cresol gives a green coloration, or one drop of codeine solution, a yellow coloration changing to deep violet (Denigès, Bull. Soc. chim. 1909, 5, 647).

The glycolates of the alkalis are deliquescent; calcium glycolate $(\text{C}_2\text{H}_3\text{O}_3)_2\text{Ca}$ (with 3 or $4\frac{1}{2}$ H_2O) and silver glycolate $\text{C}_2\text{H}_3\text{O}_3\text{Ag} \cdot \frac{1}{2}\text{H}_2\text{O}$ are sparingly soluble in water.

The ammonium salt may be distilled *in vacuo*, the distillate consisting of the acid ammonium glycolate, boiling at 160° under 10 mm. pressure (D. R. P. 247240).

GLYCOSAL. Trade name for a combination of glycerol and salicylic acid introduced as a substitute for other salicylates (v. SYNTHETIC DRUGS).

GLYCURONIC ACID

$\text{CHO} \cdot \text{HC}(\text{OH}) \cdot \text{OHCH} \cdot \text{HCOH} \cdot \text{HCOH} \cdot \text{COOH}$

occurs in urine in combination with phenol, kresol, and indoxyl. It is also present in the blood. It does not occur in the free state, but is produced in the body in considerable quantity after the administration of certain substances, e.g. camphor, menthol, phenol, &c., in combination with which it is eliminated. It thus appears to furnish a material which can be produced by the body to neutralise the toxic properties of harmful substances before their elimination. It occurs also in combination in plants. It is found in combination with euxanthone in the urine of camels: the Mg salt of the euxanthone-glycuronic acid is the basis of the pigment Indian yellow. It may be synthesised by reducing saccharic acid with sodium amalgam in acid solution (Fischer and Piloty, Ber. 1891, 521).

Preparation.—It is prepared from its compounds by boiling with acid: thus, menthol-glycuronic acid is split by boiling with dilute sulphuric acid; camphor glycuronic acid is boiled with hydrochloric acid for 2 hours; after saturating the solution with PbCO_3 the precipitated lead salt is decomposed with H_2S .

Properties.—Glycuronic acid is a syrup, readily losing water in a vacuum, forming a lactone, melting from 170°–175° (Mann and Tollens, Annalen, 290, 155). Rotation $[\alpha]_D^{18} = +19.25^\circ$. It is oxidised to saccharic, and reduced to gluconic, acid. Distilled with HCl, it breaks up into furfural and CO_2 , a reaction which may be used for its estimation. Not fermented by yeast. It is said to be one of the reducing substances left in urine from which the sugars have been removed by yeast fermentation.

Detection and Estimation.—With a solution of orcin in hydrochloric acid it gives a green colour after boiling for a short time. With naphthoresorcin and HCl it gives a blue substance soluble in ether, showing a well-marked absorption band in the neighbourhood of the D line and differentiated by its solubility in ether from the substances given under similar circumstances by the pentoses (Tollens, Ber. 1908, 1788). This reaction is, however, given by other acids (Mandel and Neuberg, Biochem. Zeitsch. 13, 148). It gives a characteristic *p*-bromphenylhydrazone, melting at 236°. The phenyllosazone is formed on heating a mixture of 1 molecule glycuronic acid with 3 molecules phenyl hydrazine in acetic solution to 40° for some days. It melts at 200°–205°. The semicarbazone melts at 188°.

GLYCYPHYLLIN *v.* **GLUCOSIDES.**

GLYCYPHYLLIN, GLYCYPHYLLIC ACID, GLYCYPHYLLIN *v.* **LIQUORICE.**

GLYOXYLIC ACID $\text{CHO} \cdot \text{CO}_2\text{H}$ or

Found in very young beet-roots (Lippmann, Ber. 1891, 3305), in grapes, unripe apples, plums, gooseberries, currants, and rhubarb (Brunner and Chaud, Ber. 1886, 595; Bull. Soc. chim. [3] 13, 126). Prepared by oxidising alcohol (Debus, Annalen, 100, 1; Boettinger, Arch. Pharm. 232, 65), glycol (Debus, Annalen, 110, 316) or glycerol (Heintz, *ibid.* 152, 325) with nitric acid; by heating ethyldichloracetate with water at 120° (Fischer and Geuther, J. 1864, 316); by exactly neutralising dichloracetic acid with potassium hydroxide (1:1) and heating with solid potassium acetate in a reflux apparatus for an hour, filtering the liquid and boiling the filtrate for several hours (Doebner, Annalen, 311, 129); by heating the silver salt of dibromodichloracetic acid with water (Debus, Zeitsch. Chem. 1866, 188; Perkin and Duppa, Annalen, 112, 24; Zeitsch. Chem. 1868, 424; Beckurts and Otto, Ber. 1881, 581); by heating one part of dibromacetic acid with 10 parts of water for 24 hours at 135°–140° (Grimaux, Bull. Soc. chim. [ii.] 26, 483); by reducing the esters of oxalic acid with sodium amalgam (Bayer & Co. D. R. P. 201895; J. Soc. Chem. Ind. 1908, 1176); by the electrolytic reduction of oxalic acid, its esters or its amide in sulphuric acid at a low temperature (Tafel and Friedrichs, Ber. 1904, 3187; Wohl and Lange, *ibid.* 1908, 3614; Kinzberger & Co. D. R. PP. 163842, 210693; J. Soc. Chem. Ind. 1906, 392; 1909, 815).

Glyoxylic acid is a thick liquid, readily soluble in water, and crystallises in rhombic prisms by long standing over sulphuric acid (Debus, Chem. Soc. Trans. 1904, 1382); the crystals have the formula $\text{C}_2\text{H}_2\text{O}_4$ (Perkin, Ber. 1875, 188). It is a tautomeric substance; it exhibits aldehydic properties in condensing with hydroxylamine, phenylhydrazine, and semicarbazide (Elbers, Annalen, 227, 353; Fischer, Ber. 1884, 576; Simon and Chavanne, Compt. rend. 143, 904), but most of its salts are of the type $(\text{HO})_2\text{CH} \cdot \text{CO}_2\text{M}$, whilst dialkyl ethers of the type $(\text{RO})_2\text{CH} \cdot \text{CO}_2\text{H}$ have been prepared. Reduction with zinc in aqueous solution yields glycollic acid; in acetic solution, tartaric acid (Genvesse, Compt. rend. 114, 555); nitric acid

oxidises it to oxalic acid, whilst potash simultaneously oxidises and reduces it with the formation of glycollic and oxalic acids: treatment with ammonia and subsequent hydrolysis yields formic acid and glycine (Erlenmeyer and Kunlin, Ber. 1902, 2438). With hydrogen cyanide, it forms a cyanhydrin which, on hydrolysis, yields tartaric acid. By warming with resorcinol and a little absolute alcohol, diluting and adding a few drops of ammonia, a deep blue coloration is produced, rapidly changing to red (Boettinger, Arch. Pharm. 232, 1); sulphuric acid gives a blue or violet coloration with glyoxylic acid (Hopkins and Cole, Proc. Roy. Soc. 68, 21). The phenylhydrazone melts at 137°, and is used for identifying the acid. It condenses with carbamide to form allantoin and with guanidine to form in the cold glyoxylic guanidide and on warming to 100°, iminoallantoin (Doebner and Gärtner, Annalen, 315, 1; 317, 157; Simon and Chavanne, Compt. rend. 143, 51; Kaess and Gruszkiewicz, Ber. 1902, 3604). For other condensations *v.* Boettinger, Arch. Pharm. 232, 549, 704; 233, 100, 199; Bougault, Compt. rend. 148, 1270. For salts *v.* Debus, Chem. Soc. Trans. 1904, 1382. Glyoxylic acid acts as a hydrolysing agent towards cane sugar and starch, and prevents fermentation of products thus formed as it acts on yeast as a poison (Boettinger, Arch. Pharm. 233, 287; Bouveault, Bull. Soc. chim. [iii.] 19, 78). For physiological action in the body, *v.* Eppinger, Beitr. chem. Physiol. Path. 6, 492; Almagia, *ibid.* 7, 459; Schloss, *ibid.* 8, 445; Granstörn, *ibid.* 11, 132; Dakin, J. Biol. Chem. 1, 271; Hofbauer, Zeitsch. physiol. Chem. 52, 425; Adler, Arch. exp. Path. Pharm. 46, 207.

GMELINOL $\text{C}_{12}\text{H}_{14}\text{O}_4$, the white deposit in the cells of the 'Colonial Beech' (*Gmelina Leichhardtii*, F. v. M.), separating from hot water in needle prisms or plates. M.p. in the crystalline state 122° (corr.). After cooling solidifies to a transparent, resin-like substance which melts at 62°–63°. When powdered the m.p. begins to rise, soon reaches 120°–121°, $[\alpha]_{\text{D}}^{20} + 123.3^\circ$ in chloroform. Soluble in 1470 parts of water at 22°. Nitric acid converts it into a *dinitro*-compound $\text{C}_{12}\text{H}_2\text{O}_4(\text{NO}_2)_2$, m.p. 128°–129°. Sodium acetate and acetic anhydride transform it into a *monoacetyl* derivative, m.p. 110°. With bromine water forms

Zeisel determinations indicate the presence of two methoxy-groups, and this is confirmed by the production of veratric acid when the substance is oxidised by a solution of chromic acid in glacial acetic acid, or by alkaline permanganate. When fused with potassium hydroxide at a temperature not exceeding 200°, phenolic substances are formed, whilst at 210°–225°, protocathechuic acid is produced, together with small quantities of a volatile acid (H. G. Smith, J. Roy. Sci. New S. Wales, 1913, 46, 187).

GNEISS *v.* **GRANITE.**

GNOSCOPINE *v.* **OPIMUM.**

GOA POWDER *v.* **CHRYSAROBIN.**

GOETHITE or **GÖTHITE**. Hydrated ferric oxide, $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$ or $\text{FeO}(\text{OH})$, crystallised in the orthorhombic system and isomorphous with the corresponding aluminium and manganese

minerals diaspre and manganite. It is included with limonite under the term 'brown iron-ore,' and when fibrous and massive the two are not readily distinguished, especially as they have the same colour and streak. Goethite, however, contains more iron (Fe_2O_3 89.9, Fe 62.9 p.c.) and less water (10.1 p.c.) than limonite ($2\text{Fe}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$). Crystals of goethite are not uncommon; limonite, on the other hand, though sometimes fibrous and crystalline, is never crystallised. They are prismatic, acicular, platy, or scaly in habit, and have a perfect cleavage in one direction (parallel to the brachy-pinacoid). Reniform and stalactitic masses with a radiating fibrous structure also occur. Sp.gr. 4.0–4.4, of crystals 4.37; H. 5–5½. The colour is yellowish-brown to brownish-black, with usually a brilliant lustre on crystal-faces. Thin crystals and splinters are blood-red by transmitted light. The colour of the streak or powder is yellowish-brown. Analyses often show the presence of small amounts of manganese oxide and silica. Several varieties are distinguished. The acicular forms, usually with a radial grouping, are known as *needle iron-ore*. The needles may be very fine and closely packed together, giving the appearance of plush, as in *Sammleblende* or *Sammeterz* (velvet-ore), also known as *prizbramite*, from Příbram in Bohemia. Another form occurring as extremely thin scales with a reddish colour is known as *Rubinglimmer* or *Pyrrhosiderite*; and a scaly-fibrous or plumose form as *lepidocrocite*. *Onegite* is acicular goethite embedded in amethyst from Lake Onega, Russia. This material is cut as a gemstone under the name 'Cupid's darts' (flèches d'amour). As an enclosure in other gem-minerals it is represented in aventurine and sun-stone. *Mesabite* is an ochreous variety abundant amongst the iron ores of the Mesabi Range in the Lake Superior district of Minnesota. The name goethite is after the poet Goethe. The modes of occurrence of goethite are the same as for limonite, and it is present in many limonitic iron ores. Fine groups of crystals were formerly obtained in abundance in the Restormel iron mines at Lanlivery and in the Botallack mine at St. Just in Cornwall. Larger, but less perfect, crystals are known from the Pike's Peak district in Colorado. L. J. S.

GOLD. Sym. Au (Aurum). At.wt. 197.2.

Historical.—Gold cannot have escaped the observation of the men of the Stone Age, but it could have been of little use to them except for ornamentation until they had discovered the art of melting. Flint daggers with gilt handles have been found in Egypt, and gold was well known in that country about 3600 B.C., when its value in relation to silver was fixed by law. It was first used for coinage in Lydia, about 700 B.C. in the form of electrum, a native alloy of gold and silver.

The earliest method of obtaining gold, other than that of collecting it by hand, was by washing with water on sloping rocks. Sheepskins were spread out for entangling the particles of metal and helping in its collection. Over 2000 years ago, the methods of ore-crushing by hammers and also by means of pestles and mortars were adopted in Egypt to release gold contained in solid rock. The powdered ore was washed on sloping tables. The use of sieves is

also attributed to the Egyptians. Heavy pestles or stampers, requiring water power or the united efforts of several men to raise them, were not employed until much later. Stamp batteries for crushing ore were established at Joachimsthal in 1519, and sieves set at the outlet of the mortars were described by Agricola in 1556 and were seen by Jars in the Hartz in 1767.

The use of mercury for separating gold from other materials by amalgamation was described by Pliny and referred to by Theophilus in the 11th century in his description of the extraction of gold from the sands of the Rhine. The method used in the Tyrol of stirring crushed ore with large quantities of mercury in circular bowls is of great antiquity, but the practice of charging mercury together with uncrushed ore into the mortars of stamp batteries and catching the gold amalgam on copper plates was not mentioned before 1850.

The chlorination process of gold ore treatment originated in 1848, and the cyanide process was invented by MacArthur and Forrest in 1887. The methods of refining gold by the cementation process and by cupellation are very ancient. Nitric acid for refining was in use in Venice in the 15th century and was not superseded by sulphuric acid until the 19th century. The electrolytic refining process, invented in 1888, has now replaced the sulphuric acid process in the United States.

Gold ores. Gold is widely distributed in nature. It occurs in minute traces in all ores of silver, copper, lead, antimony, and bismuth. It has been detected in igneous and metamorphic rocks in almost every case in which a careful search for it has been made, and sedimentary rocks are seldom quite free from it. The comparatively small quantities of gold in limestones which have been formed in clear water far from land, appear to indicate the land as the place of origin of the gold, but it is also present in sea water.

Gold occurs in quantities large enough to pay for extraction in many quartz veins or lodes in rock formations. The gold is disseminated in the quartz and is accompanied by brown oxides of iron in the upper portions of the deposits and by sulphides in the deep-seated portions. It usually occurs as native gold and even when it is present in pyrites or other sulphides, it is present in the free state. Native gold also occurs in many secondary or detrital ('placer') deposits, such as river gravels, sea beaches, &c., in the form of nuggets, grains, and flakes. The auriferous beds of conglomerate in the Transvaal are of this character.

Native gold occurs in the form of rounded, irregularly shaped nuggets, pellets, grains, &c., which show crystalline structure when polished and etched but rarely exhibit regular crystal faces or angles externally. It always contains some silver and copper, and other metals are also generally present in smaller proportions.

Telluride of gold is found in large quantities in Western Australia, Colorado, and Transylvania, and has been reported from many other localities. There is only one true compound of gold and tellurium, which corresponds with the formula AuTe_2 , and contains 43.6 p.c. of gold; but several compounds consisting of various mixtures of tellurium with gold and silver and other

metals have been recognised as mineral species. The best known of these are (1) *calaverite*, which has the composition AuTe_2 , (2) *sylvanite* or graphic tellurium which appears to be a variable mixture of AuTe_2 and Ag_2Te , (3) *petzite*, a telluride of silver, Ag_2Te , with part of the silver replaced by gold, and (4) *nagygite* or foliated tellurium, which contains some lead.

Auriferous telluride is usually dark grey or black in colour, but occasionally is silver-grey. Sometimes it contains an admixture of metallic gold which gives it a brassy-yellow colour. It is soft and brittle but its density is high, usually between 8 and 9. When heated in air, it oxidises, fuming and giving off TeO_2 , and fuses below a red heat. If the roasting process is continued, most of the tellurium is removed and the gold is left in the form of spherical pellets which have solidified from fusion. *Calaverite* may contain as much as 44 p.c. of gold, but part of this is usually replaced by silver. A specimen of *sylvanite* from Cripple Creek, Colorado, contained gold 7.64 p.c., silver 32.39 p.c., tellurium 59.96 p.c. (F. C. Smith), and a specimen of *petzite* from California contained 25.6 p.c. of gold and 41.86 p.c. of silver.

Extraction of gold from its ores. The metallurgical treatment of gold ores is usually simple and cheap and owing to this circumstance and to the high value of the metal, ores containing very small proportions of gold can be worked at a profit. Thus the ores of the Witwatersrand, now being worked, contain, on an average, only about 6 or 7 dwt. of gold per ton, or little more than 0.001 p.c., and in the case of auriferous gravel a ton rarely contains more than a few grains of gold.

Washing auriferous gravel.—The gold occurring in placers is obtained by washing away, with the aid of water, the lighter gravel from the gold disseminated through it. A large number of appliances and machines are in use for this purpose. Generally the larger stones are removed by some form of sieve and the finer material is carried by a shallow stream of water through inclined troughs ('sluice-boxes') or over sloping tables. The heavy particles of gold sink to the bottom of the stream and are caught by the rough surface of blanketing or plumb or in crevices which are formed by the supply of 'riffles' of various kinds. Sometimes the riffles consist of wooden strips or poles, sometimes of iron rails or sheets of 'expanded' metal. Mercury is sprinkled in the stream and accumulates in the crevices, where it assists in catching the gold by amalgamating with it. The gold-amalgam, recovered in the periodical 'clean-up,' is strained through canvas to remove the excess of mercury and afterwards retorted.

The gravel is mined in various ways, according to circumstances. It may be raised by the spade and thrown into the stream, or when in high banks it may be broken down and washed away by jets of water ('hydraulic mining'). Gravels cemented by infiltration are crushed before being washed. Of late years, dredgers have been largely used, originally to recover the gravel from river beds and more recently on dry alluvial 'flats.' In the latter case, the dredger floats in a pond, and travels slowly across country, scooping away the ground in front and

stacking it behind after it has been washed. Placer mining is now of less relative importance than formerly owing to the exhaustion of many of the known deposits.

Stamp battery.—Auriferous quartz is usually treated by crushing in stamp batteries and amalgamation. The residue or tailing is subsequently treated in various ways, especially by the cyanide process. In recent years, especially in the United States, the use of mercury has been discarded in many cases in favour of the cyanide process, and the use of other crushing machines instead of stamps is also increasing.

Stamps are heavy iron or steel pestles which are lifted and let fall in iron mortars. They have gradually increased in weight, the 50 lb. stamps of 100 years ago having become the 900 lb. stamps of the nineties and the 1800 or 2000 lb. stamps which have been installed in the Transvaal. The height of drop is usually about 7 or 8 inches and the number of drops per minute about 100. Water and ore are fed into the mortar continually and the fall of the stamps splashes the mixture against a wire screen or perforated metal plate set in the side of the mortar. The finely comminuted material passes through the screen and usually falls directly upon gently sloping amalgamated copper plates. Sometimes mercury is fed into the battery with the ore and amalgamated plates are fastened to the inside of the mortar, but these practices are becoming less common and are impossible with modern heavy stamps. It is now considered advantageous to remove the amalgamated plates to another building at some distance from the stamp battery in order to avoid excessive vibration. Stamps are usually in batteries of five, working side by side in a single mortar, but the Nissen stamp has a separate mortar for each stamp and has other distinctive features.

The pulp from the battery is often further reduced in size by passing through a tube-mill, a revolving cylinder half-filled with pebbles, and in that case a coarser mesh is used in the battery screens. No screens are used in tube-mills. Amalgamated plates are placed at the outlets of the tube-mills, and those between the battery and the tube-mills are sometimes omitted. Other machines are occasionally used for fine grinding, as, for example, amalgamating pans (see article SILVER for description of these machines). Roller mills, such as the Huntington mill, are sometimes used instead of stamps for crushing soft or brittle ores, or as intermediate grinders. In the Huntington mill, four rollers with vertical axes run around in an iron pan, and are pressed against its periphery by centrifugal force.

In some of the most modern gold extraction works in the Transvaal, the ore is broken to a maximum size of about $1\frac{1}{2}$ inch in rock-breakers of the reciprocating type in which the jaws alternately advance and recede. Gyrotory rock crushers are also used. The ore is then passed to the stamp battery and crushed by heavy stamps through coarse screens up to $\frac{1}{2}$ inch aperture, the maximum dimensions of ore which can be advantageously treated in tube-mills. Under these conditions, the amount of ore crushed per stamp per day is as much as 20 tons against 4 or 5 tons in adjoining mills

where lighter stamps and finer sieves are used. Such coarse material as that indicated above cannot be passed over amalgamated plates, as these would be scoured free from mercury, &c., and it is accordingly passed direct to (inverted) cone classifiers, where the coarse particles settle in water and are retained, whilst the fine material is carried away in the overflow, and sent to the cyanide works. A diaphragm guards the axis of the cone so that the settlement of the sands takes place round the periphery. The underflow or discharge from the apex of the cone, containing the coarse material, including all the coarse free gold, is fed into tube-mills together with some of the water from the overflow. On issuing from the tube-mill, the pulp, which now contains only a small proportion of material too coarse to pass through a 60-mesh sieve (aperture 0.008 inch), is slightly diluted with water and then passed over amalgamated plates where the coarse free gold is extracted. The tailing from the plates is discharged into the stream of pulp coming from the battery and again passes to the cone classifiers, the oversize being thus returned to the tube-mill. The material passing through the tube-mill contains much less water (say 2 parts of water to 1 of ore) than that coming from the battery and that going to the cyanide works. The last-named pulp is in a very finely divided state and contains no coarse free gold. It is thus in a suitable condition for treatment by cyanide.

Classifiers other than simple cones are also in use in various parts of the world, such as the Dorr classifier in North America, and their work is assisted in some mills by concentrators such as Wilfley tables. The sulphide obtained by concentration is usually rich in gold and is treated either by cyaniding or by smelting with lead ore. Formerly such material was, in many cases, ground with mercury in pans, or treated by chlorination, but these methods have been discarded.

Amalgamation depends on the property possessed by mercury of 'wetting' gold when brought in contact with it. In battery amalgamation, the crushed pulp flows in a thin stream over sloping tables covered with sheet copper, the surface of which has been amalgamated by rubbing with mercury. Particles of gold, silver, or amalgam, on coming in contact with the amalgamated surface adhere to it and so the plate becomes covered with amalgam of the precious metals. In order to increase the chances of contact between the gold and the plates, little falls or steps down of 2 or 3 inches in height are sometimes made between the upper and lower parts of the inclined tables. It has been found that the catching powers of the plate improve as amalgam of the precious metals accumulate on it, and it is accordingly usual to electroplate the copper with silver before amalgamating it or to dress it with silver-amalgam or even with gold-amalgam. The surface is kept bright and untarnished by cleaning with cyanide, and additional mercury is sprinkled on if the amalgam-surface becomes hard and dry from the accumulation of silver and gold. The excess of amalgam is brushed off at intervals and squeezed in canvas bags to separate the surplus mercury. The pasty amalgam retained by the canvas is then

retorted and the residue melted with suitable fluxes and cast into bars.

Gold will absorb about six times its weight of mercury, forming a silver-white solid amalgam containing about 13.5 p.c. of gold, but in ore treatment, time does not admit of the complete saturation of the gold with mercury, which slowly penetrates into the solid metal by diffusion. The result is that the gold-amalgam collected in cleaning-up in a gold mill consists of little 'nuggets' of gold immersed in a bath of mercury by which their outside layers are saturated. When the mixture is strained through canvas, the excess mercury passes through carrying some gold in solution and leaving behind most of the gold with its adherent mercury. If the gold is very finely divided, the penetration by mercury is more nearly complete, and the percentage of gold in the solid amalgam smaller than if the particles of gold are comparatively large. The composition of the amalgam is also affected by the extent to which other metals are present, as these also form solid amalgams with mercury and reduce the value of the product. Generally speaking, squeezed amalgam resulting from the treatment of gold ores contains from 20 to 50 p.c. of gold. It may also contain silver, copper, iron, &c., in varying proportions.

One of the difficulties in amalgamation is the 'flouring' or 'sickening' of mercury, due chiefly to the presence of arsenic or certain other impurities in the ores. The mercury is broken up into a number of excessively minute globules which have the appearance of flour, and is then swept away in the stream of ore and water and lost in the tailing. Impure mercury containing lead, zinc, &c., is easily floured, as the base metals oxidise and form a coating over the surface of the globules of mercury, thus preventing them from coalescing. The remedy is to purify the foul mercury by distillation, but in the treatment of certain ores it soon again becomes impure. The violent action of stamps on mercury when it is fed into the mortars also causes its excessive subdivision, and it is now unusual to feed mercury into the mortars, the practice being in any case permissible only with light stamps.

Another difficulty is caused by the discoloration of the copper plates, which become covered by a film of oxide or carbonate, with the result that their catching powers are impaired. The attack on the plates is generally caused by acidity of the water due to oxidation of iron sulphide, &c., in the ore. Sometimes the difficulty has been met by the addition of caustic lime to the ore in order to keep the pulp neutral or alkaline. Stains on the plates are removed by brushing with a solution of potassium cyanide. Plates which have been coated with electro-deposited silver are more easily kept in good condition than others.

The treatment of ore by passing it over amalgamated plates removes only a part of the gold, the percentage varying with the ore. In many cases from 50 to 70 p.c. of the gold can be recovered in this way, very few ores being completely 'free-milling,' i.e. yielding all their gold to mercury. Some ores are highly 'refractory,' yielding little when subjected to amalgamation, and these are treated by cyaniding or by

smelting. Concentration by flotation has also been applied successfully to gold ores and previous amalgamation is then unnecessary in some cases. The tailing is usually worth treatment by cyanide.

The cyanide process.—The tailing from amalgamation contains some finely divided gold which escapes extraction by mercury but is usually readily soluble in solutions of the cyanides of the alkali metals. The solvent action of cyanide on gold is very slow and requires the presence of an oxidising agent such as free oxygen. It may be expressed by the following equation, which represents the sum of the chemical actions:—

The potassium aurocyanide formed in this way remains dissolved in the water. The oxygen required is dissolved in the cyanide solutions from the air in contact with it. If the oxygen is exhausted owing, for example, to the cyanide solutions remaining for some time in contact with ore containing readily oxidisable sulphide or organic matter, dissolution of the gold is stopped, and it is necessary to aerate the pulp. Very dilute solutions of cyanide are used, containing from about 0.5 p.c. to as little as 0.001 p.c. of potassium cyanide.

Crushed ore or tailing is treated in large vats (containing as much as 400 tons of ore) with false bottoms provided with filter beds. Cyanide solution is run on to the ore and allowed to percolate through it. Fresh solution is added from time to time and finally the ore is washed with water. The solutions pass through the filter by which they are clarified and are conveyed to the precipitation boxes, where the gold is separated, as described later.

Some ores are not amalgamated before treatment with cyanide. In these cases, it may be advantageous to crush in cyanide solution instead of water, and the method is used at the Black Hills, Dakota, and in many other mills in America. At first the ore was crushed in stamp mills as already described, but other forms of crushers have passed into use in the last few years. Among these may be mentioned: (a) the Hardinge mill, a conical or pear-shaped mill half-filled with steel balls, working on the principle of the tube-mill; (b) the Marcy mill, a short tube-mill containing steel balls, or rods, working without screens; (c) Chilean mills, which resemble mortar mills, the crushing being effected by edge-runners rolling round a circular iron pan; (d) pairs of rolls between which the ore passes.

There are numerous modifications in the cyanide process necessitated by the conditions or introduced as improvements. Of these, the variations in mechanical treatment are the most important and complex. Difficulties in leaching crushed ore are caused by the presence of 'slime' or impalpable particles which render the ore impervious to the passage of liquids, unless it is treated in thin layers. To avoid this difficulty, the crushed ore is divided into sand and slime in 'classifiers,' by taking advantage of the difference in the rate of settlement of the particles in water. The 'sand' consists of the particles which settle readily in water. It is easily leached, liquids passing through it

under the action of gravity with great rapidity. It is sometimes separated from the excess of water contained in it ('de-watered' or 'thickened') by means of filters, and is treated by simple leaching as indicated above. The 'slime' does not readily settle in water, and cannot be leached directly except under high pressure.

The classification may be effected by merely running the stream of pulp into a large vat filled with water, when the sand settles and fills the vat and the slime is carried off in the overflow. Either the sand is cyanided where it settles or it is drained and transferred to another vat for the purpose, thus becoming well mixed and aerated. Another method of separation is by the use of 'spitzluten' or pointed troughs, in which a rising current of water carries off the slime, the heavy sand falling through the water and being discharged at the apex of the trough. Cone classifiers and other modern appliances have already been mentioned in connection with tube-mills. Various devices are in use for the even distribution of the sand in filling the treatment vats.

The treatment of slime is becoming the most important part of the cyanide process. In 'all-sliming' methods, the sand is reground until it can be included with the slime, so that no separate treatment is required. In many cases the gold is not completely laid open to attack until the ore is ground to slime and the recognition of this fact has led to a wide adoption of the all-sliming policy. The slime is treated by agitation, especially in Pachuca tanks, in which a column of pulp mixed with air rises in a large pipe placed in the tank, and overflows at the top. The gold is dissolved and the ore separated from the cyanide solution by (1) decantation, (2) filtration, or (3) counter-current decantation.

(1) In the decantation process, the slime is thickened by settlement and decantation, often with the aid of dissolved lime (by which the slime is coagulated), and is then agitated with dilute cyanide solutions and washed by decantation in conical vats. Slime is usually aerated by the passage of compressed air which is forced through perforated pipes at the bottom of the vats, thus serving to agitate the pulp at the same time. The addition of about 0.25 p.c. of oxides of manganese and iron to the slimed pulp, and the use of air-agitation on the same charge (Adair-Usher process) has been widely adopted in the Transvaal.

(2) In slime filtration, the thickened pulp is agitated with cyanide solution and filtered with the aid of a vacuum (as in the Oliver, Moore, Ridgway, and Butter's filter presses), or by direct pressure (as in the Merrill, Burt, and other filter presses). Even a thin layer of slimed ore offers great resistance to the passage of liquids, and an enormous area of filtering surface is required for operations on a large scale. This is obtained by using a number of parallel filter plates or leaves placed near together. A vacuum is formed in the narrow space between two leaves and the liquid filters into it. The slimed ore gradually forms a cake on the filter surface and is washed with clear water in that position. After being washed, the cakes of

slime are detached by blowing air through in the reverse direction or by other methods.

(3) Counter-current decantation. This is a continuous process, the slimed ore settling through a rising current of solution (or wash-water) and being withdrawn at the bottom of the vat for transference to the top of the next vat. The solution enters at the bottom of the vat and overflows at the top, so that it moves in the reverse direction to the ore through the series of vats.

The gold contained in pyrites or other sulphide is less readily soluble than ordinary free gold, owing to the absorption of oxygen by the sulphide. When the sulphide is separated as concentrate by the use of travelling-belt vanners, Wilfley tables, or other machines, this disadvantage becomes serious, and such material, as has been mentioned above, is sometimes shipped to smelting works instead of being treated by cyanidation.

Ores may also contain 'cyanicides' by which potassium cyanide is destroyed as such. Acidity of the ore due to oxidation of sulphide is not uncommon and this is corrected by washing with alkali before the cyanide solution is applied, or by crushing the ore with lime. Certain cupiferous ores destroy so much cyanide that they cannot be treated profitably by the process.

The treatment of telluride ore by cyanide presents great difficulties, as potassium cyanide acts very slowly on telluride of gold. Either the ore must be roasted in order to expel the tellurium before cyaniding, or an addition of bromocyanogen must be made to ordinary KCN. The mixture readily dissolves telluride of gold. If coarse free gold is present in the telluride ore, it is extracted by amalgamation. In Western Australia, the telluride ores, after treatment in various ways, which involve roasting the concentrate or the whole of the ore, regrounding in tube-mills, classification, agitation with cyanide, &c., are almost universally filter-pressed.

Precipitation of gold from cyanide solutions may be effected by zinc shavings contained in long boxes divided into compartments by means of partitions which force the solution to flow through the zinc upwards and downwards alternately. The zinc is coated with lead by immersing the shavings in a solution of lead acetate, in order to expedite the precipitation, especially in weak solutions. The zinc dissolves in the cyanide solution and gradually wastes away. The gold is precipitated chiefly in the form of black slime. Oxygen in the solution delays precipitation and may even reverse the action. This difficulty is overcome by the Crowe or vacuum process of de-aerifying cyanide solutions preparatory to precipitation (Morg. and Sci. Press. Aug. 23, 1919, p. 257). In 'cleaning up,' the zinc is washed free from cyanide and digested in sulphuric acid or sodium disulphate, until all action has ceased. The residue now freed from zinc is washed, filtered, dried, and fused in pots with borax, manganese dioxide, or nitre, and sodium carbonate. After casting, the bullion is separated from the slag and sold to refineries. An alternative method is to smelt the gold-zinc slime with litharge, charcoal, &c., and to cupel the base lead-bullion produced (Tavener process. In modern practice, precipitation is

often effected with zinc-dust which is agitated with the clear cyanide solution. The precipitated gold is separated by filter pressure and is smelted at once without previous acid treatment. Another method of precipitation is by means of finely ground charcoal, which is subsequently burnt, leaving the gold in the ashes. The effective agent is supposed to be carbon monoxide contained in the charcoal (Edmands, Bull. Inst. Mng. and Met. Feb. 1918).

Smelting.—Gold ores containing appreciable quantities of lead or copper are usually smelted for the production of these metals, from which the gold is subsequently extracted. Other gold ores are sometimes useful as fluxes in the smelting operations (*see* articles COPPER and LEAD).

Refining. Gold extracted from ores is usually impure and unfit for use in the arts until it has been refined. Preliminary refining or 'toughening' operations are often carried out either at the refineries or at the gold mills before the bullion is sold. Sometimes the gold is melted in crucibles with oxidising agents such as nitre, or a blast of air is directed on the surface of the molten metal or even passed through it. The base metals are oxidised and form a dross which is skimmed off with the help of bone ash, or borax is added to form a fusible slag with the oxides of the metals. In the Transvaal, the gold precipitate obtained in the cyanide process is often refined by cupellation with excess of lead (Tavener process). Toughened bullion contains little except gold, silver, and copper.

In London and on the Continent of Europe, gold bullion is usually refined by 'parting' with sulphuric acid. In this process, an alloy of gold and silver is prepared by melting gold bullion with 'doré' silver (*i.e.* silver containing small quantities of gold) or Mexican dollars or occasionally with refined silver if no other is available. The parting alloy usually contains from 20 to 30 p.c. of gold and a few p.c. of copper. If a higher proportion of gold is present, some silver remains undissolved and is retained by the gold. The copper assists the dissolution of the silver.

The alloy is granulated by being poured into water while still molten and the granulations are boiled in concentrated sulphuric acid of sp.gr. 1.85 in cast-iron kettles. The amount of acid used is four or five times the weight of the granulations, but only about half this amount is added at first. The sulphur dioxide, which is formed in large quantities, is carried away through leaden pipes. Silver sulphate is retained in solution in the hot concentrated acid, but tends to be precipitated when the acid is cooled or diluted. When the evolution of sulphur dioxide is at an end, the liquid is transferred to a settling pot, and fresh acid added. After three boilings in acid, the 'brown gold' residue is washed with boiling water, dried, melted with nitre, and cast into ingots of about 400 ozs. each in open moulds.

The acid solution of silver is poured into large lead-lined tanks containing hot water and sheet or scrap copper, and is heated by means of steam and stirred until the precipitation of the silver is complete. The silver precipitate is washed, dried, and compressed into cakes by hydraulic power before being melted. The solution is alternately concentrated by evaporation and allowed to cool, successive crops of

crystals of copper sulphate being obtained, of which the first is the purest. As an alternative the copper is removed from its solution by electrolysis. The gold produced by sulphuric acid parting is usually from 996 to 999 fine, and the precipitated silver is about 996 or 998 fine. Formerly nitric acid was used at Philadelphia as an adjunct to the sulphuric acid process before the introduction of the electrolytic process.

In the United States, in Canada, and in some refineries in London and Germany, gold is refined by electrolysis. Two processes are used successively. In the *Moebius process*, a parting alloy containing not more than 30 p.c. of gold and at least 70 p.c. of silver, copper, lead, &c., is electrolysed in a solution containing about 2 p.c. of free nitric acid and 3 p.c. of silver in the form of nitrate. Silver, copper, and some other metals are dissolved at the anodes, and silver is deposited at the cathodes which consist of rolled sheets of pure silver. The current density is 7.5 amperes per square foot of cathode surface at Philadelphia, and as much as 20 amperes per square foot at Denver. The silver is deposited in a coherent form on the cathodes with the help of a little gelatin in the electrolyte and is subsequently stripped off. The gold remains undissolved at the anodes and retains some silver. The copper, lead, zinc, &c., accumulate in the electrolyte, which is kept in condition by the addition of silver nitrate and by frequent renewal. The gold anodes are sometimes boiled in sulphuric acid, but if they contain as much as 950 parts of gold per 1000, they may be melted at once and cast into anodes for treatment by the Wohlwill process.

In the *Wohlwill process*, the anodes contain not more than 50 parts of silver per 1000 and a few parts per 1000 of base metals. By the use of a 'pulsating' current (a combination of a direct and an alternating current), it is claimed that material containing a greater proportion of silver can be treated, as the silver chloride is automatically detached from the anodes. The electrolyte contains from 2 to 10 p.c. of hydrochloric acid and from 2.5 to 6 p.c. of chloride of gold. It is heated to a temperature of 60° to 70°. The higher strengths are in use at Denver, where a high current density of 60 amperes per square foot is used. If the hydrochloric acid is insufficient in amount, or if the electrolyte is not hot enough, or if too high a current density is used, some chlorine is given off at the anodes and a corresponding amount of gold remains undissolved. The anodes are made of such thickness (4 to 12 mm.) that they can be dissolved in from 24 to 36 hours under the conditions of treatment. The cathodes consist of fine gold and the deposit on them is almost pure gold, so that copper, lead, zinc, tellurium, &c., accumulate in the solution, to which it is necessary to add gold chloride at frequent intervals. The residue at the anodes consists chiefly of silver chloride, but any platinum that may be present remains there and some gold is also left undissolved. The anode mud is boiled in sulphuric acid which converts the AgCl into Ag_2SO_4 .

The gold and silver refined by electrolysis are of high quality. They can easily be made over 999 fine and are always free from lead and other

deleterious elements which are occasionally left in small quantities in the gold refined by sulphuric acid, rendering it unfit for use in the arts.

Chlorine process. In Australia and Canada, gold is refined by the passage of a stream of chlorine gas through the molten metal, a method invented by Miller in 1867. The chlorine is conveyed through a clay pipe, which is inserted in the metal. Zinc, iron, &c., are chloridised first and are sometimes removed by a current of oxygen before chlorine is passed through. Silver is attacked last, and the end of the operation is recognised by the appearance of a characteristic 'flame,' denoting that the chlorine, which in the earlier stages is completely absorbed, has begun to pass unchanged through the metal. The fused chlorides are baled out into moulds and the refined gold stirred and cast into ingots. The chlorides, which contain from 5 to 10 p.c. of gold, are remelted and small quantities of sodium bicarbonate are added without stirring. Some silver is reduced at the surface of the charge, and falling through the chlorides carries down the gold with it. An alloy is thus produced, containing from 40 to 60 p.c. of gold, which is again passed through the refining process. The slabs of silver chloride are boiled in water to free them from the chlorides of copper, zinc, &c., and the silver is then reduced by means of iron and hydrochloric acid. The refined gold is about 996 fine. The method is inconvenient if a large proportion of silver is present in the bullion to be refined.

Properties of gold. The characteristic yellow colour of gold is made redder by the presence of copper and paler by the presence of silver. In certain proportions the effect of one of the two metals neutralises that of the other. Molten gold is green in colour, and very finely divided gold is usually of some shade of purple, as in the case of gold which has been volatilised and condensed.

Gold is the most extensible of all metals, and can be reduced by hammering to a thickness of 0.00008 mm. Its malleability and ductility are reduced by the presence of impurities, of which bismuth, lead, and tellurium have the most striking effects. Gold containing 0.25 per 1000 of bismuth is brittle. The melting-point of pure gold is 1064°, but if 0.2 p.c. of tellurium is contained in it, it softens at 432°, the melting-point of the eutectic of gold and the compound AuTe_2 . The presence of most other metals reduces the melting-point of gold, but platinum raises it and silver does not materially affect it, unless it amounts to at least 30 p.c. of the alloy. The density of cast gold is about 19.3, but that of precipitated gold is higher, varying up to 20.72.

Gold is unaffected by the air at all temperatures and can be melted and solidified without being changed. In large pieces, it is not perceptibly attacked by alkalis or by nitric, sulphuric, or hydrochloric acid, but, when finely divided, it is slightly soluble in boiling HCl and in boiling HNO_3 . It is freely soluble in *aqua regia* or other mixtures, evolving one of the halogens, and more slowly by cyanide solutions in the presence of air. Its compounds are generally formed with difficulty and decomposed very easily with the isolation of the metal.

Alloys of gold. The *gold-copper* alloys are harder, more fusible, of higher tensile strength,

and less malleable and ductile than pure gold. The metals are miscible in all proportions when molten and on solidification separate only to a slight degree. The first additions of copper to gold cause a rapid lowering of the melting-point, the minimum of 884° being reached at the alloy containing gold 82 p.c., copper 18 p.c. This alloy is somewhat brittle, breaking under the hammer with a conchoidal fracture, and is unsuitable for the manufacture of wares. The densities of the alloys when cast are as follows:—

Proportion of gold	Density
100 p.c.	19.30
91.66 „	17.35
90.0 „	17.17
75.0 „	14.74
58.3 „	12.69
25.0 „	10.03

When the alloys are rolled or hammered, the densities are higher, and the densities of gold wares, which consist of triple alloys of gold, silver, and copper, are also higher.

Gold-silver alloys are soft, malleable, and ductile and all their properties are intermediate between those of gold and silver. The colour is dominated by the silver, the alloy containing 37.5 p.c. of gold being only just distinguishable in colour from pure silver. Alloys containing not less than 65 p.c. of silver are almost completely parted by boiling nitric or sulphuric acid, the silver being dissolved and the gold left behind as a brown sponge or powder. The gold obstinately retains about 0.1 p.c. of silver, and on continued boiling in strong nitric acid, some gold is dissolved whilst the proportion of silver is reduced very slowly. The presence of copper facilitates the action of the acid but does not alter the final result.

Amalgams or alloys of gold and mercury are formed at ordinary temperatures by direct union of the two metals. Mercury dissolves 0.11 p.c. of gold at 0° and 0.126 p.c. at 100° , and gold absorbs about 6 times its weight of mercury, forming a silver-white solid alloy containing about 13.5 p.c. of gold. At 440° most of the mercury is removed by volatilisation, the residue containing about 75 p.c. of gold. At a bright red heat, almost all the remainder of the mercury is distilled off. In the alternative, the mercury can be removed by dissolving it in nitric acid. Parravano (Gazz. chim. ital. 1918, 48, ii. 123) states that gold amalgams contain at least two compounds Au_2Hg_3 and Au_3Hg (cf. Paal and Steyer, Kolloid Zeitsch. 1918, 23, 145).

Gold-iron alloys are hard but malleable and ductile. Alloys, containing between 15 and 20 p.c. of iron, are used in jewellery in France under the name *or gris*. Their colour is greyish-yellow and they melt at temperatures higher than that of pure gold. *Or bleu* contains 25 p.c. of iron. It melts at a temperature of 1160° .

Gold forms a brittle purple compound with aluminium, containing 21.5 p.c. of aluminium and having the formula $AuAl_2$ assigned to it. The compound $AuZn$, containing 25 p.c. of zinc, is of a pale lilac colour and is also brittle. There are many other intermetallic compounds containing gold, usually brittle substances of a silver-white or greyish colour. Zinc removes gold from molten lead, forming the compound $AuZn_8$, and aluminium has the same property, the compound formed being $AuAl_2$.

Uses of gold. Gold is used in the form of its alloys with copper, silver, &c., in the manufacture of coin, plate, and jewellery. Gold leaf is used for gilding by hand and potassium aurocyanide is used in gold plating baths. Gold is also used in photography (in the form of sodium chloroaurate); in dentistry (as alloys); in medicine (as the chloride); and in the manufacture of mirrors for reflecting purposes. In the form of purple of Cassius, and as leaf it is used for colouring glasses, glazes, and enamels. The aid of a flux is employed in its application in glazing and a mixture of the composition 30 parts precipitated gold, 15 of black mercurous oxide, 2.5 of basic bismuth nitrate, and 0.3 of melted borax is recommended. The addition of 3 parts of silver carbonate produces a greenish tint. After firing the gold has a matt surface and must be polished with bloodstone or agate. A cheaper process, which does not require polishing after firing, is in the use of 'Glanz gold' or 'Meissen gold,' a preparation of gold solution with an organic medium such as turpentine, lavender oil, and a balsam or resin. Gold lace consists of excessively fine strips of gold twined round silk and contains about 2.5 p.c. of gold by weight.

Manufacture of coin.—The standards of fineness of 916.6 (British Empire, Turkey, and Portugal), and 900 (most other countries) are used generally for current coin, the exception being Egypt where the standard is 875. The alloy is principally copper, but small quantities of silver are present in most coins, the proportion being higher in old ones. Fine gold was used for coinage for a time in Ancient Greece and also in Rome, under the Republic, but copper was afterwards added to reduce the cost. Fine gold is still used for some medals. It is now universally admitted that the alloy with copper is better than pure gold for coinage, owing to its lower melting-point, which is advantageous in the manufacture, and its greater hardness, which enables it to resist defacement better and perhaps to be less readily abraded. The only disadvantages of the alloy with copper are that it blackens when heated and is made brittle by the presence of a minute proportion of lead or tellurium. Fine gold is not affected until the proportion of lead is five or six times as high (0.15 p.c. as against 0.025 p.c.).

In the manufacture of coin, refined gold is melted with copper in graphite crucibles and cast into bars in upright (closed) iron moulds. Charges of about 2500 ozs. are used at the Royal Mint and the fuel is ordinary illuminating gas with a blast of air. Naphtha gas or oil are in use at some other mints, but solid fuel has now been discarded generally. The loss of gold in melting is about 0.2 per 1000, about half of which is volatilised and can be recovered by the use of suitable condensing chambers. The remainder is in the 'mint sweep.'

After being assayed, the gold bars are rolled down, blanks or discs are cut out by punches, and the blanks annealed in gas furnaces, air being excluded. The blank is placed in a collar and struck between dies by means of a lever press. A single blow suffices for the production of each coin, the design on each side being impressed simultaneously, while the metal is forced laterally by the pressure into the corrugations

of the collar. Finally, the coins are weighed singly on automatic balances which reject those outside the limits of weight allowed by law.

Gold wares.—The alloys used in the manufacture of gold wares consist of gold, silver, and copper. The wares are usually made from rolled plates which are cut out by punches and struck between dies. The pieces are fitted together by hand, usually by means of soldering. Solders generally contain less gold than the parts which have to be joined together. Decorative work is carried out by hand-hammering, engraving, chasing, &c. The wares are 'coloured' or pickled by a process which removes the silver and copper from the surface and leaves a coating of pure gold, afterwards burnished. In pickling, the wares are heated to redness in air and the blackened surface is removed by boiling in dilute sulphuric or nitric acid, after which the colour is improved by immersion in hot mixtures of nitre, common salt, alum, &c. The standards of gold wares authorised by law in the United Kingdom are 22-carat (*i.e.* containing 22 parts of gold out of 24) 18-, 15-, 12-, and 9-carat. Other standards are in use abroad.

Imitation gold wares sometimes consist of alloys of copper with aluminium, zinc, &c., and sometimes of a thin plate of gold laid on a bar of base metal and rolled out for use in manufacture. Electro-plating is carried out in baths containing potassium aurocyanide with anodes of pure gold. The bath is used hot and the anode is of about the same dimensions as the article to be gilded. Gold chloride is added to the bath, as required, to keep it at the strength of about one ounce of gold to the gallon (6·85 g. of gold per litre). In Japanese art, alloys of copper containing a small proportion of gold are used to enable a beautiful purple patina to be produced on the surface. The alloys are known as *Shakudo* and *Shibuichi*.

Gold leaf contains from 90 to 98 p.c. of gold, the rest being silver and copper. The metal is cast into little flat bars which are rolled out with frequent annealings until about 0·33 mm. thick. The strip of gold is then cut into pieces of 1 inch square and these are interleaved with vellum and beaten with a 16-lb. hammer to 4 inches square. They are again cut up and beaten out between gold-beaters' skins. The book of 25 leaves, each about $3\frac{1}{4}$ inches (8·25 cm.) square, contains from 4 to 10 grains (0·26 to 0·65 gram) of gold. The leaves are from 0·00008 to 0·0002 mm. thick.

Production of gold.—The annual production of gold, after remaining nearly stationary at 5,000,000 or 6,000,000 ozs. for many years, began to rise rapidly in 1891 and amounted to 22,850,000 ozs. of the value of 97,100,000*l.* in 1915. It is now declining, partly owing to the exhaustion of some of the mines, and partly owing to the rise in prices which has made the working of the poorer mines unprofitable. Many countries contribute to the output, and of these the Transvaal, United States, Australia, Mexico, Rhodesia, India, and Canada between them are responsible for 90 p.c. of the world's production. The British Empire produces over 60 p.c. of the total amount. The world's stock of gold is estimated at 1,800,000,000*l.*

Bibliography.—A full bibliography of gold is appended to the *Metallurgy of Gold*, by T. K.

Rose, 6th edit., London, 1915. The following are among the most important treatises on the metallurgy of gold published of late years: *The Stamp Milling of Gold Ores*, by T. A. Rickard, New York and London, 3rd ed., 1901; *Ore Dressing*, by R. H. Richards, New York, 1903; *Cyaniding Gold and Silver Ores*, by H. F. Julian and E. Smart, London, 1904; *Gold Dredging*, by C. C. Longridge, London, 1905; *Rand Metallurgical Practice*. T. K. R.

COMPOUNDS OF GOLD.

Two oxides are known, the monoxide or suboxide Au_2O , and the sesquioxide or peroxide Au_2O_3 (Bullheimer, *Chem. Zentr.* 1897, i. 522; Vanino, *Ber.* 1905, 38, 462). Auroauric oxide (AuO)_n is formed by the partial decomposition of auric hydroxide at 160°.

The *hydroxide* $Au(OH)_3$ is best prepared by heating a solution of gold chloride with magnesia, and washing the residue with nitric acid. It may be obtained pure by reducing potassium auribromide, $KAuBr_4$, with sulphurous acid, and then warming with dilute potassium hydroxide.

It possesses a yellow, olive-green, or brown colour (according to the method of preparation) while damp, and becomes brownish or black on drying. When warmed with alcoholic potash, metallic gold is precipitated in minute scales, used in *miniature painting*.

The hydroxide is soluble in potash, with formation of a very unstable *potassium aurate*. The solution may be used in electrogilding.

The alkali earth aurates have also been obtained. They are stable when dry, but decompose readily in solution under the influence of heat or light. With organic matter they yield explosive powders (Meyer, *l.c.*). When a sheet of gold is used as a positive electrode in sulphuric or nitric acid, a reddish-brown explosive powder, probably a hydroxide of gold, is formed (Hampe, *Chem. Zeit.* 14, 1778).

When acted upon by ammonia, the oxide produces a green or brown *fulminate* allied to that of silver. The fulminate may be obtained as a buff-coloured precipitate, containing some ammoniacal subchloride of gold, on addition of ammonia to gold chloride solution. For a description of the explosive nitrogenous compounds of gold obtained from auric hydroxide and the salts of gold by the action of ammonia or ammonium carbonate, see Weitz (Annalen, 1915, 410, 117).

Aurous sulphide Au_2S is formed when sulphuretted hydrogen is passed into an acidified solution of gold cyanide or chloride. It is a brown powder, soluble in water when moist, and forms double salts with potassium and sodium sulphites (Ditte, *Compt. rend.* 1895, 120, 320; Antony and Lucchesi, *Gazz. chim. ital.* 1896, 26, ii. 350).

Auroauric sulphide Au_2S_2 is formed by passing sulphuretted hydrogen into a cold neutral solution of gold chloride (Antony and Lucchesi, *Gazz. chim. ital.* 1889, 19, 545; 1891, 21, ii. 209; Christy, *J. Soc. Chem. Ind.* 1897, 332).

Auric sulphide Au_2S_3 is obtained as a deep yellow precipitate, by treating anhydrous lithium aurichloride with sulphuretted hydrogen at -10° (Antony and Lucchesi, *Gazz. chim. ital.*

1890, 20, 601, and *l.c.*). It is a graphitic amorphous powder, sp.gr. 8.754 and decomposes at 197°–200° into its elements. Caustic alkalis and hydro- and poly- sulphides of ammonia decompose it with deposition of metallic gold. The three sulphides form colloidal solutions in alcohol.

When finely divided gold is heated with sulphur and potassium carbonate, a double sulphide of potassium and gold, which resists a red heat and is soluble in water, is obtained. It is employed for the production of *Burgos lustre* in gilding china.

Various gold sodium, potassium, and ammonium sulphites and thiosulphites have been obtained (Antony and Lucchesi, *l.c.*). The sulphites, $K_2[Au(SO_3)_4] \cdot 5H_2O$; $Na_2[Au(SO_3)_4] \cdot 14H_2O$; $Au_3(SO_3)_2 \cdot 4NH_3 \cdot 4H_2O$; and

are described by Pritze (Zeitsch. anorg. Chem. 1908, 59, 198), whilst the compound $AuS_2 \cdot NH_4$ has been prepared by Hofmann and Höchtlen (Ber. 1903, 36, 3090; 1904, 37, 245).

Thiosulphate of gold and sodium

crystallises in colourless needles, freely soluble in water. It is formed by the action of sodium thiosulphate on gold chloride. This salt exists in combined fixing and toning photographic baths.

Aurous chloride $AuCl$ is formed by heating the trichloride at 170°–180°. It is a yellowish powder, sp.gr. 7.4, which combines with chlorine at ordinary temperature forming auric chloride and decomposes into its elements at about 185° (Rose, Chem. Soc. Trans. 1895, 891, 905; Campbell, Trans. Faraday Soc. 1907, 3, 103). It is insoluble in water, but decomposed by it with the formation of auric chloride and metallic gold. It dissolves in a solution of potassium bromide forming metallic gold and potassium aurichloride and bromide (Lengfeld, Amer. Chem. J. 1901, 26, 324). Liquid ammonia reacts on aurous chloride forming $AuCl \cdot 12NH_3$, which loses ammonia on warming and yields $AuCl \cdot 3NH_3$, which when heated to 180° is decomposed with formation of ammonium chloride and gold (Meyer, Compt. rend. 1906, 143, 280).

Auric chloride or **trichloride** $AuCl_3$ is prepared by dissolving gold in *aqua regia* and evaporating the solution to dryness at a temperature below 120°, the hydrochloric acid being always kept in excess over the nitric acid

The residue is dissolved in water and filtered from the aurous chloride which is always produced, and the solution is evaporated on the water-bath. Large orange-coloured efflorescent crystals of the hydrated chloride $AuCl_3 \cdot 2H_2O$ are thus produced.

According to Thomsen, the chloride is best prepared as follows. Powdered gold is converted by the action of chlorine into the dark red crystalline dichloride, and a little water is added to convert it into a mixture of mono- and trichlorides. The mass is heated gently to decompose the former, and the residue is dissolved in water, filtered from the reduced metal, evaporated and heated to 150°, with production of a brown crystalline mass of the anhydrous

chloride. The chloride is also formed when gold is treated with fuming hydrochloric acid in the presence of a trace of manganous chloride and the mixture is exposed to light (Berthelot, Compt. rend. 1904, 138, 1297).

If gold is treated with liquid chlorine in a sealed tube at the ordinary temperature, the metal is converted into a crystalline red mass, but when heated at 100°, the gold dissolves entirely, forming a deep yellow solution from which, on cooling, auric chloride separates in wine-red hygroscopic crystals.

Between 170° and 240° auric chloride dissociates into aurous chloride and chlorine (Meyer, Compt. rend. 1901, 133, 815; Rose, *l.c.*).

Under the influence of heat or light, auric chloride is decomposed in solution, thus:

and $3AuCl = 2Au + AuCl_3$ (Sonstadt, Chem. News, 1898, 77, 74; Chem. Soc. Proc. 1898, 179; Löwe, Dingl. poly. J. 279, 167). Manganous and uranous sulphate and also manganous chloride reduce gold chloride in the dark, precipitating metallic gold. The process is accelerated in the former case by heat, in the two latter by sunlight (Oechsner de Coninck, Bull. Acad. Roy. Belg, 1902, 316).

Gold chloride is also reduced by charcoal thus:

(Avory, J. Soc. Chem. Ind. 1908, 255; Hay and Tennent, Amer. Chem. J. 1909, 31, 461); by acetylene (Mathews and Watters, J. Amer. Chem. Soc. 1900, 22, 108); and by sulphuretted hydrogen under certain conditions (Schneider, Ber. 1891, 24, 2241; Antony and Lucchesi, Gazz. chim. ital. 1889, 19, 545).

When heated to 200°, the trichloride is resolved into a mixture of aurous chloride and gold. At a higher temperature the whole of the chlorine is given off.

Auric chloride is freely soluble in water, alcohol, and ether. It forms a crystalline compound, $AuCl_3 \cdot HCl \cdot 4H_2O$, with hydrochloric acid, and forms double chlorides with the alkali metals and with organic bases (Lainer, Monatsh. 11, 220). Auric chloride combines with silver chloride in presence of ammonium chloride to form a purplish-brown salt, in orthorhombic crystals, $3AgCl \cdot 4AuCl_3 \cdot 8NH_4Cl$, readily decomposed by water with the formation of chloroauric acid and silver chloride (Pollard, Chem. Soc. Trans. 1920, 99).

Auric chloride and the sodium and potassium salts, such as $NaCl \cdot AuCl_3 \cdot 2H_2O$, are employed for toning silver prints in photography (Kebler, J. Franklin Inst. 1900, 150, 235; Johnson, J. Soc. Chem. Ind. 1901, 210). The other alkali double chlorides are described by Wells and Wheeler (Amer. J. Sci. [3] 44, 157).

Gold chloride forms salts with pyridine, such as $C_5H_5N \cdot AuCl_3$, $(C_5H_5N)_2 \cdot AuCl_3$ (François, Compt. rend. 1903, 136, 1557). Auroposphorous chloride $(AuPCl_2)_3$ and complex organic compounds of phosphorus and gold chloride are described by Levi Malvano (Atti R. Accad. Lincei, 1908, [v.] 17, i. 847). The acetates and succinates are used in photography (Mercier, Brit. Journ. Phot. 39, 354).

Chloroauric acid $AuCl_3 \cdot HCl$, prepared by the action of chlorine on gold suspended in hydrochloric acid (Lengfeld, Amer. Chem. J. 1901,

26, 324), reacts with silver nitrate, forming a brown precipitate, $\text{Au}(\text{OH})_3 \cdot 4\text{AgCl}$, which, with ammonia, forms gold fulminate, $\text{Au}(\text{OH})_2\text{NH}_2$ or $\text{AuN}_2\text{H}_2\text{O} + \text{H}_2\text{O}$. Gold fulminate is very explosive when dry, and when heated with potash forms a flocculent brownish-black product, probably $\text{Au}(\text{HO})_2 \cdot \text{NH} \cdot \text{Au}(\text{OH})_2$, which is still more explosive (Jacobson, *Compt. rend.* 1908, 146, 1213; cf. Weitz, *Annalen*, 1915, 410, 117). Chloroauric acid forms salts such as KAuBr_4 , &c. (Lengfeld, *l.c.*).

By the action of aurochloric acid on sodium azoimide an orange crystalline very explosive compound is obtained (Curtius and Rissom, *J. pr. Chem.* 1898, [ii.] 58, 261).

Chloroauric acid gives a bright yellow colour with a hydrochloric acid solution of *o*-tolidine. This solution, which forms a delicate colour test for the presence of free chlorine in water, has been shown by Pollard (*Analyst*, 1919, 94) to form a delicate test for the presence of gold; 1 part of gold in 20 million parts of water can thus be detected in a depth of 10 cms. of liquid.

Aurous bromide AuBr is a greenish-yellow powder, which is formed by heating auribromic acid at 115° . Its properties are very similar to those of the corresponding chloride (Meyer, *l.c.*).

Auric bromide AuBr_3 is formed by the action of dry bromine on powdered gold; when heated it dissociates forming the monobromide (Meyer, *Compt. rend.* 1909, 148, 346). According to Lengfeld (*l.c.*), aurous bromoaurate Au_2Br_4 also exists. Bromoauric acid and bromoaurates have also been prepared.

Aurous iodide can be prepared by the action of excess of pure iodine on metallic gold above 50° , the excess of iodine being then removed by careful sublimation (Meyer, *Compt. rend.* 1904, 139, 733). It is also formed by the action of hydriodic acid on gold oxide. It is a white powder, turning green in air and decomposing at 190° ; it is also decomposed by solvents such as chloroform. With liquid or gaseous ammonia, it forms AuI_6NH_3 and AuI_3NH_3 (Meyer, *ibid.* 1906, 143, 280). Auric iodide probably does not exist.

Gold fluoride has been described by Lenher (*J. Amer. Chem. Soc.* 1903, 25, 1136).

Gold chromate can be obtained by treating silver chromate with auric chloride; $\text{Au}_2(\text{CrO}_4)_3$ is obtained in solution, whilst the chromate $\text{Au}_2(\text{CrO}_4)_3\text{CrO}_3$ crystallises from the mother liquor (Orloff, *Chem. Zeit.* 1907, 31, 1182).

When solutions of sodium aurate and chromate are mixed, sodium aurochromate containing excess of chromate is obtained, the solution of which forms an excellent toning bath, giving purple-bluish tones. It is neutral and can be kept, and the yellow colour allows the toning to be done in daylight (Mercier, *Chem. Zeit. Rep.* 24, 272; *J. Soc. Chem. Ind.* 1900, 1038).

Gold carbide. Au_2C_2 is formed by passing acetylene into aurous thiosulphate. It is very explosive when dry and is decomposed by hydrochloric acid, forming acetylene and aurous chloride. Treated with water it yields gold and carbon (Mathews and Watters, *l.c.*).

The following gold salts have also been obtained: arsenates (Stavenhagen, *J. pr. Chem.* 1895, [2] 51, 1); selenates and tellurates (Lenher, *J. Amer. Chem. Soc.* 1902, 24, 354, 355, 918);

various alkyl gold chlorides (Pope and Gibson, *Chem. Soc. Trans.* 1907, 2061); thiocarbamides (Moir, *ibid.* 1906, 1345); mercaptides (Herrmann, *Ber.* 1905, 38, 2813), and other complex organic compounds (Dunstan and Shephard, *Chem. Soc. Proc.* 1893, 212; Weigand, *Zeitsch. angew. Chem.* 1906, 19, 139; Averkieff, *J. Russ. Phys. Chem. Soc.* 1908, 40, 840).

The thio-compounds of certain resins and ethereal or fatty oils or thioacids, yield compounds with gold which are soluble in most organic solvents and which can be employed in the ceramic enamel and glass industries for the deposition of the finest layers of bright metal on various substances (Pertsch, *Frdl.* 1894-97, 1324).

According to Odenheimer (*J. Soc. Chem. Ind.* 1892, 600), textile fabrics padded or printed with a gold salt and then treated with a reducing agent assume a beautiful grey colour, the process being accelerated by heat or sunlight. The shade depends on the nature of the reducing agents employed and on the strength of the gold solution. When these grey fabrics are subjected to heat between rollers, red, purple, or pink colours are obtained, depending on the original shade of grey. The high price of gold is no disadvantage in this process as only a very minute quantity of gold solution is required. Thus, for a beautiful pearl-grey on half silk, the cost is only $\frac{3}{4}d.$ per lb. of material dyed.

Gold cyanides (see ELECTROPLATING and CYANIDES).

GOLD, MANNHEIM. A brass containing 80 p.c. of copper and 20 p.c. of zinc.

GOLD, MOSAIC. A fine, flaky yellow form of tin disulphide; is used in the arts to imitate bronze under this title, and is preferably prepared as follows. A mixture of 7 parts of sulphur, 6 parts of ammonium chloride, and 18 parts of a powdered amalgam containing 2 parts of tin to 1 part of mercury, is heated gently until the smell of sulphuretted hydrogen is no longer perceptible. The heat is then raised to low redness, and a mixture of mercurous chloride, ammonium chloride, and cinnabar sublimes, while the mosaic gold alone remains. A fine product is also obtained by heating a mixture of 5 parts of stannous sulphide and 8 parts of mercuric chloride.

The essential point is that tin must be present in a volatile form; stannous chloride itself may be used.

A pale-yellow mosaic gold is produced by heating 50 parts crystalline stannous chloride with 25 parts flowers of sulphur; a reddish-yellow product is obtained on heating together 50 parts 50 p.c. tin-amalgam, 25 parts stannous chloride, 35 parts ammonium chloride and 35 parts of sulphur. 57 p.c. of the tin taken is obtained as the sulphide (Lagutt, *Zeitsch. angew. Chem.* 1897, 557).

The temperature should not be too high, as the stannic sulphide, when strongly heated, loses one equivalent of sulphur and becomes black.

Mosaic gold is insoluble in nitric and hydrochloric acids, but dissolves in *aqua regia* and in alkaline hydroxides.

A brass, introduced by Hamilton and Parker (*Edinb. J. of Sc.* 1826), and containing 52 to 55 p.c. of zinc, is also known by this name. A

mixture of equal parts of zinc and copper is fused at the lowest possible temperature, and zinc is slowly added, with constant stirring, until the desired colour is produced. The colour passes from a brassy yellow to a purple or violet, and finally becomes perfectly white. The mass, when cooled, has the colour of gold, and is said to be not liable to tarnish.

GOLD, ORANGE, v. AZO-COLOURING MATTERS.

GOLD PURPLE (*Purple of Cassius*). This compound is obtained as a fine, flocculent purple precipitate on addition of a solution of stannous chloride containing stannic chloride, to a dilute neutral solution of gold chloride. The presence of the stannic chloride is essential, as pure stannous chloride produces only a brown precipitate.

A very fine product is obtained by adding stannous chloride to ferric chloride until the solution is of a pale green colour, and employing the mixture to precipitate the gold solution. According to another process, 1 part of tin is dissolved in the minimum of hydrochloric acid, and 2 parts of the tin are dissolved in a cold mixture of 3 parts of nitric acid and 1 part of hydrochloric acid, the solution being finally heated to ensure conversion of all the tin into stannic chloride. A solution of 7 parts of gold in a mixture of 6 parts of hydrochloric acid and 1 part of nitric acid is diluted with 3,500 parts of water, and the solution of the stannic chloride is added, the stannous chloride being then added in drops until the required colour (from violet to purple or brown) is obtained (Baisson).

According to Pelletier, a purple of Cassius of constant composition is obtained as follows. A solution of as much gold chloride as contains 20 grains of gold is diluted to 700 or 800 c.c., and tin filings are introduced. The liquid speedily becomes brown and turbid, and finally deposits the purple, which is washed and dried. It is said to contain 32.75 p.c. of stannic oxide, 14.62 p.c. of stannous oxide, 44.77 p.c. of aurous oxide, and 7.86 p.c. of water.

Purple of Cassius may also be obtained in great beauty by treating an alloy of gold 2 parts, tin 3.5 parts, and silver 15 parts, with nitric acid to remove the silver and oxidise the tin.

Zsigmondy (Annalen, 301, 361) prepares purple of Cassius by mixing 200 c.c. of gold chloride (3 grams Au per litre) with 250 c.c. stannous chloride (3 grams Sn per litre) and 4 litres of water. After 3 days, the purple is deposited, leaving a liquid free from gold and tin. The precipitate thus prepared contains, after ignition, 40.3 p.c. gold and 59.7 p.c. stannic oxides.

According to Moissan (Compt. rend. 1905, 141, 977), when gold-tin alloys are distilled in air, a finely divided mixture of stannic oxide, lime, and gold is obtained, having the colour and properties of purple of Cassius. Similar deposits of varying tint can be obtained by substituting for lime other oxides such as zirconia, silica, magnesia, or alumina.

Schneider (Zeitsch. anorg. Chem. 1893, 5, 80) obtained an aqueous solution of gold purple by treating an alloy of gold, tin, and silver with concentrated nitric acid. When the resulting black powder is washed with ammonia, a ruby-red coloured solution is obtained, which is dialysed until it contains no more ammonia.

It contains 0.5800 gram of gold and 5.4048 grams of stannic oxide per litre.

Potassium cyanide decolorises the solution and stannic acid separates. With mercury, the solution becomes brownish-red and gold is extracted; whilst with excess of hydrochloric acid, the solution becomes violet and yields finely divided gold on dialysis. According to this author, the soluble form of purple gold is, possibly, a mixture of the hydrosols of gold and stannic acid.

This body, which is used in the manufacture of artificial gems (*v. GEMS, IMITATION AND COUNTERFEIT*), and for imparting a red, rose, or pink colour to porcelain or enamel, varies in colour from a violet to a purplish-red or brown. The dry precipitate is insoluble in strong or dilute alkalis, but when moist the purple dissolves in water in the presence of very small quantities of acids and alkalis. Salts and excess of alkalis and acids precipitate the purple from these solutions.

While moist, it is also soluble in ammonia with production of a purple colour, from which the precipitate is redeposited on addition of an acid or on boiling, and, in the latter case, is not again soluble. The ammoniacal solution precipitates gold on exposure to light. The purple does not pass through the membrane of a dialyser.

When dried and triturated, the purple of Cassius acquires a metallic lustre. No gold is removed from it by the action of mercury. It retains water at 100°, but gives it up and acquires a brick-red colour when ignited, and loses its colour at the melting-point of gold, but without evolution of oxygen.

On adding a greater quantity of mercurous chloride to a solution of auric chloride than that required for the reaction

the characteristic colour of purple of Cassius is obtained. If barium sulphate suspended in water is previously mixed with the mercurous chloride, the sulphate takes up the gold and becomes the colour of the purple. Antony and Lucchesi (Gazz. chim. ital. 1896, ii. 195) therefore regard true purple of Cassius as being, not a compound, but merely stannic acid mechanically covered with gold.

The constitution of this substance, of which the composition, as found by analysis, is very variable, is not yet established. Berzelius, judging from the researches of Figuier, considered it to be a hydrated stannate of gold and tin. Macquer looked upon it as a mixture of stannic hydroxide and metallic gold; and Proust considered it to be a mixture of aurostannous stannate and stannic hydroxide.

Zsigmondy regards the purple as a mixture of colloidal gold and colloidal stannic acid; the gold acquiring the property of dissolving in very dilute acids through the presence of the stannic acid which is soluble in them. A mixture of colloids may thus behave as a chemical individual where the properties of one of the constituents may be completely hidden.

Debray (Compt. rend. 75, 1025), and also Moissan (*l.c.*), look upon it as allied to the *lakes*, and as consisting of gold combined with stannic acid, in the same way as the colouring matter of the lake is combined with alumina, the gold

being insoluble in mercury, as the colouring matter is insoluble in water. Debray has prepared the purple by boiling freshly precipitated stannic hydroxide with a mixture of gold chloride and potassium oxalate. The action of ammonia on the purple is similar to its action on stannic hydroxide, both being soluble while moist, but becoming insoluble when anhydrous.

The fact that the ammoniacal solution precipitates gold is in favour of the view that the gold is present in the metallic state, as ammonia is not known to precipitate precious metals by action on their oxides.

Debray has also produced a purple by replacing the stannic hydroxide by alumina.

Müller (J. pr. Chem. [ii.] 30, 252) has prepared purples by several processes without the use of tin. A pale rose (containing 0.1 p.c. of gold) to deep carmine pigment is produced by igniting a well washed and dried mixture of magnesium oxide and gold chloride. A similar result is obtained by heating the mixture in a current of hydrogen.

Lime, calcium carbonate, calcium phosphate, barium sulphate, and lead and zinc oxides give similar but less satisfactory results.

The most intense purple is, however, obtained by reducing a mixture of aluminium hydroxide and gold chloride with alkaline grape-sugar solution. The mixture is agitated and heated until of a bright scarlet colour, but the colour must not be allowed to reach a purplish red, or the resultant product will be of inferior brilliancy.

Similar but less brilliant purples than those with magnesia and alumina are obtained with tin. As much stannous chloride as corresponds with 9 grams of stannic oxide, is dissolved in 200 c.c. of water, and the solution is rendered alkaline by addition of potassium carbonate. Grape sugar solution is added, and the mixture is diluted to 300 litres, and is warmed until of the best colour.

These methods of preparation uphold the view that the gold is present in the metallic state.

Red, blue, violet, and green colloidal solutions of gold can be readily prepared. Colloidal solutions of gold can be formed by the addition of gold chloride solution to water, containing small quantities of the following substances: turpentine oil, pinene, rosemary oil, or potassium carbonate with formaldehyde, pinene, turpentine oil, or alcohol. The formation of the colloidal solution can be accelerated by adding to the gold chloride solution a few drops of gold solution already in the colloidal state. The colour of the solutions depends on the temperature and the concentration (Vanino and Hartl, Ber. 1905, 38, 463; 1906, 39, 1696; Zsigmondy, Zeitsch. physikal. Chem. 1906, 56, 65; Henrich, Ber. 1903, 36, 609; Garbowski, *ibid.* 1215). Colloidal gold can also be precipitated by the action of formaldehyde or acetaldehyde on gold chloride in the presence of sodium hydroxide (Zsigmondy, Annalen, 1898, 301, 29; Zeitsch. Chem. Ind. Kolloide, 1907, i. 272) or potassium carbonate (Thomas, J. pr. Chem. 1909, 80, 518).

Carey Lea (Zeitsch. anorg. Chem. 1897, 13, 447) obtained a beautiful green solution by mixing a 10 p.c. sodium hyposulphite solution with 1 c.c. of gold chloride solution (10 c.c. = 1 gram gold) and a drop of sulphuric acid. As

soon as the solution begins to darken, 30 c.c. of water are added. Gradually, a bluish-black precipitate of metallic gold separates; after filtration, the green solution again becomes turbid. If the solution is shaken and allowed to remain, a precipitate of gold is deposited on the sides of the vessel, which is yellowish brown by reflected light and bright blue by transmitted light.

Humic acid, added to gold chloride, produces colloidal gold solutions of various colours, depending on the conditions of the experiment (Ehrenberg and Pick, Zeitsch. chem. Ind. Kolloide, 1909, 5, 30).

When 1 litre of water containing 1 gram of auric chloride and made just alkaline with sodium carbonate, is boiled, and then poured into 300 c.c. of a cold solution of catechol (pyrocatechin) containing 11 grams per litre, a red coloration is produced, rapidly turning to violet. On mixing 10 such preparations and just acidifying with sulphuric acid, the liquid becomes blue and deposits a blue powder which is washed with water, then with alcohol, is dissolved in ammonia and can be reprecipitated by sulphuric acid. The substance manifests acid properties, forming salts with some of the heavy metals (Henriot, Compt. rend. 1904, 138, 1044).

A stable solution of colloidal gold of therapeutic value is obtained by reducing with atoxyl (*p*-aminophenylarsinate) a gold chloride solution made faintly alkaline with sodium hydrogen carbonate. Similar solutions are also obtained by reduction with sodium sulphanilate or naphthionate. When evaporated to dryness in a vacuum, a grey residue is obtained which dissolves completely in water, forming a characteristic ruby-red solution of colloidal gold (Poulenc Frères, D. R. P. 206343).

Red to purple colloidal solutions may be obtained by passing carbon monoxide, pure, or mixed with carbon dioxide, through a solution of auric chloride in conductivity water, containing 0.002-0.05 p.c. gold (Donau, Monatsh. 1905, 26, 525). Similar solutions have also been obtained by reducing very dilute solutions of gold chloride with phenylhydrazine hydrochloride (Gutbier and Resenschek, Zeitsch. anorg. Chem. 1904, 39, 112), hydrazine hydrate (Gutbier, *ibid.* 1902, 31, 448), hydroxylamine hydrochloride (*ibid.* 1902, 32, 347), or with sodium lysalbate or protalbate (Paal, Ber. 1902, 35, 2236), quinol, gallotannic acid, *p*-oxyphenylaminoacetic acid, 1:2:4-diaminophenol and other photographic developers. Some of these colorations are so intense that they may be used as delicate tests for gold (Saul, Analyst, 1913, 54); also by the action of *Aspergillus oryzae* on 0.01 gram gold chloride in 100 c.c. water (Vanino and Hartl, *ibid.* 1904, 37, 3620). An electric discharge between gold poles also gives reddish-purple or dark blue solutions, which can be filtered without change and retain their colour for months (Bredig, Zeitsch. angew. Chem. 1898, 951; Bredig and Reinders, Zeitsch. physikal. Chem. 1901, 37, 323). Various other methods of preparing colloidal gold solutions and precipitates have been proposed (Schottländer, Chem. Zentr. 1894, ii. 409; Brunck, Annalen, 1903, 327, 240; Donau, Monatsh. 1904, 25, 545; Whitney and Blake, J. Amer. Chem. Soc. 1904, 26, 1339; .

Vanino and Hartl, Chem. Zentr. 1907, i. 1099; Vanino, *ibid.* 1908, i. 446; Dauvé, J. Pharm. Chim. 1909, 29, 241; Doerinckel, Zeitsch. anorg. Chem. 1909, 63, 344; Hartwagner, Kolloid. Zeitsch. 1915, 16, 79; Zsigmondy, Elektrochem. 1916, 22, 102).

Gold chloride solution, with water glass and formalin heated on the water-bath gives, according to quantity, bright red, claret-red, blue, or even green colloidal solutions. Very small amounts of gold gave a rose-red coloration (Kuspert, Ber. 1902, 35, 4070).

According to Stenberg (Ann. Physik. 1908, [iv.] 26, 329), the various colours of colloidal gold solutions are due to the difference in form of the particles. Distinct forms of particles exist for the red and blue solutions; the violet colour is produced by a mixture of these, whilst green solutions are due to the condensation of the particles which give rise to the red and blue colour.

The liquid hydrosols of gold are decolorised when shaken with animal charcoal, barium sulphate, powdered porcelain, amorphous silica, fibres of filter paper or with electrolytes, but if gum arabic or gelatin is present, this reaction is prevented or diminished (Donau, Monatsh. 1905, 26, 525). An electric current in the presence of various electrolytes changes the red colloidal solutions into blue (Blake, Amer. J. Sci. 1903, [iv.] 16, 433).

Silk and cotton fibres treated with tannin or stannous chloride and pyrogallol, are coloured red and blue respectively, on addition of gold chloride. This colour is destroyed by concentrated acids, free halogens, and reducing agents, but not by dilute acids or alkalis.

GOLD, YELLOW. *v.* VICTORIA YELLOW.

GOLDEN YELLOW *v.* NAPHTHALENE.

GOMAINÉ. Trade name for a solution of iodoforn and camphor in sesamé oil.

GOMART RESIN *v.* OLEO-RESINS.

GOOSEBERRY. The fruit of *Ribes grossularia* (Linn.). There are many varieties, differing in shape, size, texture, and colour.

They are largely used, both immature and ripe, in cookery, as raw fruit and in jam making. The average composition, deduced from 34 analyses, is given by König as follows:—

Free Invert Saccha- Other carbo-						
Water	Protein	acid	sugar	rose	hydrates	Fibre Ash
83.6	0.5	1.4	7.1	0.9	0.6	3.5 0.4

The acidity is chiefly due to malic acid.

H. I.

GORNEROL. Trade name for an essential oil prepared from the leaves of *Melaleuca leucadendron* (Linn.) (Nat. Ord. *Myrtaceæ*) of New Caledonia, similar to, if not identical with, oil of Cajuput (*q.v.* under art. OILS, ESSENTIAL). Known also as Niaoul oil.

GORSE, called also **FURZE** and **WHIN.** *Ulex europæus* (Linn.). A plant belonging to the *leguminosæ*, and therefore capable, by the aid of symbiotic bacteria, of fixing atmospheric nitrogen.

It will grow in soils poor in mineral matter, and has been strongly recommended as a fodder plant, for littering, and as a green manure. It is estimated that a crop of 20,000 kilos. per hectare may be obtained, and that this, in feeding value, is equal to 8000 kilos. of hay.

Average composition, according to Girard (Ann. Agron. 1901, 27, 5):

Water	Protein	Fat	N-free extract	Cellulose	Ash
52.7	4.6	0.9	26.0	14.5	1.6

The N-free extract includes about 1.4 p.c. sugar, 9 p.c. pentosans, and 1.6 p.c. pectin.

The ash contains:

K ₂ O	CaO	MgO	Fe ₂ O ₃	P ₂ O ₅	SO ₃
27.1	11.7	4.3	2.4	6.7	4.7

With horses the digestion coefficients obtained were as follows: Ash 40, fat 22, protein 56, cellulose 43, sugar 100, total non-nitrogenous matter 55. With sheep the figures were lower. Only the tender young shoots are readily eaten by animals, unless the material be well crushed, so as to soften and break the prickles.

Experiments in 1899 and 1901 by Voelcker (Jour. Roy. Agric. Soc. for these years) showed that with sheep, gorse, properly comminuted by special machinery, could, with advantage, replace a portion of the roots used in feeding. Not more than 9 or 10 lbs. of gorse per head, per week, however, could be used.

H. I.

GOSLARITE, Zinc-vitriol, or White vitriol. Hydrated zinc sulphate $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, crystallised in the orthorhombic system and isomorphous with epsomite. It results from the weathering of zinc-blende, and usually forms white encrusting masses, or sometimes aggregates of fine, silky fibres. Being readily soluble in water it is not of common occurrence, but is occasionally found in the old galleries of zinc mines. Considerable quantities were at one time obtained from the Rammelsberg mine near Goslar in the Harz Mountains. Varieties are ferro-goslarite and cupro-goslarite.

L. J. S.

GOSSYPITRIN *v.* GLUCOSIDES.

GOSSYPOL. A toxic principle contained in cotton seed and present in glands in all parts of the cotton plant but the woody tissues; gives a blood-red solution in sulphuric acid, and a blue coloration when its alkaline solution is exposed to the air. Is found in commercial cold-pressed cotton-seed oil to the extent of 1.5 p.c., but not in the 'hot-pressed' oil, as the gossypol is then oxidised and most of it remains in the cake (Carruth, J. Amer. Chem. Soc. 1918, 40, 647).

GOUDANG WAX *v.* WAXES.

GOULARD'S EXTRACT, LOTION, WATER.

Solutions of basic lead acetate.

GRAHAMITE. A variety of bitumen allied to gilsonite (*q.v.*).

GRAIN LAC *v.* Lac resins, art. RESINS.

GRAIN OIL *v.* FUSEL OIL.

GRAIN TIN *v.* TIN.

GRAINS OF PARADISE *v.* COCCULUS INDICUS.

GRANITE. An acid igneous rock consisting of a granular (hence the name) holocrystalline aggregate of quartz, felspar, and mica. It contains about 65–75 p.c. of silica, which is present partly as free silica (quartz forming 30–50 p.c. of the rock), and partly in combination in the silicates. The felspar (36–68 p.c.) is generally a potash-felspar, usually orthoclase, but sometimes microcline; it may also, especially in the 'soda granites,' be a soda-bearing orthoclase, anorthoclase, or a plagioclase (albite

to oligoclase). The mica (5-18 p.c. of the rock) is usually of two kinds, a white mica, muscovite, and a black mica, biotite.¹ The one-mica granite biotite-granite is sometimes distinguished as granite. Less frequently, hornblende or augite may partly or wholly take the place of mica, as in hornblende-granite and augite-granite. In other varieties, especially those altered by pneumatolytic agencies, tourmaline may be present. Granites differ widely in their general appearance and character, due to variations in their coarseness of grain, the occasional presence of larger porphyritic crystals embedded in a finer-grained groundmass, the colour of the feldspars (dull white to pink), the lack or predominance of the dark-coloured minerals, biotite, and hornblende. Sp.gr. 2.6-2.8; weight per cubic foot, 160-175 lb.; crushing strength, 1000-2000, or sometimes even 3000, tons per square foot. Degree of porosity very low, 0.2-0.3 p.c. The grain of the rock is sufficiently coarse for the individual minerals to be distinguishable by the unaided eye. It varies from fine grained in aplite (a variety composed of only quartz and feldspar) to very coarse grained in pegmatite and graphic granite (the latter characterised by an intimate intergrowth of quartz and feldspar). At times granite displays a more or less pronounced foliated structure (gneissose granite), passing imperceptibly into gneiss. This rock has the same mineral and chemical composition as granite, and to a certain extent can be employed for the same purposes.

The following analyses are of: I, Coarse-grained, red biotite-granite from Peterhead, Aberdeen (J. A. Phillips, 1880). II, Fine-grained, bluish-grey muscovite-biotite-granite from Rubislaw, Aberdeen (W. Mackie, 1901). III, Biotite-granite with large porphyritic crystals of red feldspar from Shap, Westmorland (J. B. Cohen, 1891). IV, Grey muscovite-biotite-granite from Greedy near Luxullian, Cornwall (J. A. Phillips, 1880). V, Dark red, medium-grained hornblende-biotite-granite from Mount Sorrel, Leicestershire (C. K. Baker). VI, Average of nine analyses of the grey, two-mica granites, of Leinster, S.E. Ireland (S. Haughton, 1855). For a large collection of analyses of granite, v. J. Roth, Beiträge z. Petrographie d. plutonische Gesteine, Berlin, 1873-84; H. S. Washington, U.S. Geol. Survey, Prof. Paper, 1917, No. 99.

	I.	II.	III.	IV.	V.	VI.
SiO ₂	73.70	69.01	68.55	69.64	67.16	72.08

¹ These minerals carry part of the potash, each of them containing about 10 p.c. K₂O. The bulk of the potash is, however, carried by the feldspar, pure potash-feldspar containing 16.9 p.c. K₂O.

Granites are of wide distribution as rock-masses of considerable magnitude. They are extensively developed and quarried in Cornwall and Devon, where they occur as a series of bosses protruding through the killas or clay-slate. The largest of these intrusions are, proceeding westwards, those of Dartmoor, Brown Willy or Bodmin Moor, St. Austell or Hensbarrow, Carn Menezes or Penryn, and the Land's End or Penzance districts. In addition to these principal exposures there are numerous smaller masses. The granite of Devon and Cornwall is usually grey and coarse-grained, but red granite also occurs, as at Trowlesworthy in the western part of Dartmoor. Although used locally since prehistoric times, Cornish granites were not systematically quarried until early in the eighteenth century; one of the first quarries to be developed was the De Lank quarry near Bodmin, which supplied the material for the exterior of the Eddystone lighthouse in 1756. Dartmoor granite was sent to London in 1817 for the construction of Waterloo Bridge, and in 1831 for London Bridge. The granites of Scotland are of great industrial importance. Aberdeen granite was first brought to London for paving in 1764, but the great development of the trade dates from about 1850. The Aberdeen stone, valued for monumental work, is of a grey or blue tint; whilst that of Peterhead is usually of a fine pink colour. The Ross of Mull in Argyllshire furnishes a handsome pink granite, yielding blocks of exceptional size. Granite is also quarried in Kirkcudbrightshire, the grey stone of Dalbeattie being well-known in commerce. Ireland is rich in granites. The very large Leinster mass, in the counties of Dublin, Wicklow, Wexford, and Carlow was quarried as early as 1680. Other important occurrences are in the Mourne Mountains in Co. Down, and in Co. Galway and Co. Donegal. Other British occurrences are in the Scilly Islands, Jersey and Guernsey, Lundy Island, Malvern Hills, Mount Sorrel in Leicestershire, Skiddaw, Eskdale, and Shap in the Lake District, the Sarn district in North Wales, Foxdale and Dhoon in the Isle of Man; and in Scotland many other localities in addition to those mentioned above.

Granite is extensively used as a building and paving stone, and owing to its massive character and durability it is especially useful where massive constructive work is required, as in the foundation of buildings, in docks, sea-walls, piers of bridges, lighthouses, &c. Taking a high polish, which is retained on exposure to weather, and being suitable for carving, it is much in demand for ornamental and monumental work. Refuse from the quarries is dressed as paving setts, curb stones, or crushed and screened for road metal, railway ballast, and granite chips. Partly weathered granite from near the surface, especially when covered by a soil rich in humic acids, shows dull cloudy feldspars and the darker silicates have a rusty appearance, and the rock itself is often quite crumbly. This surface weathering may sometimes extend to considerable depths, and under certain conditions china-stone or china-clay may result. The solid fresh rock is, however, little affected by weathering processes when

employed as a building stone. The most important cause of disintegration under these conditions is that due to the unequal degree of expansion and contraction of the different minerals with changes of temperature; coarse-grained granites being more affected by this agency than the finer-grained varieties. The handsome coarse-grained Rapakivi granite of Finland lacks durability on this account. Granite has, however, the defect that it does not resist fire well. The cracking and scaling of the surface is due to the presence of vast numbers of microscopic cavities, containing water and liquid carbon dioxide, in the quartz. Stone containing nodules and specks of iron-pyrites should be avoided, since this mineral readily decomposes, producing free acid and unsightly brown stains. Of special varieties used for ornamental purposes mention may be made of luxullianite, and orbicular or spheroidal granite. The former, from Luxullian in Cornwall, consists of large porphyritic crystals of pink felspar set in a black matrix of tourmaline and quartz. A good set of large polished blocks and slabs of orbicular granite from several localities is displayed in the Mineral Gallery of the British Museum (Natural History). Granite was used as an ornamental stone by the ancient Egyptians and the Romans.

Granite rocks are always divided naturally by joints, which usually run in three directions, approximately at right angles, thus enabling the rock to be quarried in roughly cuboidal blocks. These are sometimes of considerable size, providing, for example, the obelisks up to 100 feet in length obtained by the ancient Egyptians in the quarries of pink hornblende-biotite-granite at Assouan (=Syene) in Upper Egypt. The blocks are split up by 'plug and feather' wedges, the splitting taking place more readily in certain directions, known to the quarrymen as the 'rift' or 'grain' of the stone. This is sometimes due to the presence of flow structure in the rock with a parallelism of the flakes of mica, but at other times it is apparently due to the effect of stresses. When the surface is required to be dressed smooth, it is 'fine-axed' by continual tapping, at right angles to the face, with a special form of axe. Slabs are cut by diamond saws, and columns up to 8 feet in diameter are turned in the lathe with diamond-set tools. The polishing of granite is effected by cast-iron planes worked over the smoothed surface, first with sand and water, and then with emery, the final polish being given with putty powder applied on thick felt. In this way even elaborate mouldings are polished. The name granite is sometimes incorrectly applied as a trade-name to stones of other kinds, e.g. 'black granite' to a gabbro or other dark-coloured igneous rock of granitic texture, 'Petit granit' to a black Belgian marble spotted with white enclinites, 'Mendip granite' to a limestone, and 'Ingleton granite' to a conglomerate.

Veins of metalliferous ores frequently occur in connection with granite masses, either in the granite itself or at its junction with the surrounding rocks. Tin ore, in particular, is almost always found only in association with granite. The pegmatite veins occurring in connection with granite often carry various gem-

stones (tourmaline, beryl, &c.) and rare-earth minerals.

GRANITE BLACK v. AZO-COLOURING MATTERS.

GRAPE. The berry of *Vitis vinifera* (Linn.). There are many varieties differing in size, shape, colour, and composition.

König gives as the average percentage composition—

Nitrogenous Water	substances	Free acid	Invert sugar	Other carbo- hydrates	Fibre	Ash
79.1	0.7	0.7	15.0	1.9	2.1	0.5

The sugar (glucose) in particular is liable to considerable variation, ranging from 9 to 18 or 19 p.c.

This variation, as well as that in the acidity—due to tartaric acid or acid potassium tartrate—is influenced not only by the variety, but also by the climate and soil; a wet winter and a hot, dry summer being generally favourable to the production of sweet grapes, suitable for wine making, whilst much rain during the ripening period dilutes the juice and leads to the bursting and consequent injury of the berries.

The proportion of skin and seeds shows considerable variation in different varieties, averaging about 2.2 p.c. of the whole fruit, and of this the seeds usually constitute about one-fourth. The skin contains tannin, and, according to Malvezin (*Compt. rend.* 1908, 147, 384), a yellow colouring matter, which, on oxidation either by exposure to air in aqueous solution, or by the action of an enzyme, present in red but absent in white grapes, changes to a red substance.

Sostegni (*Gazz. chim. ital.* 1902, 32, ii. 17) states that the red colouring matter is a tannin derived from protocathechuic acid and has the formula

According to Willstätter (*Sitzungsber. K. Akad. Wiss. Berlin*, 1914, 12, 402), the auto-cyanin of grapes—*cenin*, is obtained by digesting grape-skins with acetic acid and adding ether to the extract. The picrate of *cenin* forms long red prisms, the chloride, prisms with a green glance. *Cenin* is a monoglucoside of *cenidin*, $C_{17}H_{15}O_7Cl$.

The skin and seeds of grapes, in a moist condition, were analysed by Balland (*Rev. intern. falsif.* 1900, 13, 92), who found them to have the following percentage composition—

	Nitrogenous Water	substances	Soluble Fat	carbo- hydrates	Crude fibre	Ash
Skin	76.5	1.5	0.9	18.4	2.1	0.6
Seeds	38.7	5.5	8.6	18.9	27.6	0.7

Wittmann found about 0.4 p.c. pentosans in grapes.

The ash, according to König, contains—

Per cent. of ash in dry substance	K ₂ O	Na ₂ O	CaO	MgO	Fe ₂ O ₃	P ₂ O ₅	SO ₃	SiO ₂	Cl
Whole fruit	8.95	53.0	3.7	6.9	3.3	1.2	21.3	5.0	3.6
Skin	4.03	44.2	1.9	21.0	5.7	1.5	17.6	3.7	3.0
Seeds	2.81	28.7	—	33.9	8.6	0.6	24.0	2.5	1.1

About 0.2 p.c. of manganese oxide is also usually present.

Boric acid has been found in grapes (Cramp-ton, Amer. Chem. J. 11, 227; Baumert, Ber. 21, 3290). Salicylic acid also occurs, especially in the stalks (Mastbaum, Chem. Zeit. 1903, 27, 829).

Dried grapes constitute raisins and currants and are extensively used. Their average composition, as given by König, is respectively—

	Raisins	Currants
Water	24.5	25.4
Nitrogenous substances	2.4	1.2
Fat	0.6	—
Free acid	1.2	1.5
Invert sugar	59.3	61.8
Cane sugar	2.0	—
Other carbohydrates	1.3	5.9
Crude fibre and seeds	7.0	2.4
Ash	1.7	1.8

American analyses give considerably less water and more ash than these figures.

H. I.

GRAPE FRUIT (*Pomelo*, Shaddock). The fruits of various sub-varieties of *Citrus decumana* (Murr.), indigenous in Java, only some of which are edible. All contain a bitter principle (naringin, *q.v.*), and the non-edible varieties yield the oil of bitter orange or 'neroli-oil' (see Orange Flower Oil, Art. OILS, ESSENTIAL). By steam distillation the rind yields from 1 to 5 p.c. of a clear yellow oil with an odour like citral, $[n]_D^{20} = 1.475 - 1.4785$; optical activity in 100 mm. tube at $20^\circ = +72.5$ and $+78.5$; sp.gr. 0.845–860 at 20° . It contains *d*-limonene, 90–92 p.c.; citral, 3–5 p.c.; *a*-pinene, 0.5–1.5 p.c.; geraniol, 1–2 p.c.; linalool, 1–2 p.c.

Grape fruit is the richest of all the citrus fruits in pectin and pectose materials; the average of recoverable pectin being considerably above 10 p.c. of the peel weight.

GRAPE SEED OIL is obtained from grape seeds (*Vitis vinifera* [Linn.]) by expression or by extraction. As yet the oil is only of local importance, and is expressed only for local consumption, although it has been estimated that the waste seeds from the manufacture of oil in Italy would yield about 18,000 litres of oil per annum. In Italy and in the south of France (and even in south Germany) it is said to be used as an edible oil. The cold-expressed oil has a golden-yellow colour, and is free from odour. If the seeds have been stored for some time the expressed oil is dark, and acquires a slightly bitter flavour. The chemistry of this oil is not fully known, as the data obtained by the several observers who examined grape seed oil are very conflicting. At first it was credited with a very high acetyl value, and was compared in this respect with castor oil, so that its use for the manufacture of Turkey red oil had been proposed. More recent examinations have shown that grape seed oil has a very high iodine value, so that the oil would

seem to belong to the semi-drying or drying oils. The discrepancies in the recorded values are probably due to the oils yielded by the seeds of grapes of different varieties differing in their characteristics. For example, a genuine specimen of grape seed oil examined by Paris had an iodine value of 96, and an acetyl value of 143, whereas another oil of undoubted purity examined by dell' Acqua had an iodine value of 143, and an acetyl value of 17.8.

An dré (Comptes rend. 1921, 172, 1413) separated the hydroxy fatty acids by fractional crystallisation of the lithium salts from dilute alcohol. The average composition of the mixed fatty acids was: solid acids, 12.5, liquid acids, 62.5, and viscous hydroxy acids, 25.0 p.c. The low molec. weight (277) of the hydroxy fatty acids did not support the view that they consisted of *r*-cinoleic acid.

The oil-cake from the expressed seeds is fairly rich in proteins and potassium phosphate. A sample examined by Paris (Staz. sper. Agrar. Ital. 1911, 44, 669) contained 9.12 p.c. of proteins, 4.25 p.c. of fat, and 3.15 p.c. of ash, which contained 14.33 p.c. of phosphoric anhydride and 22.33 p.c. of potassium oxide.

J. L.

GRAPHIC TELLURIUM *v.* TELLURIUM.

GRAPHITE, a form of carbon crystallised in the rhombohedral system, known also as *plumbago*, and popularly as *black lead*. It occurs usually as compact and crystalline masses, but occasionally as six-sided tabular crystals which cleave into flexible laminae parallel to the basal plane. It is iron-black or steel-grey in colour, with metallic lustre, and has a sp.gr. of 2.25. In consequence of its softness ($H = 1$) and the ease with which it produces a metallic streak when rubbed on paper, it is largely used in the manufacture of pencils, whence the name 'graphite' given to it by Werner, from *γράφω* (I write). It was formerly called *molybdæna*, and confused with molybdenite (MoS_2), a mineral which also gives a metallic mark on paper. (On the history of these names, and of plumbago, *v.* J. W. Evans, Trans. Philological Soc. 1908, 133.) Graphite seems to have been first recognised as a distinct mineral by Gesner, who figured a lead pencil in 1565 (Roscoe). Scheele in 1779 showed that graphite was a kind of mineral carbon, since it could be converted into carbon dioxide by the action of nitric acid. As the carbon is usually associated with more or less iron, the older mineralogists described the mineral as a 'carburet of iron,' but Vanuxem demonstrated that the iron is present as ferric oxide and not as a carbide. The ash left on the combustion of graphite usually contains, in addition to the ferric oxide, silica, alumina, and lime.

Exposed on platinum foil to the flame of the blowpipe, graphite burns, but often with more difficulty than diamond. When heated with a mixture of potassium dichromate and sulphuric acid, it disappears. In order to obtain perfectly pure graphite, the mineral is first ground and washed to remove earthy matter, and then treated, according to Brodie's method, with potassium chlorate and sulphuric acid; on subjecting the resulting product to a red heat, pure carbon is obtained in a remarkably fine state of division.

The following analyses are selected from a large number by C. Mène (Compt. rend. 64, 1091):

	I	II	III	IV
Carbon . .	91.55	81.08	79.40	78.48
Volatile matters	1.10	7.30	5.10	1.82
Ash	7.35	11.62	15.50	19.70
	100.00	100.00	100.00	100.00

I. Very fine Cumberland graphite, sp.gr. 2.345. II. Graphite from Passau, Bavaria, sp.gr. 2.303. III. Crystallised graphite, from Ceylon, sp.gr. 2.350. IV. Graphite from Buckingham, Canada, sp.gr. 2.286.

Graphite when used for pencils is frequently mixed, in a powdered state, with pure clay, and the mixture consolidated by hydraulic pressure. It is also sometimes mixed with sulphur or with antimony sulphide. Brockedon first suggested the use of the hydraulic press as a means of obtaining from powdered graphite a homogeneous and coherent mass, which could be readily sawn into pieces of convenient size. The finest pencil lead was yielded by the ancient mine at Borrowdale in Cumberland, where it occurred in pipes, strings, and irregular masses, or 'sops,' associated with a dyke of diorite and with intrusive masses of diabase, in the Cambro-Silurian volcanic series known as 'the green slates and porphyries.' The Cumberland graphite was formerly termed 'wad,' a name sometimes applied also to native oxide of manganese. (For description of the old Borrowdale workings *v.* J. C. Ward in Geol. Survey Mem. on Lake District, 1876.) A small amount of graphite, about 100 tons per annum, is obtained from the Craigman mine, near Cumnock in Ayrshire; here the mineral usually exhibits a columnar structure, and it has been produced by the baking action of dykes of igneous rock on seams of coal (*v.* Special Reports on the Mineral Resources of Great Britain, Mem. Geol. Survey, vol. v. 2nd ed. 1917).

Excellent graphite is found in Siberia, especially at the Mariinskoi mine, in the Tunkinsk Mountains, Government of Irkutsk. This deposit, discovered in 1838, occurs in gneiss, associated with diorite; it has been largely worked by M. Alibert to supply Faber's pencil factory. In 1860 graphite was discovered in granite near the river Nizhne Tunguska, and workings were undertaken by M. Siderov. (For Russian graphite *v.* N. Koksharov, *Materialien z. Mineralogie Russlands*, 1862, 4, 153, where analyses are given.)

The best quality of graphite found in large quantities is that from Ceylon. The mineral is widely distributed through the western and north-western provinces of the island, and is obtained from a large number of small pits, there being but few mines of any size. The output amounts to about 30,000 tons per annum, with a value of rather over half a million pounds sterling. In 1916 the output was 33,400 tons, valued at £1,500,000, of which 80 p.c. was imported by America. (On the graphite deposits of Ceylon *v.* A. K. Coomaraswamy, *Mineralogical Survey of Ceylon*, 1903, etc.; *Quart. J. Geol. Soc.* 1900, 56, 590.) In India,

graphite is found at several localities, chiefly in the Madras Presidency, the best coming from Travancore, but even this is far inferior to that from Ceylon.

In the United States, graphite is widely diffused, but rarely in sufficient quantity to be worked. The principal locality is Ticonderoga, in Essex Co., New York, where the Dixon Crucible Co. have worked a schist containing about 10 p.c. of graphite. It has also been worked to a limited extent near Raleigh, North Carolina; at Stourbridge, Mass.; at Cumberland Hill in Rhode I.; and at Sonora in California. The graphite 'ores' are crushed or stamped, and then washed, whereby the flakes of graphite are readily separated from the denser matrix. In the Laurentian gneiss of Canada, graphite is of frequent occurrence, and has occasionally been worked, as at the Buckingham Mines. The mineral is usually found in veins and nodular masses, or finely disseminated through bands of limestone. It is widely distributed in the gneissic rocks of Madagascar, and is there mined at a number of localities. In 1917 the French colony exported over 33,000 tons, divided almost equally between France and England. Graphite is also extensively mined at several places in Korea, where the deposits have the form of beds, nests, stocks, and veins in gneiss and metamorphosed Palæozoic sediments.

In Europe, extensive deposits of graphitic schists occur in the Eastern Alps and in the mountainous region between Bohemia and Bavaria (Böhmerwald). These are extensively mined in Moravia, Styria, and particularly in the east of Bohemia, where the annual output reached 50,000 tons; but the material is of inferior quality, containing often 50 p.c. of ash. Considerable amounts are also obtained in the north of Italy, but the well-known locality at Passau in Bavaria is now little worked. (On Alpine Occurrences of Graphite *v.* E. Weinschenk, *Abh. bayer. Akad. Wiss.* 1898, 19, 509, 521; 1901, 21, 279.)

Daubrée has obtained graphite artificially by decomposing carbon disulphide in contact with metallic iron at a high temperature; while H. Sainte-Claire Deville prepared it by passing vapour of carbon tetrachloride over fused cast iron. Crystalline graphite is often formed in blast furnace slag during iron smelting, and is known to workmen as *kish*; and it is present in grey pig iron. Considerable quantities of graphite are now produced commercially, together with carborundum, in the electric furnace. The artificial production of graphite (as well as various properties of the natural mineral) is dealt with by H. Moissan (*The Electric Furnace*, London, 1904). Graphite also occurs in certain meteoric irons, such as that of Toluca in Mexico. A cubic form of graphitic carbon, discovered in a meteoric iron from Youndegin, Western Australia, has been described by Fletcher under the name of *Cliftonite* (*Min. Mag.* 1887, 7, 121).

In consequence of its refractory character, graphite is largely used in the manufacture of crucibles, retorts, twyers, and other objects required to withstand high temperatures. For crucibles, the powdered mineral is mixed with Stourbridge fire-clay, and made into a paste

with water; the kneaded mass is allowed to lie for many weeks before the crucible is moulded; the vessel when moulded is slowly dried, and carefully fired in a seggar.

As a lubricating agent graphite is highly valued, since it diminishes friction and tends to keep the moving surfaces cool. To obtain the best results the powdered mineral should be carefully selected and sized. For steam cylinders it is used dry; for heavy bearings it is mixed with grease; and for light bearings with oil. Made into a paint with linseed oil, it has been advantageously employed as a coating for metal work. Graphite is also used dry for polishing stoves and other objects of cast iron, the thin flakes forming a lustrous coating which protects the metal. Blasting powder and heavy ordnance powders are likewise glazed with graphite, for though it slightly diminishes the explosive force of the powder it protects it from damp. Being a good conductor of electricity, graphite is used in electrotyping, as originally suggested by Murray; the moulds upon which the metal is to be deposited receiving a conducting surface by being coated with finely divided graphite.

For the method of rapidly analysing graphite in use at the Pittsburgh Laboratory of the U.S. Bureau of Mines, see U.S. Bureau of Mines Bull. 112, 1920, 43; J. Soc. Chem. Ind. abstr. 1920, 70 A.

Cirkel, Graphite, its Properties, Occurrence, Refining, and Uses, Dept. of Mines, Ottawa, 1907, Publ. No. 18; H. S. Spence, Graphite, Dept. of Mines, Ottawa, 1920, Publ. No. 511; A. Haenig, *Der Graphit, eine technische Monographie*, Wien and Leipzig, 1910; O. Stutzer, Die wichtigsten Lagerstätten der 'Nicht-Erze', Berlin, 1911. L. J. S.

GRAPHITIC ACID and GRAPHITIC OXIDE.

Prepared by Balbiano from natural and Acheson graphite varied in composition between $C_{13}H_4O_7$ and $C_{14}H_4O_7$, and on being heated *in vacuo* yield carbon monoxide and dioxide, together with methane and water. They are regarded as absorption compounds of graphite, water, and carbon monoxide and dioxide, and not true chemical compounds as assumed by Brodie (*cf.* Kontschütter and Haenni, *Zeitsch. anorg. Chem.* 1919, 105, 121).

GRASSES. The term 'grass' is used by the agriculturist to denote, not only plants which belong to the *gramineae*, but also other pasture or meadow plants, or even certain weeds common on cultivated land.

The true grasses are characterised by a somewhat low content of nitrogenous substances, and by the richness of the ash in silica and its poverty in lime and magnesia, whilst clovers and other leguminous crops possess the exactly opposite features. H. I.

GREASES. The term 'grease' was applied originally to all kinds of fats having a buttery consistence. At present, however, the term 'grease' is restricted to low-class material, chiefly obtained from waste products, such as kitchen grease, ship's grease, tripe tallow, slaughter-house grease ('tankage' grease),

bone grease, skin grease, greases from carcass-rendering establishments, and garbage fats. All these greases must be looked upon as varieties and (or) mixtures of lard, tallow, bone fat, horse fat, fish stearines, &c.

Greases are characterised by a dark colour, by a high percentage of free fatty acids, and a correspondingly high proportion of unsaponifiable matter. They have also an objectionable odour.

Black grease is the dark, almost black, fatty matter which is recovered from cotton seed mucilage, on decomposing the latter with mineral acids (*see* COTTON SEED OIL). This black grease is used in the manufacture of low-class candle materials, after a purification by distillation with superheated steam, and further treatment of the distillate in the same manner as in working up the fatty acids in the candle industry (*see* SAPONIFICATION). J. L.

GREEN ALIZARIN v. MADDER.

GREEN CINNABAR. A mixture of chrome yellow and Prussian blue.

GREEN EBONY. Green ebony is a yellow dyewood formerly employed to some extent in this country, but is now almost entirely replaced by other colouring matters. It is a native of Jamaica or West India, and is obtained from the *Excoecaria glandulosa* (Siv.) or *Jacaranda ovalifolia* (R. Br.). The trunk of the tree is about 6 inches in diameter; the wood is very hard, and of an orange-brown colour when freshly cut, and stains the hands yellow. References to this dyestuff are meagre, and it does not appear to have been ever largely employed. Bancroft (*Philosophy of Permanent Colours*, 1813, ii. 106) states that green ebony contains a species of colouring matter very similar to that of the *Chlorophora tinctoria* (Gaudich) (Old fustic), and is sometimes employed in its stead; and O'Neill (*Dictionary of Calico Printing and Dyeing*, 1862) mentions that it is used in dyeing greens and other compound shades. Until recently it had a limited sale in Yorkshire as a dye for leather, but appears to have entirely passed out of use as a woollen dyestuff. It is now little used in silk dyeing, but was formerly employed for greening blacks.

Green ebony contains two crystalline colouring matters, which are distinguished by the fact that whereas one, *excoecarin*, is not precipitated by lead acetate solution, the second, *jacarandin*, is completely deposited by this reagent (Perkin and Briggs, *Chem. Soc. Trans.* 1902, 81, 210).

Excoecarin $C_{13}H_{12}O_5$, crystallises in lemon-yellow needles, sparingly soluble in cold alcohol, and melting with effervescence at 219° – 221° . It is soluble in aqueous and alcoholic alkaline solutions with a violet-red coloration, and these liquids, on exposure to air, are rapidly oxidised, and assume a brown tint.

Excoecarin does not dye mordanted fabrics, but is a substantive dyestuff in that it has a weak but decided affinity for the animal fibres with which it gives, preferably in the presence of tartaric or oxalic acid, yellow shades. *Benzoyl-excoecarin* $C_{13}H_8O_5(C_6H_5O)_2$, consists of colourless needles, m.p. 168° – 171° , and *excoecarindimethyl ether*, $C_{13}H_{10}O_5(CH_3)_2$, of yellow needles, m.p. 117° – 119° . On fusion with alkali *excoecarin* gives *hydroquinonecarboxylic acid*

and a substance melting at 124°, which is probably *hydrotoluquinone*

By the action of bromine upon a solution of *exocæcarin* in alcoholic potassium acetate *exocæcarone* $\text{C}_{13}\text{H}_{10}\text{O}_5$, flat copper-coloured needles or leaflets, melting at about 250°, is produced, and this by the action of sulphurous acid is reconverted into *exocæcarin*. With alcoholic quinone solution *exocæcarin* gives the compound $\text{C}_6\text{H}_4\text{O}_2 \cdot \text{C}_{13}\text{H}_{10}\text{O}_5$, minute green-coloured leaflets, melting with decomposition at 190°, and from this sulphurous acid also regenerates *exocæcarin*. From these results it appears evident that *exocæcarin* contains free hydroquinone hydroxyls.

Jacarandin $\text{C}_{14}\text{H}_{12}\text{O}_5$, yellow plates or leaflets, m.p. 243°–245°, dissolves sparingly in alcohol and the usual solvents to form pale yellow liquids having a green fluorescence. With caustic alkali solutions it gives orange-red liquids; with alcoholic lead acetate a bright orange-coloured precipitate; and with alcoholic ferric chloride a dark greenish-black solution. It dyes mordanted woollen fabrics the following shades:

Chromium	Aluminium	Tin	Iron
Dull yellow-brown	Orange-brown	Bright golden yellow	Deep olive

Acetyljacarandin $\text{C}_{14}\text{H}_{10}\text{O}_5(\text{C}_2\text{H}_3\text{O})_2$, pale-yellow needles, melts at 192°–194°, and when digested with boiling alcoholic potassium acetate gives the salt $(\text{C}_{14}\text{H}_{12}\text{O}_5 \cdot \text{C}_{14}\text{H}_{11}\text{O}_5)_2\text{K}$, yellow needles. *Benzoyljacarandin* $\text{C}_{14}\text{H}_{10}\text{O}_5(\text{C}_6\text{H}_5\text{O})_2$, forms yellow prismatic needles, m.p. 167°–169°.

As indicated by Bancroft (*l.c.*) the colours given by green ebony are similar in character to those yielded by old fustic. Employing mordanted woollen cloth the following shades are produced:

Chromium	Aluminium	Tin	Copper	Iron
Dull yellow-brown	Dull brown-yellow	Golden yellow	Pale brown	Olive green

With 40 p.c. of the dyewood the iron mordant gives greener and brighter shades than with larger amounts, in which case a browner colour is produced. Possibly from this green shade, and the extremely hard and compact nature of the wood, the name 'green ebony' has originated.

A. G. P.

GREEN, EMERALD. *v.* CHROMIUM.

GREEN, GUIGNET'S. *v.* CHROMIUM.

GREEN SMALT. *Cobalt green.* *v.* PIGMENTS.

GREEN ULTRAMARINE. *Chromium sesquioxide.* *v.* CHROMIUM.

GREEN VITRIOL. *Ferrous sulphate.* *v.* IRON.

GREENALITE. A hydrated iron silicate occurring in the form of green granules in sedimentary rocks, and closely resembling glauconite (*q.v.*), from which it differs in containing no potassium. The composition varies somewhat; one analysis gives the formula

It occurs abundantly on the Mesabi Range in the Lake Superior district of Minnesota, and by its alteration has given rise to ferruginous cherts and immense deposits of iron ore (C. K. Leith, Monograph U.S. Geol. Survey, 1903, xliii.).

L. J. S.

GREEN-EARTH. (Ger. *Grünerde*). A term loosely applied to a variety of earthy minerals of a bluish-green, or dark olive-green colour

occurring as alteration products in basic igneous rocks. It includes more particularly the species *celadonite* (or *seladonite*), and various indefinite members of the chlorite group, *e.g.* *delessite*, *chlorophæite*, *kirwanite*, *viridite*, &c. Many of these are of indefinite composition and probably mixtures. They are often met with as a green lining in the amygdaloidal cavities of altered basaltic rocks, and form the 'skin' of agates and other secondary minerals filling these cavities. Crystals of *augite* in the same rocks are sometimes completely altered to a soft aggregate of green-earth still preserving the sharp outlines of the original crystals. Similar pseudomorphs after *hornblende* also occur. Larger irregular masses fill cavities and fissures in these rocks. The well-known green-earth of Monte Baldo near Verona is referable to *celadonite*. An analysis of material from this locality gave: SiO_2 , 54.84; TiO_2 , 0.10; Al_2O_3 , 1.22; Fe_2O_3 , 19.16; FeO , 4.39; MnO , 0.28; CaO , 0.24; MgO , 5.34; K_2O , 9.75; Na_2O , 0.82; H_2O , 3.77=99.9 (C. W. Gümbel, 1896). This composition is very similar to that of *glauconite*, with which *celadonite* is perhaps identical, differing only in its state of aggregation and mode of origin and occurrence. This *celadonite* green-earth is worked commercially as a pigment on both sides of the Tyrolean-Italian border; and similar material could be obtained from many other localities.

L. J. S.

GREENLAND SPAR *v.* CRYLOITE.

GREENOCKITE. Cadmium sulphide CdS , crystallised in the hexagonal system with hemimorphic development and isomorphous with *wurtzite* (ZnS). This and the still rarer cadmium oxide, and *otavite* (basic carbonate), are the only minerals that contain cadmium as an essential constituent. Distinct, though small, crystals are found only in Scotland, in the neighbourhood of Glasgow. They occur very sparingly with *prehnite* in amygdaloidal basalt in the Bishopton railway-tunnel and the Boyleston quarry at Barrhead in Renfrewshire, and in the Bowling quarry in Dumbartonshire. They are honey- to orange-yellow, transparent to translucent, and have a resinous to adamantine lustre; the streak is orange- to reddish-yellow. Sp.gr. 4.8–4.9; H. 3–3½. Traces of cadmium are often present in zinc-blende (up to 1.5 p.c., and in the ores of the Joplin district in Missouri averaging 0.358 p.c.), and with the weathering of this mineral cadmium sulphide remains as a thin, powdery, canary-yellow coating ('cadmium-ochre'), or it may impart a tinge of colour to the secondary zinc minerals *hemimorphite* and *smithsonite* ('turkey-fat ore'). In this form the mineral is known from many localities, though never in large amount. Being colloidal, it does not agree with the definition of *greenockite* as given above; and, again, the possible existence of a cubic form of cadmium sulphide is suggested by the isomorphous presence of this constituent in zinc-blende, although this modification has not been prepared artificially. The new name *xanthochroite* (A. F. Rogers, 1917) has therefore been suggested for this colloidal form of cadmium sulphide. Hemimorphic hexagonal crystals of cadmium sulphide have been prepared artificially, and they are not uncommon as furnace products. The

artificial crystals have sp.gr. 4.820 and the high refractive indices ϵ_{Na} 2.529, ω_{Na} 2.506.

L. J. S.

GREENSAND *v.* GLAUCONITE.

GREENSTONE *v.* DIABASE and JADE.

GRENAT BROWN *v.* iso-PURPURIC ACID.

GREY ANTIMONY ORE, *Antimony sulphide*, *v.* ANTIMONY.

GREY OIL. A mixture of lanoline vaseline, and metallic mercury. Used in the treatment of syphilis.

GRIFA. Trade name for lithium acetyl-salicylate.

GRIGNARD REAGENT. Grignard, in 1901, showed that magnesium reacts with alkyl and aryl halides in presence of ether at ordinary temperatures forming compounds of the type $R.Mg.X$ (where R is an aryl or alkyl radicle and X a halogen radicle) which are synthetic reagents of great value and capable of extensive application.

For a discussion of the probable constitution of these magnesium compounds, see Meisenheimer and Casper, Ber, 1921, 54 [B], 1665. Chem. Soc. Abstr. 1921, i., 654.

GRINDELIA. (B.P.) The dried leaves and flowering tops of *Grindelia camporum* (Greene).

GRISERIN. Trade name for the sodium salt of iodo-hydroxy-quinoline-sulphonic acid. Used in treatment of tuberculosis.

GRISHI-BU-ICHI. Japanese name for an alloy of copper and silver of a rich grey colour.

GRISOUTINE. An explosive consisting of a mixture of nitroglycerin, nitrocellulose, ammonium nitrate, and kieselguhr.

GROSSULARITE *v.* GARNET.

GROTAN. A chlorinated cresol used as a bactericide.

GRÜNLINGITE *v.* TETRADYMIT.

GUACAMPOL, **GUAIACETIN**, **GUAIACIFORM**, **GUAIKINOL**, **GUAIAMAR**, **GUAIASANOL**, **GUATANNIN** *v.* SYNTHETIC DRUGS.

GUACHINOL. Trade name for quinine dibromoguaicolate.

GUAIACENE *v.* *Guaicum*, art. RESINS.

GUAIACIC ACID *v.* *Guaicum*, art. RESINS.

GUAIACOL (*Monomethoxycatechol*)

$OH \cdot C_6H_4 \cdot OMe$

is a constituent of guaiacum resin (Herzig and Schiff, Monatsh. 1898, 19, 95), and occurs in beechwood tar, from which it can be separated by treating the fraction of the tar that comes over at 200° – 205° with ammonia to remove acids; it is then again fractionated, and the lower boiling fraction is dissolved in ether and treated with potassium hydroxide. The potassium salt of guaiacol is filtered, washed with ether, and recrystallised from alcohol, after which it is decomposed with sulphuric acid, and the guaiacol redistilled. (For other methods of separation, cf. D. R. P. 87971, 56003, 100418, Chem. Zentr. 1899, i. 764.) Guaiacol is prepared from *o*-anisidine. 500 grams *o*-anisidine are diazotised, and the solution of the diazo salt is then poured into a boiling solution of 600 grams of copper sulphate in 600 c.c. of water. The guaiacol is then separated by distillation in steam (D. R. P. 167211; Frdl. 1905–7, 128; cf. also D. R. P. 95339; J. Soc. Chem. Ind. 1898, 269, 314).

Pure guaiacol can be obtained by dissolving

catechol (55 parts) in ethyl alcohol (2000 parts) and adding nitrosomonomethyl urea. The mixture is cooled to 0° and 20 parts of sodium hydroxide dissolved in a small quantity of water is added, drop by drop, with constant stirring. The solution is filtered, the alcohol distilled off, and the residue is fractionated *in vacuo* (D. R. P. 189843; Frdl. 1905–7, 1151).

Guaiacol is also prepared by heating an equimolecular mixture of catechol, potash, and potassium methyl sulphate in tightly closed vessels at 170° – 180° , or by heating catechol and methyl iodide in methyl alcohol. A weak base, such as sodium carbonate or sodium hydrogen carbonate, is gradually added to a mixture of catechol, with the alkali or alkali earth salts of methylsulphuric acid in the presence of veratrole as diluent at 160° – 180° (Zollinger and Röhling, D. R. P. 305281; Chem. Soc. Abst. 1918, i. 497). Thompson (Eng. Pat. 5284, 1893) suggests the purification of guaiacol by treatment with a freezing mixture.

Guaiacol has a characteristic odour and crystallises in long vitreous transparent prisms, which appear rose-red in sunlight; m.p. 28.5° , b.p. $202.4^\circ/738$ mm. (Freyss, Chem. Zeit. 1894, 18, 565); sp.gr. 1.140 at 25° . When quite pure it is non-caustic and non-poisonous (Béhal and Choay, Compt. rend. 1893, 116, 197; Kuprianow, J. Soc. Chem. Ind. 1895, 57).

It is soluble in most organic solvents, and to a less extent in water. With a trace of ferric chloride its alcoholic solution gives a blue colour, which becomes emerald-green on the addition of more ferric chloride. Guaiacol also gives a blue colour with traces of hydrogen peroxide (Denigès, J. Pharm. Chim. 1901, 31).

Guaiacol is employed in pharmacy as an expectorant and intestinal antiseptic; also in pulmonary tuberculosis in cases of typhoid and other fevers, and for the relief of superficial neuralgia.

Kuprianow (Centralbl. f. Bakteriöl. 1894, 15, 933, 981) has suggested the use of pure guaiacol in the internal treatment of cholera, since he found that a solution of 1 in 500 of this reagent completely prevents the development of the cholera bacillus.

Guaiacol should be preserved in amber-coloured bottles protected from the light, and should only be used in pharmacy when quite pure.

Tests.—(1) 2 c.c. of guaiacol mixed with 4 c.c. of light petroleum, should separate at once into 2 layers. (2) 1 c.c. of guaiacol should dissolve in 2 c.c. of N. sodium hydroxide when heated; on cooling the mixture should congeal to a white saline mass, which gives a clear solution with 20 c.c. of water. (3) 1 c.c. of guaiacol treated with 10 c.c. of N. sulphuric acid should give a pure yellow colour. For other tests, *v.* Marfori, J. Soc. Chem. Ind. 1891, 487; Fonzes Diacon, Bull. Soc. chim. 1898, 19, 191; Guérin, J. Pharm. Chim. 1903, [vii.] 17, 173.

Guaiacol can be estimated approximately by conversion into catechol, by heating with water in a current of hydrobromic acid; or 0.5 gram of the guaiacol is dissolved in a little water, 10 c.c. of alcohol added, and the solution made up to 1000 c.c., and 20 c.c. of this solution are mixed in a test-tube with 1 c.c. of sodium nitrite solution (1 : 100), and 1 c.c. dilute nitric

acid (1 : 200). A characteristic red-brown colour is produced, which is compared within about 10 minutes with the colorations given by suitable standard solutions (Adrian, Zeitsch. anal. Chem. 1901, 40, 624).

Guaiacol, when treated with hydrogen cyanide, in the presence of sodium or zinc chloride, yields vanillin (Roesler, D. R. P. 189037; Frdl. 1905-7, 1280; Guyot and Gry, Compt. rend. 1909, 149, 928; Bull. Soc. chim. 1910 [iv.] 7, 902).

Guaiacol monosulphonic acids can be obtained by treating guaiacol with sulphuric acid at 30°-60°, the ortho- and para- acids formed being separated by converting them into the basic salts of the alkaline earths, or of the heavy metals, the ortho- salts being readily soluble in water, whereas the para- salts are insoluble or sparingly soluble. By the action of sulphuretted hydrogen, or some suitable acid, the salts are then converted into their respective acids (D. R. P. 188506; Frdl. 1905-7, 936; D. R. P. 132607; Frdl. 1900-02, 1113; Hähle, J. pr. Chem. 1902, [ii.] 65, 95; Lamière and Perrin, Bull. Soc. chim. 1903 [iii.] 29, 1228; Rising, Ber. 1906, 39, 3685; Paul, *ibid.* 2773, 4093; Ginhorn, Fr. Pat. 391601, 1908; J. Soc. Chem. Ind. 1908, 1176; André, J. Pharm. Chim. 1898, 7, 324).

The most striking difference between the ortho- and the para- acids is their action with calcium or barium chloride, with which the para- acid yields a white precipitate, whereas the ortho- remains unchanged. With nitric acid the para- acid forms yellow dinitroguaiacol (m.p. 122°), whilst the ortho- acid merely gives a dark red coloration. It is important that when the ortho- acid is used therapeutically, it should be free from the para- compound, as the latter gives rise to secondary reactions (Ellis, J. Soc. Chem. Ind. 1906, 335).

The alkali guaiacol sulphonates are employed as drugs (Alpers, U.S. Pat. 692588; J. Soc. Chem. Ind. 1902, 364). Tagliavini has prepared salts of the sulphonates with antipyretic and analgesic bases (Boll. Chim. farm. 1909, 48, 6).

Carbonyl chloride condenses with the alkali guaiacol sulphonates in alkaline solutions, giving derivatives such as *potassium carbonatodiguaiacol disulphonate* $\text{CO}[\text{OC}_6\text{H}_3(\text{OMe})\text{SO}_3\text{K}]_2$, and *potassium carbonatodiguaiacol sulphonate*

$\text{C}_6\text{H}_4(\text{OMe})\text{O}\cdot\text{CO}_2\text{C}_6\text{H}_3(\text{OMe})\text{SO}_3\text{K}$ (Einhorn, D. R. P. 203754, 1909).

Guaiacol 5-sulphonic acid is obtained by sulphonating an acetyl derivative of guaiacol with or without the addition of dehydrating agents, the resulting acetyl guaiacol sulphonic acid is hydrolysed, neutralised, and the resulting acid is isolated as such, or in the form of its salts (D. R. P. 212389; J. Soc. Chem. Ind. 1909, 1005). The corresponding *carbonate*

is formed by treating guaiacol carbonate with sulphuric acid in the cold until the product is soluble in water. It melts at 115°-117°, with evolution of carbon dioxide (D. R. P. 215050; J. Soc. Chem. Ind. 1909, 1223).

Triphenyl guanidine guaiacol sulphonate is obtained by the action of triphenyl guanidine sulphate on barium guaiacol sulphonate. It

crystallises in leaflets, m.p. 50°, and can be used as a local anæsthetic (Goldschmidt, Chem. Zeit. 1901, 25, 628).

A number of important compounds of *o*-guaiacol sulphonic acids with alkaloids are described by Schaefer (J. Soc. Chem. Ind. 1910, 928). They are used in medicine and are also of scientific interest. The alkaloid salts are prepared by neutralising the guaiacol sulphonic acid with the required alkaloid, and purifying the product by filtration and recrystallisation, or the amorphous salt is obtained by evaporation at low temperature or *in vacuo*. The salts may also be obtained by double decomposition between a soluble alkaloid, and a readily soluble salt of the acid in molecular proportions, using alcohol, water, &c., as a solvent. Most of the alkaloid salts are non-crystalline or crystallise with difficulty. The most important of the salts described by Schaefer are:

Quinine guaiacol bisulphonate (guaiaquin) $[\text{C}_6\text{H}_3(\text{OH})(\text{OMe})\text{SO}_3\text{H}]_2\cdot\text{C}_{20}\text{H}_{24}\text{N}_2\text{O}_2$ is a yellowish crystalline powder, soluble in water, alcohol, and dilute acids. The solution is coloured blue by a drop of ferric chloride solution. It softens at about 80°, and becomes liquid at 130°.

Cocaine-o-guaiacol sulphonate

m.p. 164°-165°, is a well-crystallised neutral salt. It is readily soluble in hot water and in alcohol, but almost insoluble in ether and chloroform. It gives the characteristic blue coloration of *o*-guaiacol sulphonic acid with ferric chloride, and when its aqueous solution is treated with an alkali, cocaine is precipitated. Other opium and cinchona compounds, as well as compounds with strychnine, brucine, atropine, hyoscyne, hyoscyamine, and cocaine, are described.

Guaiacol iron and lithium sulphonates have been prepared (Schaefer, Eng. Pat. 21747, 1899).

Guaiaikinol, *quinine derivative of bromo-guaiacol*, $\text{C}_{20}\text{H}_{24}\text{N}_2\text{O}_2\cdot 2\text{HBr}\cdot\text{C}_6\text{H}_4(\text{OH})(\text{OMe})$, forms fine crystalline yellow scales, readily soluble in water. It is said to be practically non-toxic, and its aqueous or alcoholic solution is readily absorbed by the skin (Pharm. J. 1901, 66, 132; Schaefer, Eng. Pat. 8227, 1897).

Guacamphol, the camphoric acid ester of guaiacol $\text{C}_6\text{H}_{14}(\text{CO}\cdot\text{OC}_6\text{H}_4\cdot\text{OMe})_2$, obtained by the action of camphoric acid chloride on sodium derivative of guaiacol. Forms white, odourless, tasteless needles, and has been recommended for the relief of night sweats in phthisis.

Guaiacol benzoate (benzosol, benzoyl guaiacol) $\text{C}_6\text{H}_3\cdot\text{CO}\cdot\text{OC}_6\text{H}_4\cdot\text{OMe}$ is prepared by heating an alcoholic solution of potassium derivative of guaiacol with the requisite amount of benzoyl chloride, and purifying the substance by crystallisation from alcohol. It is a colourless, odourless, tasteless powder, almost insoluble in water, readily soluble in organic solvents. It has m.p. 56°, and is used in the treatment of pulmonary tuberculosis (Eng. Pat. 5366, 1890; J. Soc. Chem. Ind. 1891, 383; Walzer, Chem. Zeit. Rep. 1891, 15, 165).

Guaiacol cinnamate (styracol, cinnamyl guaiacol) $\text{C}_6\text{H}_3\cdot\text{CO}\cdot\text{OC}_6\text{H}_4\cdot\text{OMe}$ is formed by the interaction of molecular weights of guaiacol and cinnamyl chloride. It forms colourless needle-shaped crystals, m.p. 130°, which are employed

in catarrhal affections of the digestive tracts, and in the treatment of phthisis.

Guaiacol combines with tannin and cinnamic acid to form a compound which is said to be of use in medicine. It melts above 300° , is insoluble in most organic solvents, and dissolves in alkalis and also in pyridine, from which the pyridine derivative crystallises in well-shaped rhombic needles (D. R. P. 133299; Frdl. Nissel. 1900-02, 1111).

Guaiacol valerate $C_4H_9\cdot CO\cdot OC_6H_4\cdot OMe$, a yellowish oily liquid, b.p. 245° - 265° , is used in medicine under the name of *geosote* (Rieck, J. Soc. Chem. Ind. 1897, 632). It is prepared by the action of valeryl chloride on sodium derivative of guaiacol.

Guaiacol salicylate (guaiacol salol)

is a white crystalline, odourless, tasteless powder; m.p. 65° . It is formed by the action of phosphorus oxychloride on a mixture of sodium guaiacol salicylate, and is used as an intestinal antiseptic.

Guaiacol succinate $C_2H_4(CO\cdot OC_6H_4\cdot OMe)_2$ is formed by the action of phosphorus oxychloride on a mixture of guaiacol and succinic acid in molecular proportions. It forms fine silken crystalline needles; m.p. 136° .

Guaiamar, the *glyceryl ether of guaiacol* $C_6H_4(OMe)OC_3H_7O_2$, is formed by the action of anhydrous glycerol on guaiacol. It is a white crystalline body, m.p. 75° , soluble in water and in most organic solvents. It has a bitter aromatic taste, and is employed in medicine as an antiseptic for internal and external application (J. Soc. Chem. Ind. 1900, 371; 1902, 1346).

Guaiasanol (diethylglycocolguaiacol hydrochloride) $MeO\cdot C_6H_4\cdot O\cdot CO\cdot CH_2\cdot NEt_2\cdot HCl$, m.p. 184° , is non-poisonous, and said to possess slight anæsthetic, antiseptic, and deodorising properties (Einhorn, Chem. Zeit. Rep. 1900, 24, 33; J. Soc. Chem. Ind. 1900, 464). By the action of the monochloroacetic esters of phenols with secondary amines of the fatty series, many compounds, similar to the above, have been prepared (Einhorn and Heinz, Arch. Pharm. 240 [8] 631; D. R. P. 105346). They are non-poisonous, odourless, and strongly antiseptic substances.

Guaiaperol (piperidine derivative of guaiacol) is prepared by dissolving 85 parts of piperidine and 248 parts of guaiacol in benzene or light petroleum, and allowing the solution to evaporate (Tunnicliffe, Chem. Soc. Trans. 1898, 145).

Valuable albuminous products said to be applicable in medicine for tuberculous and other cases are obtained by the interaction of guaiacol with egg or other albumin in aqueous or alcoholic solution (D. R. P. 162656; Frdl. 1905-7, 931).

Guaiacol, when treated with ethoxyacetyl chloride, bromide, or iodide, reacts thus:

The product is a colourless, odourless oil; b.p. $150^{\circ}/10$ mm. The corresponding methoxy derivative boils at 170° - $171^{\circ}/10$ mm., and has very similar properties to the ethoxy derivative. Both substances are non-poisonous, and can be used therapeutically as external remedies (D. R. P. 171790; Frdl. 1905-7, 933).

Guaiaciform (geoform) is produced by the

condensation of guaiacol (2 mols.) with formaldehyde (1 mol.). It is a tasteless, yellow, non-irritant, and non-toxic powder, but on keeping it acquires the vanilla flavour. It is insoluble in water, but readily soluble in ether, benzene, or alcohol (Ehlert, Pharm. J. 1902, 68, 61).

Guaiacol carbonate $OMeC_6H_4O\cdot CO$ is pre-

pared by passing phosgene into a solution of guaiacol in sodium hydroxide. The substance is filtered off, washed with sodium hydroxide solution, and recrystallised from alcohol. It is a white crystalline powder, m.p. 84° - 87° , of neutral reaction, and almost odourless and tasteless, soluble in most organic solvents, but insoluble in water. Its alcoholic solution yields no characteristic colour with ferric chloride. When taken internally its action is very similar to that of guaiacol, but it is less liable to derange the stomach. It is employed as an expectorant in the treatment of tuberculosis and bronchitis, and also as an intestinal antiseptic in the treatment of typhoid fever and intestinal indigestion (D. R. P. 99057, 58129, 117346, of 1901; D. R. P. 224160; Einhorn, Chem. Zentr. 1910, ii, 518).

Guaiacol chlorocarbonate is a colourless oil; b.p. $112^{\circ}/25$ mm. It is prepared by the interaction of antipyrine, carbonyl chloride, and guaiacol (D. R. P. 117624 of 1901; Einhorn, D. R. P. 224108, 1910; Chem. Zentr. 1910, ii, 517).

Guaiacol carboxylic acid $C_6H_4(OH)(OMe)CO_2H$ is formed by the action of carbon dioxide on sodium derivative of guaiacol, previously heated; the product is heated for some time, and is then acidified with hydrochloric acid, the free acid being recrystallised from water or dilute alcohol. It is a white, odourless crystalline powder; m.p. 148° - 150° . It has a bitter taste, is readily soluble in hot water, and its aqueous solution is coloured blue by ferric chloride. The acid and its salts have been recommended as antiseptics and antirheumatics (Pharm. J. 1890, 977).

Guaiacol, when oxidised with laccase, yields

tetraquaiacoinone $\left\{ O(C_6H_3\cdot OMe)_2O \right\}_2$, a fine crystal-

line powder, m.p. 135° - 140° , having a purplish-red colour with a faint green metallic lustre. It is insoluble in water, but gives mahogany-red solutions with chloroform and with acetic acid. It also forms coloured solutions in alkalis (Bertrand, Compt. rend. 1903, 137, 1269).

Dimethylamino ϵ -guaiacylamyl ether, the corresponding piperido derivative and the piperido- γ -guaiacyl-propyl ether are formed by the interaction of a halogen hydrocarbon alkyl ether of guaiacol with a secondary amine, thus:

(where x =halogen). They are employed in medicine as anæsthetics (D. R. P. 184986; Frdl. 1905-7, 1050).

Hexamethylenetetraminetriguaiacol crystallises in brilliant needles, which become soft at 80° , and melt to a turbid liquid at about 95° . When distilled in steam it yields guaiacol (Eng. Pat. 24072, 1908; J. Soc. Chem. Ind. 1909, 490).

Chloroacetyl guaiacol $OMeC_6H_4\cdot O\cdot CO\cdot CH_2Cl$ is prepared by treating a mixture of guaiacol

monochloroacetic acid and pyridine with phosphorus oxychloride. It forms white needles, m.p. 58°–60° (Einhorn and Hentz, *l.c.*).

Guaiacol chloroformic ester is a colourless oil; b.p. 112°/25 mm. (D. R. P. 117624; Frdl. 1900–02, 1165).

Benzyl guaiacol is a yellow, beautifully fluorescent oil; b.p. 269°–270°/430 mm. (Bosco-grande, Chem. Zentr. 1898, i. 207).

Guaiacol picrate forms orange-red needles; m.p. 80°. Many other guaiacol derivatives have been prepared, some of which have been recommended for use in medicine (Eng. Pat. 5856, 1894; Ruhemann, Chem. Soc. Trans. 1902, 421; D. R. P. 120558; Frdl. 1900–02, 1112; D. R. P. 157355; Frdl. 1902–04, 616; Knapp and Suter, Chem. Zentr. 1904, i. 391; Moureu and Lazenec, Compt. rend. 1906, 142, 894; Bischoff, Ber. 1906, 39, 3846; Gattermann, Annalen, 1907, 357, 313; Fourneau, J. Pharm. Chim. 1910, [vii.], 1, 55, 97; Manchot, Ber. 1910, 43, 949; Wohl and Berthold, *ibid.* 2175; Hoffmann, D. R. P. 255924; Chem. Zentr. 1910, ii. 1105).

A number of azo derivatives of guaiacol are described by Leonardi (Atti R. Accad. Lincei. 1907 [v.] 16, ii. 639); some nitro and amino derivatives by Reverdin and Crepieux, Ber. 1903, 36, 2257; 1906, 39, 4232; Paul, *ibid.* 2773; Kühling, *ibid.* 1905, 38, 3007; Fichter and Schwab, *ibid.* 1906, 39, 3339; Pollecoff and Robinson, Chem. Soc. Trans. 1918, 113, 645.

Thioguaiacol and *thioguaiacol xanthate* have been prepared by Mauthner (Ber. 1906, 39, 1347).

Guaiacol forms mono-, di-, tri-, and tetra-halogen derivatives (Cousin, Compt. rend. 1898, 127, 759; Tassily and Lerride, *ibid.* 1907, 144, 757; Bull. Soc. chim. 1908, [iv.] 3, 124; Mameli Gazz. chim. ital. 1907, 37, ii. 366; Robertson, Chem. Soc. Trans. 1908, 791). The iodo derivatives are said to be applicable to medicine (Mameli and Pinna, Chem. Zentr. 1907, ii. 2044).

Guaiacol phosphite, m.p. 75–5°, is a white crystalline powder, with a piquant non-caustic taste and slight odour, soluble in most organic solvents, but only sparingly in water (Bollard, D. R. P. 95578; J. Soc. Chem. Ind. 1897, 632; Ellis, Eng. Pat. 27527, 1896). Its medicinal properties are similar to those of guaiacol.

Another *guaiacol phosphite*, m.p. 59°, is described by Dupuis (Compt. rend. 1910, 150, 622).

Guaiacol phosphate ($C_6H_4OMe)_3PO_4$ is prepared by the interaction of phosphorus oxychloride and sodium derivative of guaiacol. It forms colourless crystals; m.p. 98°, insoluble in water and alcohol, but soluble in ether, chloroform, and acetone. It is used as an intestinal antiseptic and in hectic fever.

A number of other phosphorus compounds of guaiacol are described by Auger and Dupuis (Compt. rend. 1908, 146, 1151), and by Dupuis (*ibid.* 1910, 150, 622).

Guaiacol-cacodylate $AsMe_2O_2 \cdot C_6H_4OMe$ is a white hygroscopic, crystalline, very unstable salt (Astruc and Murco, J. Pharm. Chim. 12, 553).

GUAIAZONE *v.* *Guaiacum*, art. RESINS.

GUAIACONIC ACID *v.* *Guaiacum*, art. RESINS.

GUAIACAM *v.* RESINS.

GUAIAMALTIN. Trade name for a mixture of potassium sulpho-guaiacolate and malt extract.

GUAIAPEROL. An addition product of guaiacol and piperidine $C_5H_{11}N(C_7H_8O_2)_2$.

GUAIARETIC ACID $C_{22}H_{24}O_4$ an optically active unsaturated acid, related to eugenol, contained in guaiacum resin and resins.

GUAITHOL. A condensation product of catechol and ethyl alcohol $C_6H_4OC_2H_5.OH$.

GUAIENE 2-3-dimethyl naphthalene, obtained by dry distillation of guaiacum resin. *v.* *Guaiacum*, art. RESINS.

GUAIAL *v.* *Guaiacum*, art. RESINS.

GUANIDINE $HN : C(NH_2)_2$ occurs in small quantities in etiolated vetch seedlings, 3 kilos. of dried material yielding 1 gram of the nitrate (Schulze, Ber. 1892, 25, 658); in beet juice (Lippmann, *ibid.* 1896, 29, 2651; in *Boletus Edulis* (Winterstein, Landw. Vers.-Stat. 79, 80, 541); and in the developing embryo chick (Burns, Bio-Chem. J. 1916, 10, 263). Guanidine and methyl guanidine are found in the blood and urine in cases of tetania parathyreopriva (Burns and Sharpe, Quart. J. Esp. Physiol. 1917, 10, 203).

Guanidine was first prepared by Strecker (Annalen, 1861, 118, 159) by oxidising guanine with potassium chlorate and hydrochloric acid; and it is obtained in small quantity by oxidising egg albumen with potassium permanganate, or gelatin with barium or calcium permanganate (Lossen, J. Pharm. Chim. [iii.] 31, 32; Kutscher and Kickgraf, Sitzungsber. K. Akad. Wiss. Berlin, 1903, 28, 624); it is formed synthetically (1) by heating biuret and hydrogen chloride at 160°–170° (Finckh, Annalen, 1862, 124, 332); (2) from chloropierin and alcoholic ammonia at 100° (Hofmann, Ber. 1868, 1, 145); (3) from ethyl orthocarbonate and aqueous ammonia at 150° (Hofmann, Annalen, 1866, 139, 111); (4) from carbonyl chloride and ammonia (Bouchardt, Zeitsch. Chem. 1870, 58); (5) from ammonium chloride and alcoholic cyanamide at 100° (Erlenmeyer, Annalen, 1868, 146, 259); (6) from cyanogen iodide and alcoholic ammonia at 100° (Bannow, Ber. 1871, 4, 161); (7) by the action of *aqua regia* on dicyanodiamide, when a quantitative yield of the nitrate is obtained (Ulpiani, D. R. P. 209431); reduction of tetranitro methane yields guanidine hydrochloride (Rakshit, J. Amer. Chem. Soc. 1914, 36, 1221; *see also* Stähler, Ber. 1914, 47, 909).

Guanidine is usually prepared by heating ammonium thiocyanate for 20 hours at 180°–190°, treating the fused mass with water and allowing the guanidine thiocyanate to crystallise from the solution; it is then purified by animal charcoal and recrystallised from alcohol and water. The thiocyanate is converted into the carbonate by treating the concentrated aqueous solution with one equivalent of potassium carbonate, the solution is evaporated and the residue extracted with hot alcohol in which the guanidine carbonate is insoluble, and this is afterwards recrystallised from water (Delitsch, J. pr. Chem. 1871, [ii.] 9, 2; Volhard, *ibid.* 15; Krall, Chem. Soc. Trans. 1913, 103, 1378; Sharpe, J. Biol. Chem. 1917, 28, 399). According to Goldberg, Siepermann, and Flemming (D. R. P. 1898, 97820), a better yield of guanidine salts is obtained when the ammonium thiocyanate is mixed with wood charcoal and the oxide or salt of a heavy metal, and the mixture heated in a current of ammonia

or guanidine thiocyanate can be prepared by heating the thiocyanate of a heavy metal under pressure in an atmosphere of ammonia at 180°

Levene and Senior (J. Biol. Chem. 1916, 25, 623) recommend the preparation of guanidine sulphate, starting with dicyanodiamide, and Schmidt (Arch. Pharm. 1916, 254, 626) prepares it from thio urea and from cyanamide (*see* D. R. P. 1909, 242,216 and 1912, 267,380); preparation from dicyanodiamide or its equivalents (Lidholm, Ber. 1913, 46, 156; Caro, Zeitsch. angew. Chem. 1910, 23, 2405).

According to Werner and Bell (Chem. Soc. Trans. 1920, 117, 1133), the best method of preparation consists in heating an intimate mixture of dicyanodiamide and dry ammonium thiocyanate to 120° for some hours, treating the melted mass with water, filtering, and concentrating the solution, and recrystallising the product; 90 p.c. yields are thus obtained. For further details the original memoir must be consulted.

Guanidine is a deliquescent crystalline solid, readily soluble in alcohol or water; it is volatile and strongly alkaline, absorbs carbon dioxide from the air and forms crystalline salts. The thermal value of the basic function of guanidine is +32.1 Cal., intermediate between that of barium hydroxide +31.7 Cal. and sodium hydroxide +36.4 Cal. (Matignon, Compt. rend. 1892, 113, 1432). Guanidine is decomposed into ammonia and urea on boiling with baryta water or dilute sulphuric acid (Ossikowsky, Bull. Soc. chim. 1872, [ii.] 18, 161; Baumann, Ber. 1873, 6, 1376); and is completely decomposed into carbon dioxide and ammonia by heating with concentrated acids or alkalis. Guanidine is decomposed, evolving two-thirds of its nitrogen, when mixed with sodium hypochlorite or hypobromite (Fenton, Chem. Soc. Trans. 1879, 14). The salts of guanidine, like the free base, part with their nitrogen quantitatively unless the hydrogen of the amino group has been substituted by $-\text{COMe}$, $-\text{COPh}$ or $-\text{CONH}_2$ (Cordier, Monatsh. 1912, 33, 759; *ibid.* 1914, 35, 9; *cf.* Kossel and Cameron, Zeitsch. physiol. Chem. 1911-12, 76, 457).

When guanidine hydrochloride is heated at 180° , ammonia is evolved and *biguanide* is formed, the reaction being similar to the formation of biuret from urea:

In its physiological action, guanidine is highly toxic; doses smaller than poisonous ones are in rabbits excreted unchanged in the urine (Pommerenig, Beitr. Chem. Physiol. Path. 1902, i, 561; Garino, Arch. d. Farm. sperim. 22, 229, from Chem. Zentr. 1916, 11, 1047). The injection of guanidine hydrochloride into a rabbit is followed by symptoms which are almost identical with those of tetanus produced by extirpation of the parathyroid glands (Watanabe, J. Biol. Chem. 1918, 33, 253; 34, 51, 65, 73; 36, 531). Guanidine acts on

frogs' muscles, producing spontaneous twitching and affecting their contractility, and it is supposed that the guanidine acts by combining with two different substances in the muscle, one of which is responsible for the twitching, and the other for the changes in contractility (Camis, J. physiol. 1909, 39, 73; Fühner, Arch. F. exp. Pathol. u. Pharm. 65, 401-27; Langley, J. of Physiol. 1916, 50, 419; Meighan, J. of Physiol. 1917, 51, 51). Although guanidine does not appear to be a normal oxidation product of arginine in the body (Pommerenig, *l.c.*), it is found among the products of pancreatic auto-digestion (Kutscher and Otori, Zeitsch. physiol. Chem. 1904, 43, 93). Small quantities of guanidine, 0.1 per thousand, are injurious to chlorophyllous plants, whilst fungi utilise it as a source of nitrogen but not of carbon (Kawakita, Bull. Coll. Agr. Tōkyō, 1904, 6, 181; Kossawitz, Chem. Zentr. 1913, 1, 1279).

Many salts of guanidine give a yellowish-white flocculent precipitate with Nessler's reagent, which can thus be used as a test for small quantities of the salts of the base; a 0.05 p.c. aqueous solution of guanidine nitrate gives a bulky precipitate and a 0.01 p.c. solution is rendered turbid (Schulze, Ber. 1892, 25, 661). 22.8 parts of guanidine phosphotungstate are soluble in 100 parts of a mixture of acetone (4 vols.) with water (3 vols.) (Wechsler, Zeitsch. physiol. Chem. 1911, 73, 141; Drummond, Biochem. J. 1918, 12, 5). Another test for guanidine is the development of a deep yellow to orange-red coloration with alkali hypochlorites (de Coninck, Compt. rend. 1898, 126, 142). Certain guanidine derivatives precipitate colouring matter (Suida, Zeitsch. physiol. Chem. 1910, 68, 381). Guanidine is usually estimated as the picrate, the salt being collected on a Gooch asbestos filter, dried at 110° and weighed (Vozarik, Zeitsch. angew. Chem. 1902, 15, 670); or it can be converted into the strongly alkaline carbonate and titrated with standard acid (Grossmann and Schück, Chem. Zeit. 1906, 30, 1205).

Guanidine forms crystalline salts with mineral and with organic acids; it also forms characteristic double salts. The *hydrochloride*

forms double salts with *mercuric chloride*

(Byk, J. pr. Chem. [ii.] 20, 233); with *gold chloride* $\text{CH}_5\text{N}_3\cdot\text{HCl}\cdot\text{AuCl}_3$, deep yellow, sparingly soluble needles (Hofmann, Ber. 1868, 1, 146); with *platinic chloride* $(\text{CH}_5\text{N}_3\cdot\text{HCl})_2\cdot\text{PtCl}_4$, yellow needles, soluble in water, sparingly so in alcohol (Strecker, Annalen, 1861, 118, 160); with *platinic iodide* (Datta and Ghosh, J. Amer. Chem. Soc. 1914, 36, 1017). The *nitrate*, $\text{CH}_5\text{N}_3\cdot\text{HNO}_3$, crystallises in large plates, m.p. 214° , 10.75 parts dissolve in 100 parts of water at 15.9° . The *compound* with silver nitrate $\text{CH}_5\text{N}_3\cdot\text{AgNO}_3$ crystallises in needles, whilst the *compounds* with palladous trichloride and tribromide are brown or red crystals (Gutbier and Fellner, Zeitsch. anorg. Chem. 1916, 95, 169). The *nitrite* $\text{CH}_5\text{N}_3\cdot\text{HNO}_2$ forms glittering prisms, m.p. $76^\circ\text{--}78.5^\circ$ (Lossen, Annalen, 1891, 265, 129). The *sulphate* $(\text{CH}_5\text{N}_3)_2\cdot\text{H}_2\text{SO}_4$ crystallises in the regular system and is soluble in water (Bodewig,

J. 1876, 763); it forms a double salt with *aluminium sulphate*

crystallising in large, well-developed hexagonal prisms belonging to the scalenohedral class of the rhombohedral system, and having sp.gr. 1.806 at 13.5° (Ferraboschi, Proc. Camb. Phil. Soc. 1908, 14, 471). The *carbonate* $(\text{CH}_5\text{N}_3)_2 \cdot \text{H}_2\text{CO}_3$ forms octahedral or tetragonal prisms; sp. gr. 1.238–1.251 (Schröder, Ber. 1880, 13, 1072). The *metaphosphate* $\text{CH}_5\text{N}_3 \cdot \text{HPO}_3$ forms a fine crystalline precipitate (Pohl, Zeitsch. physiol. Chem. 1889, 13, 296). Guadinium molybdoarsenate $(\text{CN}_5\text{H}_9)_3[\text{As}(\text{Mo}_2\text{O}_7)_3]$, yellow crystals, (Rosenheim, Weinberg, Puisker, Zeitsch. anorg. Chem. 1913, 84, 217). The *perchromate*

forms small brownish-yellow, double-refracting prisms, and yields the usual blue solution with ether and dilute sulphuric acid (Hofmann and Buchner, Ber. 1909, 42, 2773). The chlorate, white crystals, decomp. 148° (Datta, Choudhury, J. Amer. Chem. Soc. 1916, 38, 1079). The *thiocyanate* $\text{CH}_5\text{N}_3 \cdot \text{HCNS}$ has m.p. 118°, and 100 parts of water dissolve 73 parts at 0°, or 134.9 parts at 15° (Engel, Bull. Soc. chim. 1885, 44, 424). For preparation of the thiocyanate from ammonium thiocyanate see Krall (Chem. Soc. Trans. 1913, 103, 1378). The *platinothiocyanate* $(\text{CH}_5\text{N}_3)_2 \cdot \text{H}_2\text{Pt}(\text{CNS})_2$ forms beautiful red crystals that blacken at 170°–175° (Guarschi, Chem. Zentr. 1891, ii. 620). The *platinibromide* $\text{C}_2\text{H}_{12}\text{MoPtBr}_6$ lustrous red crystals of complicated structure (Guthiera Ransch, J. pr. Chem. 1913, [iii], 88, 409–24). The *cyanurate* $(\text{CH}_5\text{N}_3)_3 \cdot (\text{CNHO})_3$ forms silky needles (Bamberger, Ber. 1887, 20, 71). The *dioxalate* $\text{CH}_5\text{N}_3 \cdot \text{C}_2\text{H}_2\text{O}_4 \cdot \text{H}_2\text{O}$ is sparingly soluble (Strecker, l.c.). The *picrate* $\text{CH}_5\text{N}_3 \cdot \text{C}_6\text{H}_2(\text{NO}_2)_3\text{OH}$ is a sparingly soluble, yellow, crystalline salt, 1 part dissolves in 2630 parts of water at 9°, and it does not melt at 280° (Emich, Monatsh. 1891, 12, 24). According to von Cordier (Chem. Zentr. 1906, i. 340), guanidine picrate exhibits stereoisomerism. The salt, as usually prepared, forms dark yellow plates that, owing to repeated twinning, have a hook-like structure, but when guanidine prepared by decomposing methylguanidine sulphate with barium hydroxide is used, the picrate crystallises in rosettes of bright yellow needles. The two forms are identical in composition, sp.gr., temperature of decomposition, and electric conductivity, but differ in colour, crystalline form and solubility, 100 parts of water dissolve 0.037 part of the plates at 0°, 0.061 at 20°, and 0.574 at 80°. The solubility of the needles is 0.043, 0.060, 0.800 at these temperatures respectively. One form cannot be converted into the other by crystallisation, and the author suggests that they are stereoisomerides, the plates being the stable modification, $\text{NH}_2 \cdot \text{C}(\text{NH}) \cdot \text{NH}_2 \cdot \text{C}_6\text{H}_3\text{O}_7\text{N}_3$, and the needles the labile

has m.p. 200°, the *p*-toluene-sulphonate, m.p. 206°, and the α - and β -naphthalenesulphonates, m.p. 257° (Remsen and Garner, Amer. Chem. J. 1901, 25, 173). The 4-nitroacetylanthravilale has m.p. 247° (corr.) (Bogert and Klaber, J.

Amer. Chem. Soc. 1908, 30, 807). The *acetate* $\text{CH}_5\text{N}_3 \cdot \text{C}_2\text{H}_3\text{O}_2$ forms shining needles, m.p. 229°–230° (Ostrogovich, Gazz. chim. ital. 1897, 27, i. 223). The *picrolonate* $\text{CH}_5\text{N}_3 \cdot \text{C}_{10}\text{H}_8\text{O}_5\text{N}_4$ is soluble in alcohol (Schenck, Zeitsch. physiol. Chem. 1905, 44, 427). A number of salts of guanidine (*guanidinium* salts) with iso- and hetero-poly acids have been prepared (Gutbier, Mehler and Ottenstein, Zeitsch. anorg. Chem. 1914, 89, 313, 333, 343; Rosenheim and Garfunkel, Ber. 1911, 44, 1865; Rosenheim and Felix, Zeitsch. anorg. Chem. 1913, 79, 292; Rosenheim and Schwer, *ibid.* 1914, 89, 224; Rosenheim and Traube, *ibid.* 1915, 91, 75; Rosenheim, Zeitsch. elektro. Chem. 1911, 17, 694).

Allyl Malonyl Guanidine

m.p. 265°–266°, crystallises from acetic acid in hexagonal plates (Johnson and Hill, Amer. Chem. J. 1911, 46, 537).

For guanido-glycylglycine and the introduction of guanidine into the polypeptide molecule (see Clementi, Gazz. chim. ital. 1915, 45, 56–59, and 276–280).

Guanamines. When the guanidine salts of the first seven of the fatty acid series are heated at 220°–230°, water and ammonia are eliminated and heterocyclic bases called *guanamines* are formed: these are well-characterised crystalline compounds. *Formoguanamine*

melts and decomposes at a high temperature;

acetguanamine $\text{CH}_3 \cdot \text{C} \begin{array}{c} \text{N} : \text{C}(\text{NH}_2) \\ \text{N} : \text{C}(\text{NH}_2) \end{array} > \text{N}$ melts at 265°; *propionoguanamine* blackens at 300°; *acanthoguanamine* melts at 130° (Nencki, Ber. 1874, 7, 1584; Haaf, J. pr. Chem. 1891, [ii.] 43, 75).

Cyanoguanidine (dicyandiamide)

results from the polymerization of cyanamide; it can be prepared from calcium or sodium cyanamide (Chem. Zentr. 1905, 11, 1530), m.p. 205°. It is a neutral body. Ammonia converts it into diguanide; dilute acids into guanyl urea. Heated with hydrazine hydrochloride in alcoholic solution it gives guanazole

A mixture of cyanoguanidine and acetamidide hydrochloride gradually heated to 230° yields 4 : 6-diamine-2-methyl-1 : 3 : 5-triazine dihydrochloride, and, similarly, cyanoguanidine and benzamidide yield the corresponding phenyl derivative, m.p. 225°; or the same triazine derivatives may be obtained on heating cyanoguanidine with aceto nitrite in a sealed tube for three hours at 225°–230°, or with benzo nitrite for four or five hours at 190°–200° (Ostrogovich, Atti. R. Accad. Lincei, 1911, [v.], 20, 1, 182, and 249).

When cyanoguanidine is heated with an ethereal solution of thioacetic acid until the evolution of hydrogen sulphide ceases, 6-thiol-2-inimo-4-methyl-1 : 3 : 5-triazine is formed; small colourless needles which decompose without

melting (Ostrogovich, *ibid.* 1912, [v.], 21, 1, 213).

Chloroguanidine CH_2ClN_3 , obtained by the action of bleaching powder solution on guanidine carbonate in ice water, forms a pale yellow crystalline powder that decomposes at 150° (Kamenski, Ber. 1878, 11, 1602).

Bromoguanidine CH_2BrN_3 , formed from equimolecular proportions of bromine and guanidine carbonate, crystallises in yellow needles. By the action of 3 mols. bromine on 1 mol. guanidine carbonate, the compound

is formed, crystallising in dark red prisms. The corresponding *iodine compound* $\text{CH}_2\text{N}_3\cdot\text{HI}\cdot\text{I}_2$ crystallises in prisms the colour of iodine (Kamenski, *l.c.*).

Nitroguanidine $\text{NH}:\text{C}(\text{NH}_2)\text{NH}\cdot\text{NO}_2$ was first prepared by Jouselin (Compt. rend. 1877, 85, 548; 1879, 88, 814, 1086) by the action of fuming nitric acid and nitric oxide on guanidine nitrate, and called by him nitrosoguanidine. Pellizzari (Gazz. chim. ital. 1891, 21, ii. 405) showed that it was the *nitro* compound, and his results were confirmed by Thiele (Annalen, 1892, 270, 1), who also prepared it by the action of fuming nitric acid and sulphuric acid on guanidine thiocyanate. It crystallises from water in colourless needles, melts and decomposes at 230° with evolution of ammonia; it dissolves in 372–375 parts of water at 19.3° , or in 11 parts of boiling water. The heat of combustion at constant pressure is $+210.3$ Cal. and the heat of formation from its elements is $+22$ Cal. (Matignon, Compt. rend. 1892, 114, 1432). The *silver* derivative $\text{CH}_2\text{N}_4\text{O}_2\text{Ag}$ is colourless and almost insoluble in water; the *nitrate* $\text{CH}_4\text{O}_2\text{N}_4\cdot\text{HNO}_3$ is crystalline and melts at 147° ; the *hydrochloride* $\text{CH}_4\text{O}_2\text{N}_4\cdot\text{HCl}$ crystallises in plates or prisms.

Nitrosoguanidine $\text{NH}:\text{C}(\text{NH}_2)\text{NH}\cdot\text{NO}$ is obtained by the partial reduction of nitroguanidine with zinc dust and sulphuric acid. It forms yellow needles, explodes violently at 160° – 165° , is soluble in alkalis and reprecipitated by carbon dioxide; it also gives the Liebermann reaction. The alkali solutions give a beautiful purple coloration with ferrous salts. The *silver salt* $\text{CH}_3\text{ON}_4\text{Ag}$ is a colourless explosive precipitate; the *copper salt* $(\text{CH}_3\text{ON}_4)_2\text{Cu}$ is reddish-brown, and the *nickel salt* $(\text{CH}_3\text{ON}_4)_2\text{Ni}$ is vermilion-red (Thiele, Annalen, 1893, 273, 133). According to Hantzsch, Schumann, Engler (Ber. 1899, 32, 575, 1703), nitrosoguanidine is a true nitrosamine and its constitution is represented by the formula $\text{NH}:\text{C}(\text{NH}_2)\text{NH}\cdot\text{NO}$, since it has a neutral reaction, yields mainly nitrous acid and not nitrogen when decomposed by acids, and does not interact with phosphorus pentachloride or acetyl chloride. On the other hand, Whiteley (Chem. Soc. Trans. 1903, 31) and Tschugaeff (Ber. 1906, 39, 3383) consider that the coloured metallic derivatives are salts of the tautomeric diazo-hydrate, form $\text{HN}:\text{C}(\text{NH}_2)\text{N}:\text{N}\cdot\text{OH}$.

Aminoguanidine $\text{HN}:\text{C}(\text{NH}_2)\text{NH}\cdot\text{NH}_2$, is obtained by reducing nitroguanidine with zinc dust and acetic acid at 40° until a test portion develops no coloration with ferrous sulphate and an alkali (Thiele, Annalen, 1892, 270, 23). The mixture is filtered, the filtrate evaporated till it is only feebly acid, and the aminoguanidine bicarbonate precipitated in the cold by adding

a concentrated solution of alkali bicarbonate (D. R. P. 59241). Also prepared by heating an alcoholic solution of hydrazinehydrochloride, and cyanamide in a reflux apparatus (Pellizzari and Cuneo, Gazz. chim. ital. 1894, 24, i. 450; Pellizzari and Gaiter (Gazz. chim. ital. 1914, 44, 11, 72). A yield of 81 p.c. of the theoretical is obtained by the electrolytic reduction of the nitro compound, suspended in water slightly acidified with sulphuric acid, using a tin cathode and a current density of 250 amperes per square metre and a temperature of 10° (Boehringer and Söhne, D. R. P. 167637); cf. also Ponzio and Gastaldi (Gazz. chim. ital. 1914, 44, 1, 257).

Aminoguanidine is crystalline, soluble in water or alcohol, decomposes on boiling with dilute acids or alkalis, yielding first semicarbazide and finally ammonia, carbon dioxide, and hydrazine (Curtius, Ber. 1896, 29, 759). For the toxicity of guanidine and its amino derivatives, v. Garino (Arch. Farm. sper. 1916, 22, 229). Aminoguanidine forms crystalline salts with mineral acids: the *hydrochloride* $\text{CH}_6\text{N}_4\cdot\text{HCl}$ forms large prisms, m.p. 163° ; the *hydrobromide*, prismatic needles, m.p. 149° (decomp.); the *double salt* with platinic chloride

is a yellow precipitate, m.p. 145° – 146° ; the *nitrate* $\text{CH}_6\text{N}_4\cdot\text{HNO}_3$ forms large shining plates, m.p. 144° ; 100 parts of water dissolve 12.01 parts at 15.9° ; the *sulphate* $(\text{CH}_6\text{N}_4)_2\cdot\text{H}_2\text{SO}_4\cdot\text{H}_2\text{O}$ crystallises in needles, m.p. 207° – 208° ; the *bisulphate* $\text{CH}_6\text{N}_4\cdot\text{H}_2\text{SO}_4$ crystallises in large plates, m.p. 161° ; the *picrate* $\text{CH}_6\text{N}_4\cdot\text{C}_6\text{H}_3\text{O}_2\cdot\text{N}_3$ is precipitated as yellow needles from hot water. The *copper compounds* $\text{Cu}(\text{CH}_5\text{N}_4)_2\cdot 2\text{HNO}_3$ and $\text{Cu}(\text{CH}_5\text{N}_4)_2\cdot\text{H}_2\text{SO}_4$ are violet crystalline precipitates; the *bicarbonate* $\text{CH}_6\text{N}_4\cdot\text{H}_2\text{CO}_3$ (Thiele, Annalen, 1898, 302, 332) melts at 172° and is almost insoluble in cold water.

Acetaminoguanidine $\text{CH}_5\text{N}_4(\text{C}_2\text{H}_3\text{O})$ forms a crystalline *nitrate*, m.p. 85° – 90° and *picrate*; *formylaminoguanidine nitrate*

melts at 143° , the *picrate* melts at 193° ; *oxalylaminoguanidine* $\text{HN}:\text{C}(\text{NH}_2)\text{NH}\cdot\text{NH}\cdot\text{CO}\cdot\text{CO}_2\text{H}$ melts at 231° – 232° (Thiele and Manchot, Annalen, 1898, 303, 37).

Aminoguanidine and its alkyl and aryl derivatives contain the grouping $-\text{NH}\cdot\text{NH}_2$, present in hydrazines, and semicarbazide, and like them readily form condensation products with aldehydes, ketones, sugars, and ketonic acids; these are usually well characterised crystalline compounds, forming crystalline salts with mineral and organic acids. For the condensation products with aldehyde, chloraldehyde, chloral, v. Thiele and Dralle (Annalen, 1898, 302, 278); with benzaldehyde, v. Thiele (*ibid.* 1892, 270, 1), Wedekind (Ber. 1897, 30, 444); with diacetyl, acetylacetone, acetonylacetone, v. Thiele and Dralle (*l.c.*); with galactose, glucose, and lactose, v. Wolff (Ber. 1895, 28, 2613); with glyoxylic acid, v. Thiele and Dralle (*l.c.*), Doebner and Gärtner (Annalen, 1901, 315, 1); with pyruvic acid, v. Wedekind and Bronstein (*ibid.* 1899, 307, 297). For the preparation and properties of *alkyl* and *aryl* substituted derivatives of aminoguanidine, v. Pellizzari and Cuneo (Gazz. chim. ital. 1894, 24, i. 450), Pellizzari and Rickards (*ibid.* 1901, 31,

i. 526). Sodium nitrite and a solution of aminoguanidine dinitrate yield a β -nitroso hydrazine derivative

$\text{NH}_2 \cdot \text{C}(\text{NH}) \cdot \text{NH} \cdot \text{NH} \cdot \text{N} = \text{N} \cdot \text{C}(\text{NH}) \cdot \text{NH} \cdot \text{NH} \cdot \text{NO}$ which is extremely stable. The sulphate $(\text{C}_2\text{H}_5\text{N}_{10})_2\text{SO}_4$ crystallises in long colourless prisms. Hofmann, Hock, Kirmreuther (Annalen, 1911, 380, 131).

Diaminoguanidine $\text{HN} \cdot \text{C}(\text{NH} \cdot \text{NH}_2)_2$ does not exist in the free state; its *hydrobromide* $\text{CH}_3\text{N}_5\text{HBr}$ is formed by the action of cyanogen bromide (1 mol.) on hydrazine (2 mols.); it crystallises in plates, m.p. 167° ; the *picrate*, $\text{CH}_3\text{N}_5\text{C}_6\text{H}_3\text{O}_7\text{N}_3$, melts at 191° ; the *hydrochloride* at 185° ; the *nitrate* at 143° ; the *platinchloride* at 172° – 173° ; all the salts reduce Fehling solution and ammoniacal silver nitrate solution. *Dibenzylidenediaminoguanidine*

yellow crystals, m.p. 180° ; *disalicylidenediaminoguanidine* $\text{AH} : \text{C}(\text{AH} : \text{N} : \text{CH} \cdot \text{C}_6\text{H}_4\text{OH})_2$, yellow prisms, m.p. 201° – 203° ; the *hydrobromide* melts at 240° . *Dibenzoyldiaminoguanidine*

m.p. 210° – 211° ; the *hydrobromide* melts at 243° , and the *hydrochloride* at 230° , the *nitrate* at 211° – 212° (Pellizzari and Cantoni, Gazz. chim. ital. 1905, 35, i. 291); Pellizzari and Gaiter (*l.c.*); Gaiter (*ibid.* 1915, 45, 450).

Triaminoguanidine $\text{NH}_2\text{N} : \text{C}(\text{NH} \cdot \text{NH}_2)_2$ does not exist in the free state; its salts may be obtained by heating concentrated solutions of the salts of either guanidine or its amino, or its diamino derivative with hydrazine hydrate. The salts readily react with aldehydes. The *nitrate* colourless needles has m.p. 210° (decomp.); the *hydrochloride*, m.p. 231° ; *tribenzylidenediaminoguanidine*, small yellow needles, m.p. 198° ; *triaminoguanidinedithiocyanate*, m.p. 136° ; the *picrate* $\text{CH}_3\text{N}_6\text{C}_6\text{H}_3\text{O}_7\text{N}_3$, m.p. 171° , Pellizzari and Gaiter (*l.c.*).

Dihydroxyguanidine hydrobromide

is formed by the interaction of cyanogen bromide and hydroxylamine in methyl alcohol and ether at -20° ; it forms colourless, flat, hygroscopic needles that decompose at 95° (Wieland, Ber. 1905, 38, 1445).

Methylguanidine $\text{HN} : \text{C}(\text{NH}_2)\text{NHMe}$ has been isolated from extract of muscle (Gulewitsch, Zeitsch. physiol. Chem. 1906, 47, 471; see also Ewins (Bio-Chem. J. 1916, 103); for its presence in urine of dogs see Koch (J. of Biol. Chem. 1913, 15, 313)), and is prepared by boiling creatine with mercuric or lead oxide and dilute sulphuric acid (Dessaignes, Annalen, 1854, 92, 407; 1856, 97, 340). It can be synthesised from methylamine hydrochloride and cyanamide (Erlenmeyer, Ber. 1870, 3, 896). It is a strongly alkaline, volatile, crystalline substance, and liberates ammonia and methylamine on heating with potassium hydroxide. The *aurichloride* $\text{C}_2\text{H}_7\text{N}_3\text{HCl} \cdot \text{AuCl}_3$ melts at 198° – 200° ; the *platinchloride* $(\text{C}_2\text{H}_7\text{N}_3\text{HCl})_2 \cdot \text{PtCl}_4$ melts at 194° – 195° (Schenck, Arch. Pharm. 1909, 247, 466). The *oxalate* $(\text{C}_2\text{H}_7\text{N}_4)_2 \cdot \text{C}_2\text{H}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ is crystalline and soluble in water. The *picrate* crystallises from water in two distinct modifications (Gulewitsch, *l.c.*). The *picrolonate*

melts at 291° (Wheeler and Jamieson, J. Biol. Chem. 1908, 4, 111). Eleven methylated guanidines are possible: three of these, containing the grouping $\text{NMe} : \text{C}(\text{NH}_2)\text{N} =$ have not been obtained; *S*- α - β -Trimethylguanidine, is formed whenever the conditions are in any way favourable (Schenck, Arch. Pharm. 1911, 249, 463; *ibid.* 1912, 250, 306; Zeitsch. physiol. Chem. 1912, 77, 328).

For other *alkyl* and *aryl* substituted derivatives of guanidine, some of which have therapeutic properties, v. Strakosch (Ber. 1872, 5, 692); Tatarinow (J. 1879, 401); Noah (Ber. 1890, 23, 2196); Hofmann (*ibid.* 1869, 2, 601); Fischer (*ibid.* 1897, 30, 2414); Alway and Vail (Amer. Chem. J. 1902, 28, 158); Kämpf (Ber. 1904, 37, 1681); Reidel (D. R. PP. 1892, 66550, 1898, 104361); Schmidt (Arch. Pharm. 1911, 249, 465, and 473; *ibid.* 1912, 250, 311). For *acyl* derivatives see Traube (Ber. 1910, 43, 3586); Pierrou (Compt. rend. 1910, 151, 1364); Wheeler and Johnson (Amer. Chem. J. 1901, 26, 417). Formyl guanidine

has m.p. 178° (decomp.); acetyl guanidine, m.p. 185° ; acetyl guanidine hydrochloride, m.p. 145° (Korndörfer, Arch. Pharm. 1903, 241, 449, gives m.p. 142°); benzoyl phenylguanidine $\text{C}_6\text{H}_5\text{CONHC}(\text{NH})\text{NHPh}$, m.p. 91° – 92° *m*-Tolylbenzoylguanidine

begins to soften 71° , the hydrochloride melts at 170° .

Guanidine forms condensation products with *dicarboxylic acids* (Traube, Ber. 1893, 26, 2551; Ruheman and Stapleton, Chem. Soc. Trans. 1900, 805; Kaess and Gruszkiewicz, Ber. 1902, 35, 3600); with β -*ketonic acids* (Jaeger, Annalen, 1891, 262, 365); with β -*diketones* (Evans, J. pr. Chem. 1892, 45, 489; Wense, Ber. 1886, 19, 761); with *malononitrile* (Merck, D. R. PP. 165692, 165693); with *ethyl cyanacetate* (Traube, D. R. P. 1900, 115253).

Guanidine forms *compounds* with sugars containing 3 mols. of sugar and 1 mol. of guanidine; these exhibit mutarotation and have a lower optical activity than the sugars from which they are derived (Morrell and Bellars, Chem. Soc. Trans. 1907, 1010). M. A. W.

GUANINE, 2-amino-6-oxypurine,

was discovered by Unger in guano in 1844 (Annalen, 51, 395; 58, 18; 59, 58), and though Hoppe-Seyler failed to find it in the excrement of fowls and geese, Haerter obtained it from the excrement of a heron (*Ardea cinerea*) fed on fish and flesh (Med. Chem. Untersuch. 1871, 582); Will and Gorup Besanez found it in the excrement of a spider, in the organ of Bojanus of the mussel, and in the green gland of the crayfish (*cp.* Weinland, Zeit. Biol. 25, 390); and Pecile found 0.0068 gram of guanine per litre in the urine of a pig fed on bran, and in an unhealthy condition (Annalen, 1876, 183, 141). In addition to its occurrence among the excretory products of the animal, guanine is fairly widely distributed throughout the tissues; thus it

is found in the liver, Smorodinzeff (Zeitsch. physiol. Chem. 1912, 80, 231; in muscle (Bennett, J. Biol. Chem. 1912, 11, 221); and it occurs, together with hypoxanthine, in the protamine from salmon roe, forming 6-8 p.c. of the ripe organ (Piccard, Ber. 1874, 7, 1714); it occurs in the pancreas, spleen, liver, and muscle of the ox, in quantities varying from 0.020 to 0.746 p.c. (Braginsky, Zeitsch. physiol. Chem. 1883, 8, 395; Kossel, *ibid.* 404; Schindler, *ibid.* 1889, 13, 432); and it is found in the skin of fishes (Ewald and Kruckenberg, Chem. Zentr. 1883, 705; see Heller, Intern. Zeitsch. Biol. 3, 106 for possible connection between bioluminescence and guanine). Guanine is widely spread throughout the vegetable kingdom, Schützenberger found it, together with other purine bases, in yeast extract (Compt. rend. 1874, 78; Chem. Zentr. 1877, 73); Drummond and Funk in rice polishings (Bio-Chem. J. 1914, 8, 598). Schulze and Bosshard isolated it, together with hypoxanthine and xanthine, from young potato tubers, sugar beet, leaf buds of plane and maple, bark of plane, from lupins, red clover, vetch, young grass, and oats (Zeitsch. physiol. Chem. 1884, 9, 420); and v. Lippmann obtained it from beet juice (Ber. 1896, 29, 2645); molasses residues boiled with copper sulphate and sodium hydroxide yield about 0.04 p.c. guanine pentoside

(Andrlík, Zeitsch. Zuckerind. Böhm. 1911, 35, 437). This is identical with the guanosine obtained from nucleic acid (Levene and Jacobs, Ber. 1909, 42, 2474; Biochem. Zeitsch. 1910, 28, 127); and with *vernine* (guanine-*d*-ribose), $[\alpha]_{\text{D}}^{20} = -8.4^\circ$ (Schulze and Trier, Zeitsch. physiol. Chem. 1911-1912, 76, 145; Smolenski, Chem. Zentr. 1912, 2, 769). According to Levene and Mandel (Biochem. Zeitsch. 1908, 10, 215; see also Jones and Richards, J. Biol. Chem. 1915, 20, 25), guanine is one of the cleavage products of nucleic acid, when the hydrolysis is effected by acetic acid in the presence of lead acetate at 150° ; cf. Levene and Jacobs (J. Biol. Chem. 1912, 377); Scaffidi (Biochem. Zeitsch. 47, 215); it is found among the products of steam-heated soils, Lathrop (J. Amer. Chem. Soc. 1912, 34, 1260).

Guanine exists in guano partly as the calcium compound, partly in substances like nuclein; from these it is liberated by boiling for 4 hours with dilute sulphuric acid, the liquid is cooled and filtered, and the filtrate made alkaline with sodium hydroxide and again filtered. The guanine and uric acid are precipitated in the filtrate by the addition of ammoniacal silver solution, the precipitate washed with cold and hot water, and then decomposed by hot dilute hydrochloric acid, the silver chloride filtered off, the filtrate decolorised with animal charcoal, and the guanine precipitated by ammonia, a small quantity of urea in hot nitric acid is added, and the mixture set aside to crystallise. The guanine nitrate now free from uric acid is dissolved in dilute sodium hydroxide and the guanine precipitated by the addition of ammonium chloride, this last operation removing the xanthine (Wulff, Zeitsch. physiol. Chem. 1893, 17, 468). It may be precipitated as the phosphotungstate—for

the solubility of this in a mixture of acetone and water, see Wechsler (Zeitsch. physiol. Chem. 1911, 73, 141).

Fischer (Ber. 1897, 30, 559) has shown that guanine is 2-amino-6-oxypurine from the fact that *imino- ψ -uric acid*

obtained synthetically by Traube (Ber. 1893, 26, 2551) from guanidine and ethylmalonate, yields, on treatment with hydrochloric acid (sp.gr. 1.19), at 120° , the same 2-amino-6:8-

obtained from bromoguanine $\text{C}_5\text{H}_4\text{BrON}_5$ (Fischer and Reese, Annalen, 1883, 221, 342) by the action of hydrochloric acid at 130° . Further, a synthetic guanine, identical in every way with the natural product, is obtained when 6-oxo-2:8-dichloropurine is heated with alcoholic ammonia, and the resulting chloroguanine reduced by means of hydriodic acid (Fischer, Ber. 1897, 30, 2226). The synthetical production of guanine has also been effected by Traube (Ber. 1900, 33, 1371) from 2:4-diamino-6-

hydroxy-pyrimidine $\text{H}_2\text{N}\cdot\text{C} \begin{array}{c} \text{CH}\cdot\text{C}(\text{OH}) \\ \text{N}:\text{C}(\text{NH}_2) \end{array} \text{N}$, obtained by the condensation of guanidine and ethyl cyanoacetate in the presence of sodium ethoxide. The nitroso derivative of this compound yields, on reduction with ammonium sulphide, 2:4:5-triamino-6-hydroxypyrimidine, which, when heated with an equivalent amount of sodium formate and 8-10 times its weight of anhydrous formic acid, is converted into guanine. A similar synthetic production of guanine from 2-cyanamino-4-amino-6-hydroxypyrimidine

obtained by the condensation of dicyanodiamide and ethyl cyanoacetate in the presence of sodium ethoxide, forms the subject of certain patents of Merck (D. R. PP. 1905, 158591, 162336).

Guanine is an amorphous powder, insoluble in water, alcohol, or ether, but soluble in acids or alkalis, forming salts of a di-acid base, or dibasic acid respectively. It can be obtained in the form of small rhombic crystals when the freshly precipitated compound is dissolved in a large excess of ammonia at 30° - 35° , and the filtered solution allowed to evaporate slowly (Drechsel, J. pr. Chem. 1881, 24, 44); or in crystals resembling those of creatinine zinc chloride, when a warm dilute alkaline solution (1:2000) is mixed with about one-third its volume of alcohol, acidified with acetic acid and allowed to cool (Horbaczewski, Zeitsch. physiol. Chem. 1897, 23, 226).

The administration of guanine as food to rabbits produces neither increase in purine excretion nor pathological changes in the kidney; but subcutaneous or intravenous injections of guanine dissolved in caustic soda, cause a great increase of purine substances, especially uric acid, in the urine (Schittenhelm, Chem. Zentr. 1902, i. 1306; Schittenhelm and Bendix, Zeitsch. physiol. Chem. 1905, 43, 365; Ewald, Zeitsch. exp. Path. u. Ther. 2, 348), and diminishes the arterial blood pressure (Desgrez

and Dorléans, Compt. rend. 1912, 154, 1109; Benelli, Arch. farm. sper. 17, 193-215; *see also* Desgrez and Dorléans (*ibid.* 1913, 157, 946) for the effect of introducing guanine in presence of adrenaline.

Guanine is converted to the extent of 60-70 p.c. into xanthine when heated with excess of 25 p.c. hydrochloric acid for 32 hours (Fischer, Ber. 1910, 43, 805); and undergoes profound decomposition, yielding ammonia, carbon dioxide, formic acid, and glycochol on prolonged treatment with concentrated hydrochloric acid at 180°-200° (Wulff, Zeitsch. physiol. Chem. 1893, 17, 468). A micro-organism belonging to the class of coccus bacteria and found in the excrement of pigeons, flourishes in a culture containing guanine, which is decomposed into urea, guanidine, and carbon dioxide (Ulpiani and Cingolani, Atti. R. Accad. Lincei, 1905, [v.] 14, ii. 596); it is assimilated by a number of moulds as a source of nitrogen and carbon (Kossowicz, Chem. Zentr. 1913, 1, 1297 from Zeitsch. Gährungs physiol. allg. landw. Techn. Mykologie, 1912, 2, 84).

The following derivatives of guanine have been described:

Salts. (1) *With bases, the sodium*

barium $\text{C}_5\text{H}_5\text{N}_5\text{O}_6\text{Ba}$; and *copper*

derivatives. (2) *With acids, the hydrochloride* $\text{C}_5\text{H}_5\text{N}_5\text{O} \cdot \text{HCl} \cdot \text{H}_2\text{O}$, forms double salts with zinc, cadmium, mercury, or platinic chloride; *hydrobromide* $\text{C}_5\text{H}_5\text{N}_5\text{O} \cdot \text{HBr} \cdot 2\frac{1}{2}\text{H}_2\text{O}$; *hydriodide* $\text{C}_5\text{H}_5\text{N}_5\text{O} \cdot \text{HI} \cdot 2\frac{1}{2}\text{H}_2\text{O}$ forms a double salt with bis-muth iodide; *nitrate* $\text{C}_5\text{H}_5\text{N}_5\text{O} \cdot \text{HNO}_3 \cdot 1\frac{1}{2}\text{H}_2\text{O}$;

sulphate $(\text{C}_5\text{H}_5\text{N}_5\text{O})_3 \cdot \text{H}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$; *oxalate*

dichromate $\text{C}_5\text{H}_5\text{N}_5\text{O} \cdot \text{H}_2\text{Cr}_2\text{O}_7$; *picrate*

picrolonate $\text{C}_5\text{H}_5\text{N}_5\text{O} \cdot 2\text{C}_4\text{H}_3\text{O}_5\text{N}_4$; *ferricyanide* $(\text{C}_5\text{H}_5\text{N}_5\text{O})_4 \cdot \text{H}_3\text{Fe}(\text{CN})_6 \cdot 8\text{H}_2\text{O}$; *nitroferricyanide* $(\text{C}_5\text{H}_5\text{N}_5\text{O})_2 \cdot 2\text{H}(\text{CN})_5\text{NOFe} \cdot 1\frac{1}{2}\text{H}_2\text{O}$; *metaphosphate* $\text{C}_5\text{H}_5\text{N}_5\text{O} \cdot \text{HPO}_3 \cdot \text{H}_2\text{O}$. (3) *With salts, mercuric chloride* $\text{C}_5\text{H}_5\text{N}_5\text{O} \cdot \text{HgCl}_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$; *silver nitrate* $\text{C}_5\text{H}_5\text{N}_5\text{O} \cdot \text{AgNO}_3$, the *silver picrate compound* $\text{C}_5\text{H}_4\text{AgN}_5\text{O} \cdot \text{C}_6\text{H}_3\text{N}_3\text{O}_7 \cdot 1\frac{1}{2}\text{H}_2\text{O}$ is insoluble in cold water; (*Cp.* Unger, L. c.; Strecker, Annalen, 118, 152; Balke, J. pr. Chem. [ii.] 47, 539; Neubauer and Kerner, Annalen, 103, 268; Wulff, Zeitsch. physiol. Chem. 1893, 17, 468; Levene, Biochem. Zeitsch. 1907, 4, 320). *Guanine-d-glucoside*

m.p. 298° (corr.) (Fischer and Helferich, Ber. 1914, 47, 210).

Alkyl derivatives. 1-Methylguanine

$\text{NMe} \cdot \text{CO} - \text{C} - \text{NH} \begin{array}{c} \parallel \\ \text{CH} \end{array}$, forms a heavy, colourless, crystalline powder which chars without melting (Traube and Dudley, Ber. 1913, 46, 3839).

7-methylguanine, $\text{NH} - \text{CO} - \text{C} \begin{array}{c} \parallel \\ \text{CH} \end{array} \text{NMe}$, $\text{C}(\text{NH}_2) : \text{N} - \text{C} - \text{N} \begin{array}{c} \parallel \\ \text{CH} \end{array}$,

crystallises in slender, colourless needles which decompose about 390°. 1:7-dimethylguanine $\text{NMe} \cdot \text{CO} - \text{C} \begin{array}{c} \parallel \\ \text{CH} \end{array} \text{NMe}$, crystallises with water of crystallisation, becomes anhydrous at 100° and melts at 343°-345° (corr.); 1:7-dimethylguanine methiodide crystallises in large colourless plates, m.p. 330°-333°. Trimethylguanine methiodide crystallises in colourless, slender needles, m.p. 295°-300° (decomp.) (Fischer, Ber. 1897, 30, 2400; Traube and Dudley, Ber. 1913, 46, 3839).

Acyl derivatives. *Acetylguanine*

is crystalline, sparingly soluble in water, alcohol, or ether, and may be heated at 260° without change. *Propionylguanine* $\text{C}_5\text{H}_4\text{ON}_5(\text{C}_3\text{H}_5\text{O})$ is crystalline, and remains unchanged when heated at 260°. *Benzoylguanine* $\text{C}_5\text{H}_4\text{ON}_5(\text{C}_7\text{H}_5\text{O})$ is also crystalline (*cp.* also Bayer & Co., D. R. P. 213711).

Azo derivatives. Guanine and other purine bases that are not substituted in position 7 react with diazobenzenesulphonic acid to form coloured *azo* compounds, in which the $\text{N} : \text{NR}$ group is attached to carbon atom 8. Guanine and *p*-dichlorodiazobenzene chloride yield a dark red dye, which forms 8-aminoguanine when reduced. The amino compound does not itself couple with diazo compounds, but can be diazotised at 40°, and then yields a violet dye with an alkaline solution of R salt (Burian, Ber. 1904, 37, 696, 708; Hans Fischer, Zeitsch. physiol. Chem. 1909, 60, 69). This reaction has been applied by Amatore de Giacomo (Zeitsch. wiss. Mikroskop. 1910, 27, 257) to a micro-chemical method for demonstrating the presence of guanine in the renal system of birds.

Bromoguanine $\text{C}_5\text{H}_4\text{N}_5\text{OBr}$ is a white crystalline powder, almost insoluble in water, alcohol, or ether. It forms crystalline salts with acids, *e.g.* $\text{C}_5\text{H}_4\text{N}_5\text{OBr} \cdot \text{HCl}$, and also unites with lead or silver to form crystalline compounds, which, when heated with methyl iodide at 100°, yield bromocaffeine. Nitrous acid converts bromoguanine into bromoxanthine (Fischer and Reese, Annalen, 1883, 221, 336).

Deoxyguanine $\text{NH} \cdot \text{CH}_2 \cdot \text{C} \begin{array}{c} \parallel \\ \text{CH} \end{array} \text{NH} \begin{array}{c} \parallel \\ \text{CH} \end{array}$ is

obtained when guanine is electrolytically reduced in 60 p.c. sulphuric acid solution, it crystallises in microscopic needles, melts and decomposes at 204°, and has strongly basic properties, combining with atmospheric carbon dioxide. It is oxidised by bromine to 2-amino-

purine $\text{N} : \text{CH} \cdot \text{C} \begin{array}{c} \parallel \\ \text{NH} \end{array} \text{CH} \begin{array}{c} \parallel \\ \text{CH} \end{array}$, a crystalline base more readily soluble than its isomeride, *adenine*.

Guanine-Mononucleotide, guanylic acid, has been obtained from yeast-nucleic acid as a white amorphous powder, $[\alpha]_D - 2.4^\circ$. Its brucine salt

has m.p. 203° (Read, J. Biol. Chem. 1917, 31, 47; Jones and Read, *ibid.* 337; Feulgen, Zeitsch. physiol. Chem. 1919, 106, 249; *ibid.* 1920, 108, 147; *ibid.* 1920, 111, 257). Levene has obtained the crystalline acid $\text{C}_{10}\text{H}_{14}\text{O}_8\text{N}_5\text{P}_2 \cdot \frac{1}{2}\text{H}_2\text{O}$ from

the brucine salt, this has $[\alpha]_D^{20} -7.5^\circ$ in aqueous solution; it yields the brucine salt

$C_{56}H_{64}O_{16}N_9P \cdot 7H_2O$
m.p. 233° , $[\alpha]_D^{20} -26.0^\circ$ in 35 p.c. alcohol (J. Biol. Chem. 1919, 40, 171).

Tests. Warm dilute solutions of guanine hydrochloride give with a saturated solution of picric acid, an orange-red crystalline insoluble precipitate; xanthine and hypoxanthine give a similar reaction in very concentrated solutions only (St. Capranica, Zeitsch. physiol. Chem. 1880, 4, 233). It can be detected in animal tissue by treating it with a solution of diazobenzenesulphonic acid (sensitive to guanine) when, on addition of sodium hydroxide (after about ten minutes), a red colour appears (de Giacomo, Zeitsch. wiss. Mikroskop. 1910, 27, 257).

When guanine nitrate solution is evaporated it leaves a yellow residue, soluble in potassium hydroxide with a yellow coloration. On evaporating the yellow solution to dryness, it affords first a purple, then a violet coloration, and on exposure to air the original colour returns (Brücke, Montash. 1886, 7, 617).

Estimation. The formation of the insoluble picrate has been recommended by Wulff (Zeitsch. physiol. Chem. 17, 468) for the estimation of guanine M. A. W.

GUANO *v.* FERTILISERS.

GUANOSINE, identical with *Vernin*

a compound of guanine and *d*-ribose, occurs in certain plants, and forms one of the products of hydrolysis of nucleic acid; it decomposes at 237° , and has $[\alpha]_D^{20} -60.52^\circ$ (Levene and Jacobs, Ber. 1909, 42, 2469; Schulze, Zeitsch. physiol. Chem. 1910, 66, 128; Schulze and Trier, *ibid.* 1910, 70, 143).

GUANYLIC ACID, guanine-mononucleotide, *v.* GUANINE.

GUANYLUREA, *Dicyandiamidine*, *v.* DICYANDIAMIDE.

GUARA. A tanning material, identical with cascalotte, consisting of the ground fruits of a variety of divi found in South and Central America, containing a pyrogallotannin closely resembling the tannins of sumach or myrobalans. It contains from 43.5 to 48.4 p.c. of tannins, 23.1-25.8 non-tannins, 17.7-22.0 of insoluble matter, and 9.0-10.7 p.c. moisture. For its characters as a tanning material, see Callan (J. Soc. Chem. Ind. 1915, 34, 646).

GUARANA, U.S.P. (*Uarana*). Guarana is a dried paste prepared from the seeds of *Paullinia Cupana* (H. B. and K.), a climbing shrub inhabiting the northern and western provinces of Brazil. It is made for the most part by different sections of the Guaranis, a tribe of South American Indians, and probably by different methods. Generally, however, the ground or powdered seeds are moistened by exposure to dew, or by the addition of water, kneaded into a paste, made into cylindrical or globular masses and dried before fires, in chimneys, or by the heat of the sun. These cakes as they appear in commerce are hard, with a rough reddish-brown exterior, and somewhat lighter colour inside. They evolve a chocolate-like odour, and have a bitter astringent taste. In South America guarana is an article of food used much in the

same manner as we employ cocoa, and in European medicine it is administered as a nervous stimulant for the relief of certain kinds of headache. For further details as to its source, preparation, and uses *v.* Cooke (Pharm. J. [iii.] 1, 221; Hallawell *ibid.* [iii.] 3, 773; Squibb *ibid.* [iii.] 15, 165; Rusby *ibid.* [iii.] 18, 1050; and Marsden (Annals Trop. Med. 4, 105).

The physiological activity of guarana depends upon the presence of *caffeine* (*v.* CAFFEINE). Of known drugs it is the richest in caffeine. For methods of extraction *v.* Greene (*ibid.* [iii.] 8, 87), who extracts a mixture of guarana and three times its weight of litharge with boiling water; C. J. Williams (Chem. News, 26, 97), who exhausts a moistened and slowly dried mixture of guarana and lime with benzene; Squibb, (Pharm. J. [iii.] 15, 165) and Bochefontaine and Gusset (Ch. Tech. C. Anzeiger, 4, 322), who treat a mixture of guarana and magnesia with weak alcohol and chloroform respectively. Kremel (Ph. Post. 21, 101) determines the caffeine in guarana by placing 10 grams in a flask with 100 c.c. of 25 p.c. alcohol, noting the total weight, and digesting for 1 or 2 hours at 100° . The weight lost by evaporation is made up with similarly diluted alcohol, and 50 c.c. of the solution, corresponding to 5 grams of guarana, is separated by filtration, mixed with calcium hydroxide, and evaporated to dryness. The residue is extracted with chloroform, from which the alkaloid is obtained in crystals, dried at 100° and weighed. The following percentages of caffeine are selected from published analyses of guarana; 5.10, 5.04 (Stenhouse); 5.05 (Greene); 4.20-5.00 (5 samples, Feemster, Pharm. J. [iii.] 13, 363); 4.5 (B. and Gusset); 3.12, 3.80 (Kremel). Feemster found in the seeds 5.08 p.c. and Peckolt (J. 1866, 709), in the shelled seeds 4.81 p.c.; seed shells 2.44 p.c. and pulp 4.29 p.c. Thoms (Pharm. Centh. 1890, 533) however states that the proportion of caffeine in guarana has been overestimated, and this has been confirmed by Kirmsse (Arch. Pharm. 236, 122), who found in three samples 2.68, 2.97, and 3.10 p.c. respectively. The U.S.P. demands a minimum of 4 p.c. assayed by weighing the caffeine.

Besides caffeine, guarana contains gum, starch, an acid green fixed oil, a concrete volatile oil, and tannin (Fournier, J. Pharm. Chim. 1861, 291). The tannin further examined by Greene (Pharm. J. [iii.] 8, 328) was found to behave towards reagents unlike previously known varieties, and the term *paullinitannic acid* was, therefore, applied to it. It forms a yellowish-white amorphous mass, having an astringent taste. It is easily soluble in water or alcohol. By extraction of the crude tannin with ether, crystals are obtained identical with those of the catechin of Pegu catechu (Kirmsse, *l.c.*). Kremel found 1.3-2.0 p.c. of ash consisting chiefly of phosphates.

A specimen of guarana examined by Nierenstein, probably derived from *Paullinia trigonia* (Vell.), was found to contain an alkaloid, β -*guaranine*. This was obtained in the form of small needles, m.p. 217° - 219° ; after drying, the substance had the composition $C_{40}H_{47}O_{21}N_4$ (?). The guarana contained 4.3 p.c. of tannic acid, which, after purification, was obtained in small colourless needles; m.p. 199° - 201° . The tannin,

guaranatannic acid, appears to resemble the chlorogenic acid obtained from coffee (Gorter, Annalen, 358, 327; 359, 217) rather than catechin, but is not identical with either of these substances (Annals Trop. Med. 4, 115). G. B.

GUATANNIN. Syn. for guaicol tannocinnamate.

GUAVA. The fruit of *Psidium Guajava* (Linn.). Prinsen-Geerligs (Chem. Zeit. 1897, 21, 719), gives the following data:

Average wt. in grammes	The fruit consists of			The flesh contains		
				Glu- cose	Levu- lose	Su- crose
	Flesh	Skin	Seeds	p.c.	p.c.	p.c.
65.0	85.0	12.0	3.0	2.0	0.5	1.7

H. I.

GUERNSEY BLUE. A colouring matter belonging to the INDULINE group (*q.v.*).

GUIASANOL. Trade name for diethyl-glycocol guaiacol hydrochloride.

GUIGNET'S GREEN *v.* CHROMIUM.

GUINEA GREEN B. The sodium salt of the disulphonic acid of diethyl-dibenzyl-diamino-triphenyl-carbinol. Is a dark green powder resembling Light-green S or Acid Green, *v.* TRIPHENYLMETHANE COLOURING MATTERS.

GULAMAN DAGAT. A seaweed of the genus *Gracilaria*, found throughout the Philippine Islands; may be used as a substitute for gelatin where only the physical properties of gelatin are important. It is not a protein, and contains less than 1 p.c. of nitrogen and is of little value as a food. It resembles agar-agar, but has less strongly marked solidifying power, does not melt so freely, is not so fluid when melted, and solidifies at a higher temperature; it is unsuitable for bacteriological work owing to its low crushing pressure and slight surface strength (Wells, Philippine J. Sci. 1916, 11, 267; Analyst, 1917, 42, 391).

GULAUCHA, GULOE, and GILOE. Indian names for *Tinospora cordifolia* (Miers.). This plant flourishes in India, the drug being sold extensively in the bazaars as a tonic and antiperiodic, in the form of cylindrical pieces 2-5 cm. long and 1-5 cm. in diameter. It is a perennial creeper, climbing to the summits of the highest trees, its branches putting forth roots which, reaching to the ground, initiate a fresh growth. Roots, stems, and leaves are equally in demand as a drug. The Indian pharmacopœia commends its use as a tincture, 4-8 c.c. *in die*; as an extract (0.6-1 gram *per diem*) in the form of pills; and as an infusion (1:10), of which 60-90 c.c. are to be taken thrice a day. The stems contain *verberin*, an uncrystallisable bitter substance, changed by dilute sulphuric acid into a glucoside, and a bitter kind of starch meal known as 'palo' (J. Soc. Chem. Ind. 6, 49).

GUM RESINS. This article includes the more important members of that group of products which consist essentially of a mixture of gum and resin. They are generally the exudated milky juice of plants dried by spontaneous evaporation. When triturated with water they give more or less perfect emulsions, the gum dissolving and the resin remaining insoluble. Conversely, alcohol dissolves the resin but not the gum. 10-15 parts of a 60 p.c. aqueous chloral hydrate solution dissolve both, leaving impurities such as sand and woody fibre behind. From the solution alcohol precipitates the gum,

leaving the resin in solution. Compare introduction to article RESINS.

Ammoniacum, B.P.; *Gummi-resina ammoniacum.* *Gomme-résine ammoniacque, Fr.;* *Ammoniak Gummiharz, Ger.*

Persian ammoniacum. The ammoniacum of the early Greek physicians came from Africa, and was probably that variety known as African ammoniacum. The drug, which has however since the tenth century been an article of European commerce, is obtained from Persia and neighbouring districts, reaching our markets according to Dymock (Pharm. J. [iii.] 6, 321) now generally by way of Bombay. It is the inspissated juice collected from the stems of the *Dorema Ammoniacum* (D. Don). For plates *v.* Benth. a. Trim. 131. This plant attains a height of 6-8 feet, and the flow of juice from its stem is caused by punctures made by beetles.

The gum-resin occurs in commerce as brittle grains or tears, or roundish lumps, pale yellow externally and waxy milky-white within. It softens readily when warmed. In taste it is bitter and acrid, and it possesses a characteristic odour. Triturated with water it forms an emulsion. A very complete account of the literature of ammoniacum, including the result of the examination of some twenty specimens, will be found in the memoir of Hirschsohn (Pharm. Zeit. 1875, 225; Pharm. J. [iii.] 7, 612, 710, and 770). The spr. of ammoniacum is 1.19-1.21, and 3 parts of it dissolve in 4 of alcohol. Hypochlorites, as for example a solution of bleaching powder, impart to it a bright orange colour, a character that serves to distinguish it from the African variety which is not affected by these reagents. The allied gum-resin galbanum also gives no colour reaction with hypochlorites.

Ammoniacum consists essentially of *resin, gum*, and a small proportion of *volatile oil*. The resin constitutes 70 p.c. of good specimens of the drug. A sample of ammoniacum examined by Luz (Arch. Pharm. 233, 540) contained 4.5 p.c. of water, 69 p.c. of resin, 22.7 p.c. of substances soluble in water, and 3.5 p.c. of substances, other than resin, insoluble in water. A considerable amount of salicylic acid was present, but no aldehydes or terpenes. Normal butyric and valeric acids were also present largely in combination with a resin alcohol *ammoresinotannol* $C_{15}H_{30}O_8$, a chocolate-brown, tasteless and odourless powder, soluble in alkalis and acids. The resin consists essentially of *ammoresinotannol salicylate*. It melts at from 35° to 50°, is soluble in alcohol, chloroform, glacial acetic acid, sulphuric acid, and alkalis, partly soluble in carbon disulphide, benzene, and solution of ammonia, and insoluble in light petroleum. Sommer (J. 1859, 573) was unable to obtain umbelliferone from the gum-resin, but resorcinol, $C_6H_4(OH)_2$, and protocatechuic acid, $C_6H_3(OH)_2COOH$, are formed when it is fused with potash (Hlasiwetz and Barth, Annalen, 130, 354). It yields styphnic acid, trinitro-resorcinol, $C_6H(NO_2)_3(OH)_2$, when treated with nitric acid (Will and Böttger, Annalen, 58, 269; cf. Schwanert, *ibid.* 128, 123).

Ammoniacum gum is partly soluble and partly insoluble in water. The insoluble portion, which constitutes a fourth of the gummy constituents, appears to be identical with the similar bassorin-like gums which occur in *asafœtida* and

galbanum. When treated with 20 p.c. hydrochloric acid, besides humus substances, it yields levulic acid, and, on oxidising with nitric acid, 31.3 p.c. of mucic acid (equivalent to 41.75 p.c. of galactose), but no saccharic acid. When distilled with dilute hydrochloric acid, it yields 9.35 p.c. furfuraldehyde (equivalent to 16.67 p.c. of arabinose), and when boiled with dilute sulphuric acid reducing sugars are obtained, consisting chiefly of galactose (Frischmuth, Chem. Zentr. 1897, ii. 1078).

Hirschsohn obtained no volatile oil by distillation with water, but light petroleum gave him 1.4-6.7 p.c. of volatile oily residues. Flückiger and Hanbury describe the oil as unlike that of galbanum, possessing in a high degree the odour of the drug, and being free from sulphur.

To test ammoniacum for galbanum resin 5 grams is boiled with 15 grams of strong hydrochloric acid for 15 minutes, 15 c.c. of water is then added, and the liquid filtered through a wetted, double filter; ammonia is added to the clear filtrate, when a blue fluorescence reveals the presence of galbanum (Dieterich. Chem. Zentr. 1896, ii. 1137). For method of examination and table giving analytical constants, see Dieterich, l.c., and Pharm. Centh. 40, 467.

Ammoniacum is employed in medicine internally as an expectorant, and externally as a constituent of plasters.

African ammoniacum. This, according to Hanbury (Pharm. J. [iii.] 3, 741), is the ammoniacum of Dioscorides and the older writers. It is derived, according to Lindley (Pereira, Mat. Med. 1853, 1715), from the *Ferula tingitana* (Linn.), a plant inhabiting the African coast of the Mediterranean Sea.

African ammoniacum, which is scarcely known in European markets, is described by Pereira as consisting of dark-coloured masses which internally have much the appearance of the Persian variety. The odour is, however, quite distinct. It forms an emulsion with water. Moss examined a specimen in 1873 (Pharm. J. [iii.] 3, 742) which consisted of resin 67.76 p.c., gum 9.01 p.c., water and volatile oil 4.29 p.c., and bassorin and insoluble matter 18.85 p.c. It contained 13.47 p.c. of ash. It softened between the fingers more readily than Persian ammoniacum. Similar results were obtained by Hirschsohn. By distilling it, however, the last observer isolated *umbelliferone*

Goldschmiedt (Ber. 11, 850) announces that by fusion with potash African ammoniacum yields resorcinol, together with an acid $\text{C}_{11}\text{H}_{10}\text{O}_6$. This acid is not produced when the Persian drug is similarly treated.

Asafetida; *Asafetida*, B.P.; *Asafetida*, U.S.P.; *Gummi-resina Asafetida*. *Asafetida* Fr.; *Asant*, *Stinkasant*, *Teufelsdreck*, Ger.

Gum-resin asafetida is the dried juice of the roots of two large herbaceous plants which inhabit Tibet, Afghanistan, Turkestan, and the country from the Sea of Aral to the Persian Gulf. These are *Ferula Narthex* (Boissier) and *Ferula fetida* (Regel). For drawings v. Benth. a. Trim. 126-127, and Holmes (Pharm. J. [3] 19, 21, 41, and 365). Details of the mode of preparing the roots and of collecting

the dried exudation are given by Flückiger and Hanbury (Flück. and Hanb. 316) and by Pereira (Mat. Med. 1853, 2, 1704). It is certain that asafetida was known to the Arabian writers of the tenth century, and there is reason to believe that a knowledge of the drug is far more ancient.

Supplies of asafetida are now almost entirely derived by way of India from Afghanistan. It occurs as tears more or less agglutinated, and sometimes as a honey-like mass. It is often largely mixed with earthy matter. When broken the milky white surface changes gradually to a pink, which passes into a brown hue (characteristic). Touched with nitric acid (sp.gr. 1.2) it gives a green colour. With water it forms an emulsion. The tears are brittle, and may be powdered when cold. Asafetida has a powerful alliaceous odour and an acrid bitter alliaceous taste.

The chief constituents of asafetida are *resin*, *gum*, and *volatile oil*. Their proportion varies with the age of the drug. For results of early investigations v. Gm. 17, 398. The resin is only partly soluble in ether and chloroform, but is entirely dissolved without alteration by concentrated nitric acid (cf. Johnston, Phil. Trans. 1840, 354). The U.S.P. demands that not less than 60 p.c., or, if powdered, not less than 50 p.c., shall dissolve in alcohol. The ash varies from 3-5 p.c. in pure 'tears' to 10 p.c. and higher in commercial 'mass.' For analyses and methods of assay, see Umney and Bunker (Pharm. J. 1910, 31, 147), Harrison and Self (ibid. 1912, 34, 205; 35, 139), Pearson (J. Ind. Eng. Chem. 1910, 2, 421). The use of the lead number is criticised by Rippetoe (Amer. J. Pharm. 1913, 199) and by Harrison and Self (Pharm. J. 1913, 36, 218). Hlasiwetz and Barth (Annalen, 138, 64) discovered in the resin *ferulic acid*, the methylphenolic ether of hydroxycinnamic or caffeic acid

An alcoholic solution of asafetida is precipitated by an alcoholic solution of lead acetate, and from the insoluble lead salt the ferulic acid is regenerated. It consists of needles melting at 168°-169° (Tiemann, Ber. 9, 416). Vanillin was shown to be present in asafetida by Schmidt (Arch. Pharm. [3] 24, 534).

Pure drops of *Asafetida amygdaloides* examined by Polásek (Arch. Pharm. 235, 125), gave the following, more or less typical, results: resin, soluble in ether, *asaresinotannol ferulate*, 61.40; resin, insoluble in ether, free *asaresinotannol*, 0.60; gum, 25.1; essential oil, 6.7; vanillin, 0.06; ferulic acid, 1.28; moisture, 2.36 p.c. On hydrolysis with potassium carbonate, the soluble resin yields *asaresinotannol* and ferulic acid; with sulphuric acid, however, it is hydrolysed into the same tannol and umbelliferone; for the latter compound, see under GALBANUM. Asaresinotannol is a brownish-yellow amorphous substance, and has the composition $\text{C}_{24}\text{H}_{34}\text{O}_5$.

When asafetida resin is distilled alone, variously tinted oils are obtained, with $\frac{1}{4}$ p.c. of umbelliferone (Sommer J. 1859, 573).

The gum of asafetida consists of two portions, the one soluble and the other insoluble in water. The volatile oil is described by Flückiger and

Hanbury as of a light yellow colour with the odour of asafetida. The taste is at first mild and then irritating, but it does not stimulate when applied to the skin like mustard oil. The oil is neutral, but becomes acid by exposure to the air, at the same time evolving sulphuretted hydrogen. Semmler (Ber. 1890, 23, 3530; 1891, 24, 78; especially Arch. Pharm. 1891, 229, 1) finds that it contains two terpenes $C_{10}H_{16}$ (together 6-8 p.c.); a substance ($C_{10}H_{16}O$) x (20 p.c.), yielding with sodium a sesquiterpene $C_{15}H_{24}$ related to cadinene, a disulphide $C_7H_{14}S_2$ (45 p.c.), b.p. 80°-85°/9 mm., and a disulphide $C_{11}H_{20}S_2$ (20 p.c.), b.p. 120°-130°/9 mm. To the latter the odour is mainly due; on distillation under atmospheric pressure it decomposes with evolution of most repulsive smelling gases.

Asafetida is used in medicine as a nervous stimulant and antispasmodic, and in the East as a condiment. In the United States it is extensively used in a disease of horses called 'heaves.'

Other varieties of asafetida. The *Hing* used by the natives of Bombay is a variety of asafetida. It is derived from *Ferula alliacea* (Boissier). It is more repulsive, and contains a larger proportion of volatile oil than asafetida (Flückiger, Pharm. J. [iii.] 6, 401; Flück. a. Hanb. 319).

Bdellium.

Indian Bdellium; False Myrrh; Bdelium. This is the bdellium of the Bible, and is now used chiefly as an adulterant of myrrh. It is the product of *Balsamodendron Mukul* (Hooker) and, according to Dymock, also of the *B. Roxburgii* (Arnott) (cf. Pharm. J. [iii.] 6, 661; Holmes, *ibid.* 1898, 19, 547). Both are indigenous to India, but grow perhaps also in Southern Arabia. The gum-resin breaks with a flat conchoidal fracture, and though somewhat darker in colour, it resembles myrrh in appearance. It may be distinguished from myrrh by its not giving the violet colour reaction (*v. Myrrh*). (For analytical constants of bdellium *v. Dieterich*, Pharm. Centr. 40, 467.)

African Bdellium. A more highly esteemed bdellium, the product of *Balsamodendron africanum* (Arnott), a shrub indigenous to West Africa. It is used in France as a constituent of plasters. In fracture and other respects it resembles myrrh, but it does not give the violet colour reaction (*v. Myrrh*). African bdellium was analysed by Pelletier (Ann. Chim. Phys. [ii.] 80, 38), who found resin 59 p.c., soluble gum 9.2 p.c., insoluble gum 30.6 p.c., volatile oil and loss 1.2 p.c. The resin was further examined by Johnston (Phil. Trans. 1840, 368). Cf. Bley and Diesel (Arch. Pharm. [ii.] 43, 304).

Euphorbium. *Gomme-résine d'Euphorbe*, Fr.; *Euphorbium*, Ger. This extremely acid drug has been known since the time of Dioscorides, but is now seldom employed in human medicine. It is the inspissated milky juice of *Euphorbia resinifera* (Berg), a cactus-like plant inhabiting Morocco and neighbouring districts of Northern Africa. A drawing is given by Benth. a. Trim. 240. Euphorbium consists of irregular masses of a waxy-yellow or brown appearance, often inclosing spines and other fragments of the plant. It has a slight aromatic odour and an extremely acid taste, its dust causing violent and even dangerous irritation to the nose or throat.

Flückiger (Flück. and Hanb. 560) found a selected specimen to consist of *amorphous resin*, 38 p.c.; *euphorbon*, 22 p.c.; *mucilage*, 18 p.c.; *malates of calcium, sodium, &c.*, 12 p.c.; *mineral compounds*, 10 p.c. It contains no volatile oil.

Tschirch and Paul (Arch. Pharm. 234, 249) found, in addition to amorphous substances, 25 p.c. of malates and 40 p.c. of a crystalline substance, *euphorbon*, m.p. 115°-116°, to which they gave the formula $C_{30}H_{48}O$, but which has received three other formulae from other investigators. It appears to be related to cholesterol.

When a filtered light petroleum extract of euphorbium resin is floated on a solution of one drop of concentrated sulphuric acid in 20 c.c. of water, a very stable blood-red layer is formed at the surface where the two liquids touch; on shaking, the whole of the acid liquid becomes red, and this colour only slowly changes to brown. This reaction may be used for purpose of identification; an extract of the most suitable concentration is obtained from 0.1 gram of euphorbium and 10 c.c. of light petroleum.

Euphorbium is now used mainly in veterinary medicine. Applied externally to the human subject it is irritant and vesicating, and internally administered it causes violent vomiting and purging. It is said to be an efficient preservative of iron and steel against corrosion (Year Book Pharm. 1880, 344).

Power and Browning (Pharm. J. 1913, 36, 506) examined *Euphorbia pilulifera* from Fiji and isolated a number of crystalline alcohols and phenols, but no physiologically active substance. Von Wiesner (Monatsh. 1912, 33, 461) found that the latex of *E. lactiflora* from Chile contains 3.88 p.c. rubber and 28.3 p.c. resin. This low rubber and high resin content is characteristic of the latex of other species, which always contains also some euphorbon $C_{18}H_{24}O$.

Galbanum. *Gummi-resina Galbanum*, Galbanum, Fr.; *Mutterharz, Galbanumharz*, Ger. Galbanum has entered into the constitution of incense, and has been employed in medicine from the earliest times. It was used by the Israelites, and was well known to Hippocrates, Theophrastus, and Dioscorides, also to the Arabians, but has now disappeared from the British and United States pharmacopœias. Notwithstanding its antiquity, the precise plant from which galbanum is derived still remains uncertain. It is most probably obtained from the *Ferula galbaniflua* (Boissier and Buhse), and perhaps from other allied species of *Ferula*, natives of Persia. For figure *v. Benth. a. Trim.* 128 (cf. Holmes, Pharm. J. [iii.] 19, 365). Marsden (Pharm. J. 1915, 41, 356) gives an analysis of a Persian sample and concludes that it is not derived from *F. galbaniflua*. The commonest commercial and late B.P. variety is from the Levant.

The gum-resin occurs in commerce in drops or tears, usually adhering into solid masses. In colour it exhibits various shades of light yellowish-brown, sometimes tinted with green. The odour of galbanum is aromatic, and the taste unpleasant, bitter, and alliaceous. Flückiger and Hanbury (Flück. a. Hanb. 323) note that when galbanum is warmed with concentrated hydrochloric acid a red colour is

developed, which on the careful addition of spirit of wine, turns violet or bluish. *Asafetida* treated in the same manner assumes a dingy colour, whilst *ammoniacum* gives no colour change at all. Further details of the characters of galbanum and its behaviour towards reagents are given in an elaborate memoir by Hirschsohn (Pharm. Zeit. 1875, 225; Pharm. J. [iii.] 7, 369, 389, 429, 531, and 571).

Galbanum resin examined by Conrady (Arch. Pharm. 232, 98) was found to contain 9.5 p.c. of ethereal oil; 63.5 p.c. of a resin soluble in alcohol; and 27.0 p.c. of impurities and gum. The pure resin obtained from the commercial product by extraction with alcohol and subsequent treatment with sodium salicylate contains 20 p.c. of combined umbelliferone; 50 p.c. of galbaresinotannol; and 0.25 p.c. of free umbelliferone. The resin which most probably consists of a galbaresinotannyl ester of umbelliferone is best hydrolysed by boiling with moderately diluted sulphuric acid since umbelliferone is unattacked by this reagent. *Galbaresinotannol* on analysis gives numbers agreeing with the formula $C_{18}H_{30}O_3$; on distillation with phosphoric anhydride it yields a hydrocarbon $C_{15}H_{20}$ and, on oxidation with nitric acid, camphoric and camphoronic acids. The volatile oil is obtained by distillation with water or by extraction with light petroleum. According to Flückiger and Hanbury, the crude oil possesses an aromatic taste and is dextro-rotatory. On the addition of bromine to the oil extracted from Persian galbanum a red to violet or blue colour appears. The oil D 0.910–0.930 consists of *terpenes*, *d-pinene*, *nopinene*, *camphene*, and *myrcene*, of the sesquiterpene *cadinene*, of a substance $C_{10}H_{16}O$, and of the sesquiterpene alcohol *cadinol* $C_{15}H_{26}O$. (Semmler and Jonas, Ber. 1914, 47, 2068, where the older literature is given.) Cadinol is a new substance.

When galbanum resin is distilled a small quantity of umbelliferone is obtained (Sommer, J. 1859, 573). This compound is now known to be a product of the distillation of many other resins or gum-resins, especially those of the *Umbelliferae*. Galbanum yields 0.83 p.c., *sagepenum* 0.32 p.c., *asafetida* 0.28 p.c. Synthetically, umbelliferone may be produced, as pointed out by Pechmann (Ber. 17, 932), by acting upon a mixture of resorcinol and malic acid with dehydrating agents such as sulphuric acid, thus:

$$C_6H_4(OH)_2 + C_2H_3(OH)(COOH)_2 \\ = C_6H_3(OH) < \underset{O}{\text{C}} = \text{CH} - \text{CO} + \text{HCOOH} + 2H_2O$$

Another product of the destructive distillation of galbanum resin is a thick *brilliant blue oil*. The oil deposits in the cold crystals of umbelliferone. It has a bitter acid taste and aromatic odour. Kachler (Ber. 4, 36) separated it into a *colourless hydrocarbon* $C_{10}H_{16}$ boiling at 240° , and a *blue oil* $C_{10}H_{16}O$ which boiled at 289° . The flowers of the wild chamomile *Matricaria Chamomilla* (Linn.) yield a blue oil very similar to that obtained from galbanum. Both oils are converted by potassium into the hydrocarbon $C_{10}H_{16}$, which on the addition of bromine vapour gives the blue colour reaction. Hlasiwetz and Barth (Annalen, 130, 354) have shown that by fusing galbanum resin with potash as much as 6 p.c. of resorcinol is formed (cf. Goldschmied, Ber. 11, 850); and by treatment with

nitric acid, Will and Boettger (Annalen, 58, 269) obtained styphnic acid (cf. Schwanert, Annalen, 128, 123).

Galbanum is administered in medicine internally as an expectorant, and externally it is applied in the form of plasters.

A table of the acidity, ether, and saponification numbers of galbanum resin is given by Dieterich (Pharm. Centh. 40, 467).

Gamboge. *Cambogia*, U.S.P.; deleted from B.P. in 1914. *Cadie Gum*, *Gummi Gambogia*, *Gummi Gutti*, *Gomme Gutte*, Fr.; *Gutti*, *Gummigutt*, Ger. This beautiful orange-red gum-resin comes to us from Camboja, Siam, and Cochin China, where it is the product of a laurel-like tree, the *Garcinia Hanburyi* (Hook.); v. Benth. a. Trim. 33. Indian gamboge is obtained from *G. Morella* (Desrouss.) Gamboge was known to the Chinese in the thirteenth century, but it was not until the seventeenth century that it appeared in European markets. For the purpose of collecting it the trees are incised, and sections of bamboo are attached to collect the milky juice, which, hardening by evaporation, takes the cylindrical shape of the receiving vessel. Gamboge as it occurs in commerce is brittle, and may be powdered readily. In presence of water it forms at once a yellow emulsion. It has a disagreeable and acid taste.

Costelo (Amer. J. Pharm. 1879, 174) finds the resin to vary from 68 to 79 p.c., and the gum from 19 to 27 p.c. (cf. Hurst, Pharm. J. [iii.] 19, 761). The gum is extracted by water. Its solution, like arabic, is not precipitated by neutral lead acetate, but its behaviour towards other reagents shows it to be a different gum.

Alcohol dissolves the resin. By fusion with potash, Hlasiwetz and Barth (Annalen, 138, 68) obtained phloroglucinol, pyrotartaric, isouvicic, and various fatty acids.

For the detection of gamboge in mixtures, v. Hirschsohn (Pharm. Zeit. 24, 609). The material is ground up with hydrochloric acid, when ether extracts a yellow colouring matter, soluble in dilute ammonia with an orange colour. In medicine gamboge is employed as a drastic purgative, usually in combination with other substances. It is also an important water colour.

Ivy gum resin. *Gummi-resina Hederæ*. In Southern Europe and in the Levant a gum-resin is obtained from the old trunks of the common ivy, *Hedera Helix* (Linn.). It consists of irregular masses of a reddish or yellowish-brown colour externally, but showing a deep red by transmitted light. The taste is bitter and acid, but when heated it evolves a balsamic odour. Pelletier (Bull. Pharm. 4, 504) found the gum-resin to consist of resin 23 p.c., gum 7 p.c., and 70 p.c. of woody fibre. Examined by Sommer (Arch. Pharm. [ii.] 98, 11) it gave no umbelliferone.

Myrrh. *Myrrha*, B.P.; U.S.P.; *Herabol Myrrh*; *Gummiresina Myrrha*. *Myrrhe*, Fr.; *Myrrhe*, Ger. Together with olibanum, myrrh has been used as a constituent of incense from the earliest times. It is mentioned in Genesis and in other places in the Bible. The Egyptians employed it not only in fumigations, but also in embalming and in medicine. It has retained its place down to the present day, and is included

in all the pharmacopœias. Myrrh is the spontaneous gum-resinous exudate of the shrubs or small trees of the *Balsamodendron Myrrha* (Nees) = *Commiphora Myrrha* (Holmes), an inhabitant of the Somali coast of the Gulf of Aden and of the Red Sea coast of Arabia (Trimen, Pharm. J. [iii.] 9, 893). A drawing of the tree is given by Benth. a. Trim. 60. The exudate is allowed to harden on the tree before collection. It occurs in irregular-shaped masses of a red-brown colour and dusty appearance. When cold it is brittle, and breaks with an uneven, waxy, oily-looking fracture, often exhibiting lighter-coloured semicircular striations. With water it readily yields an emulsion. The odour of myrrh is fragrant and agreeable, and the taste bitter, aromatic, and acid.

The chief constituents of myrrh are *gum*, *resin*, and *volatile oil*. The relative proportions, even in the case of true myrrh, vary greatly in different specimens. Generally the gum constitutes 40–65 p.c., the resin 25–40 p.c., and the volatile oil 2·5–8 p.c. Flückiger and Hanbury (Flück. a. Hanb. 143) found 27 p.c. of resin in a good specimen, and Köhler (Arch. Pharm. 228, 291) found 7–8 p.c. of volatile oil. Brückner's analysis (Neues Rep. Pharm. 16, 76) gave: soluble in water, gum, 67·76 p.c.; resin soluble in carbon disulphide, 14·06 p.c.; resin soluble in ether, 12·57 p.c.; resin insoluble in ether, 4·81 p.c.; substances soluble in diluted alcohol, 0·43 p.c.; insoluble (sand, bark, &c.), 0·38 p.c. The U.S.P. demands that at least 35 p.c. shall be soluble in alcohol, and that the ash shall not exceed 8·5 p.c.

Myrrh resin is soluble in alcohol or chloroform, but it is only partly soluble in ether, carbon disulphide, or alkalis. According to Köhler (*l.c.*) it is a mixture of several resins, the greater portion of which is a soft resin $C_{26}H_{34}O_5$ soluble in ether. There are also present two dibasic acids $C_{13}H_{16}O_{18}$ and $C_{26}H_{32}O_9$ respectively.

Tschirch and Bergmann (Arch. Pharm. 1905, 243, 641) have made an examination of so-called *Myrrha electa*, which is the true or Herabol myrrh obtained by sorting from the other resins (Indian and African bdellium, Bisabol myrrh, Opoponax) mixed with which myrrh is imported into the United Kingdom. Holmes (Pharm. J. 1913, 37, 116), in describing Somali myrrh, disputes this, and maintains that it is derived from *Balsamodendron Myrrha*. Tschirch and Bergmann (*l.c.*) and Friedrichs (Arch. Pharm. 1907, 245, 427) have described a large number of amorphous constituents, but the chemistry of myrrh abounds in contradictions, perhaps owing to difference in origin of the material examined (*cf.* Greenish, Pharm. J. 1901, 67, 666).

Myrrh resin gives a violet colour when a fragment moistened with alcohol is treated with nitric acid, or the ethereal extract is treated with bromine vapour. It is best to dilute the alcoholic extract with water, shake out with light petroleum, and treat the residue after evaporating the petrol, with nitric acid. The colour is not so marked as in the case of galbanum (*cf.* Ruickholdt, Arch. Pharm. [ii.] 41, 1; Held, Annalen, 63, 59; Hager, Pharm. Centh, 1865, 58). Bdellium (*q.v.*), also derived from *Balsamodendron* species, is somewhat similar to myrrh, but does not give this colour reaction. Dis-

tilled, myrrh gives no umbelliferone, but by fusion with potash Hlasiwetz and Barth (Annalen, 139, 78) obtained small quantities of catechol and protocathechuic acid. The property of giving a violet colour when oxidised by nitric acid, or better, by bromine vapour, is confined to that resin which dissolves in carbon disulphide, and which, according to Brückner, contains 75·6 p.c. of carbon.

The gum of myrrh on analysis gives numbers agreeing with the formula $C_6H_{10}O_5$. On treatment with hydrochloric acid it yields lævulinic acid (Köhler). It contains an oxydase (Tschirch and Bergmann von Friedrichs).

The quantity of volatile oil in myrrh varies very greatly. Gladstone (Chem. Soc. Trans. 17, 11) describes it as a viscid brownish-green oil that, boiling at 266°, gives an oxidised product. Its sp.gr. was 1·0189. The oil prepared by Flückiger (*cf.* Ber. 9, 471) was lighter than water, the sp.gr. at 13° being 0·988, and the boiling-point 270°–290°. Redistilled in a current of carbon dioxide it passed over between 262° and 263°. After redistillation the oil, on addition of a drop of nitric acid, gave after an hour or two a permanent violet hue, but this is better observed when bromine vapour is applied to a solution of the crude oil in carbon disulphide.

Samples of the oil examined by Lewinsohn (Arch. Pharm. 1906, 244, 412) contained cuminaldehyde up to 1 p.c. and small quantities of eugenol and *m*-cresol, and of acetic and palmitic acids. By distillation over sodium, pinene, dipentene, and limonene were isolated, and in one commercial sample, a fourth *terpene* $C_{10}H_{16}$, b.p. 78°–80° (20 mm.). Two other possibly new *sesquiterpenes* $C_{15}H_{24}$, b.p. 151°–154° (15 mm.) and b.p. 163°–168° (12 mm.) respectively, were obtained from two other samples of the oil. Von Friedrichs (*l.c.*) obtained from the essential oil, formic and acetic acids; a crystalline *acid*, m.p. 159°; *m*-cresol; cuminaldehyde and cinnamaldehyde; crystalline monobasic *myrrholic acid* $C_{17}H_{22}O_5$, m.p. 236°; and the *sesquiterpene herabolene* $C_{15}H_{24}$, b.p. 130°–136° (16 mm.).

According to Flückiger, the *bitter constituent* of myrrh is a glucoside. V. Bolton (Zeitsch. Elektrochem. 14, 211), by extracting myrrh with alcohol, evaporating to dryness and then extracting with water, obtained a substance *burseracin*, which forms 1·5–2 p.c. of the original drug. It is a yellow hygroscopic powder, m.p. 78°, and has the composition $C_{20}H_{28}O_8$. It is not a glucoside. On treatment with hydrogen peroxide a compound is obtained, which appears to be radioactive.

Myrrh is a reputed stimulant and tonic, but its employment in medicine depends chiefly on its aromatic properties.

Other varieties of myrrh. Several gum-resins more or less resembling true myrrh are occasionally found in commerce. Two are described by Flückiger and Hanbury. One of these, often incorrectly called *East Indian myrrh*, but which is really an African drug, is known as *bisabol* or *hebbakhade*. In outward appearance it is very similar to true myrrh, but it is more acid, and its resin, soluble in carbon disulphide, gives no violet colour with bromine vapour. An analysis of bisabol-myrrh from

Somaliland gave the following results: gum soluble in water, 22.1; gum soluble in soda, 29.85; resin, 21.5; bitter principles, 1.5; volatile oil, 7.8; water, 3.17; and inorganic matter, &c., 13.4 p.c. (Tucholka, Arch. Pharm. 235, 289).

The other variety is *Arabian myrrh*. It is collected in Southern Arabia east of Aden, and is probably the product of a distinct species (Hanbury). It is very nearly related to true myrrh in appearance, and some specimens give the violet colour reaction.

Olibanum. *Frankincense*; *Gummi-resina Olibanum*; *Thus masculum*. *Encens*, Fr.; *Weihrauch*, Ger. Olibanum or frankincense has been the favourite basis of incense from the earliest times. It is frequently referred to in the Bible, and the Egyptians employed it for fumigations and for embalming.

Duemichen, in his book on the Paintings of the Temple of Dayr el Bahri in Upper Egypt, which represent the traffic between Egypt and a land called Punt as early as the seventeenth century B.C., has shown that these paintings include, not only representations of olibanum in bags, but boxes or tubs containing living olibanum trees. Tribute offerings of frankincense were common throughout the ancient world. At the present day the incense of the Roman and Greek Churches is largely composed of olibanum.

The gum-resin is the dried exudated juice of several species of *Boswellia*. These trees, the fragrance of which is noticeable even at a distance, inhabit Eastern Africa, near Cape Gardafui, and the southern coast of Arabia. They were studied by Birdwood (Trans. Linn. Soc. 27, 111, 148). One of them is figured by Benth. and Trim. 58 (Flück. a. Hanb. 134). Olibanum is a solid which softens in the mouth, and has a slightly terebinthinous, not disagreeable, taste. It consists of tears of various shapes, generally detached. The odour, especially on heating, is pleasantly aromatic. It has a pale yellow or brown colour, and the larger fragments are more or less milky and translucent. Triturated with cold water it yields an emulsion.

The chief constituents of frankincense are *resin*, *gum*, and *volatile oil*. The oil is obtained by distillation; alcohol dissolves the resin and water the gum. Braconnot (Ann. Chim. Phys. [i.] 68, 60) found resin 56 p.c., soluble gum 30 p.c., insoluble gum 6 p.c., and volatile oil 8 p.c.; whilst the analysis of Kurbatow gave resin 72 p.c., gum 21 p.c., and volatile oil 7 p.c. (Zeitsch. Chem. [ii.] 7, 201). From the resin Tschirch and Halbey (Arch. Pharm. 236, 487) obtained *boswellic acid* $C_{32}H_{52}O_4$, a white powder, m.p. 150°, which shows little tendency to crystallise. The resin probably contains *boswellic acid* in the form of an ethereal salt, and also *olibano-resene* ($C_{44}H_{72}O_8$), a powder insoluble in sodium hydroxide and melting at 62°. According to Kurbatow, an oil boiling at 360° is obtained when the resin is subjected to destructive distillation. No umbelliferone is obtained (Sommer, J. 1859, 573).

The gum of olibanum behaves towards reagents exactly as gum arabic (Heckmeijer, J. 1858, 482).

Volatile oil of olibanum, examined by Stenhouse (Annalen, 35, 306), gave the

following data (Schimmel & Co., Semi-Annual Report, April, 1914) D^{15}_D 0.8775, $\alpha_D + 19^\circ 18'$, n^{20}_D 1.47245, acid number 1.8, ester number 7.5, ester number after acetylation 106.0. The sample dissolved in 2 vols. or less of 90 p.c. alcohol, but became turbid on addition of a further quantity. The terpene fraction consisted mainly (99 p.c.) of α -pinene and camphene, with a little dipentene and cymene, but no phellandrene. Formerly commercial samples were laevorotatory, but are now generally dextrorotatory. Fromm and Autin (Annalen, 1913, 401, 253) found for the oil freed from terpenes, b.p. 70°/12 mm. D^{15}_D 0.9685, $\alpha_D + 20^\circ 48'$ and separated it into a small fraction b.p. about 150°, two main fractions b.p. 210°–211° and 260° and a viscous residue. The fraction b.p. 210°–211° contains a substance *olibanol*, $C_{10}H_{16}O$ which is not an ether; its constitution is discussed. The same name was given by Haensel (Chem. Zentr. 1908, i, 1837) to an alcohol $C_{26}H_{44}O$, b.p. 333°–334° from oil of frankincense with D^{17}_D 0.8810, $\alpha_D + 22.08^\circ$, acid number 2, ester number 15.5. At the present day olibanum is seldom employed in medicine. It is used almost exclusively in the preparation of incense.

Opopanax. A bright orange-brown gum-resin occurring in hard nodular or earthy-looking lumps. It was used by Hippocrates, and several varieties were known to Theophrastus and Dioscorides. It is said to be derived from the *Opopanax Chironium* (Koch), a native of Southern Europe.

Opopanax consists essentially of *resin*, *gum*, and a little *volatile oil*. The most recent examination of opopanax is that by Tschirch and Knitl (Arch. Pharm. 237, 256), who found a specimen from the *Opopanax Chironium* (Koch) to contain: resin soluble in ether 51.8, resin insoluble in ether 1.90, gum 33.8, volatile oil 8.3, free ferulic acid 0.22, vanillin 0.0027, moisture 2.0, bassorin and plant remains 2.0 p.c. The resin soluble in ether is the ferulate of a resinotannol, and on hydrolysis ferulic acid and *oporesinotannol* are obtained. The latter is a light brown powder having the composition $C_{12}H_{18}O_8(OH)$. The resin of opopanax insoluble in ether consists of free *oporesinotannol*. The purified gum contained 3.53 p.c. of ash, and an arabic acid was prepared from it containing C 43.17, H 6.42 p.c. From the volatile oil a product was obtained in needles, which melted at 133°–134° and had the composition C 66.6, H 2.7 p.c. This substance is named *oponol*.

A sample of opopanax examined by Baur (Arch. Pharm. 233, 209) contained plant fragments which showed it to be derived from some member of the genus *Balsamodendron*, order *Burseraceae*, probably from *B. Kafal* [*Commiphora abyssinica* (Engl.)]. It contained 19 parts p.c. of resin, 6.5 of ethereal oil, and 70 of gum, besides plant fragments.

The resin of opopanax gives no umbelliferone when distilled. When fused with potash, Hlasiwetz and Barth found the resin to yield catechol, together with protocathechuic acid (Annalen, 139, 78). The substance formerly known by the name of opopanax was altogether different in odour and appearance from the

resin described above. It was probably derived from a Persian member of the *Umbelliferae* (Powell, Economic Products of the Punjab, 1, 402; Flück. a. Hanb. 327). This resin differs from the usual variety by yielding umbelliferone on dry distillation, also the volatile oil obtained from it contains sulphur.

Opopanax was highly esteemed in ancient medicine, but it has now gone entirely out of use.

Sagapenum. This gum-resin, which, like galbanum and asafetida, has been known from the earliest times, is now seldom met with. Its botanical origin is not known with certainty. Flückiger and Hanbury (Flück. a. Hanb. 324) describe sagapenum as consisting of a tough, softish mass of closely agglutinated tears. The tears are brownish, not milkwhite like asafetida, and when broken do not acquire a pink tint, and are without alliaceous odour. The specimen of sagapenum examined by these observers contained no sulphur, but yielded umbelliferone. Seven out of the eight specimens examined by Hirschsohn (Pharm. Zeit. 1875, 225; Pharm. J. [iii.] 7, 771), however, contained sulphur, and this character served to distinguish sagapenum from ammoniacum, galbanum, and opopanax. Umbelliferone was always obtained. Unlike galbanum, sagapenum dissolves in light petroleum; it further contains a much larger proportion of resin. When some specimens of sagapenum are immersed in hydrochloric acid (sp.gr. 1.13) they acquire a permanent blue colour, but others do not exhibit this behaviour.

A specimen of sagapenum investigated by Hohenadel (Arch. Pharm. 233, 259) was found on examination of the plant fragments contained in the drug to have been obtained from the stems and fruits of a Persian species of *Ferula*, order *Umbelliferae*. It contained resin, 56.8; volatile oil, 5.8; water, 3.5; gum, 23.3; and impurities, 10.6 p.c. The purified resin is yellowish-brown, and melts at 74°–76°; when hydrolysed by boiling with sulphuric acid it is decomposed into umbelliferone and *sagaresinotannol*, a brown substance having the composition $C_{24}H_{28}O_5$. The 56.8 parts of purified resin contained 40 of *sagaresinotannol*, 15.7 of combined, and 0.11–0.15 of free umbelliferone. The ethereal oil contains 9.7 p.c. of sulphur.

Scammony. *Scammonée*, Fr.; *Scammonium*, Ger. A purgative gum-resin derived from the *Convolvulus Scammonia* (Linn.), a native of Greece, Asia Minor, Syria, and Southern Russia.

The gum resin obtained by incision from the living root, and known as scammony or 'virgin scammony,' has been used medicinally for many centuries, but was deleted from the B.P. in 1914, and from the U.S.P. in 1916. The value of this drug depends on its resinous constituent, which, however, is now usually prepared by extracting the dried scammony root with alcohol, and precipitating the resin from the solution with water; but the resin from both of these sources appears to have been displaced in the market, to a large extent, by the resin obtained from the root of *Ipomoea orizabensis* (Ledanois), commonly known as 'Mexican scammony root,' and until lately these two resins have usually been considered to be chemically identical. The B.P. now has *Scammonia resina*, *Scammonia radix* (from *Convolvulus Scammonia* L.)

and *Ipomoea* (Mexican Scammony, the root of *I. orizabensis*, added 1914) the U.S.P. now has *Resina Scammonia* and *Scammonia radix* (root of *C. Scammonia* L., yielding 8 p.c. resin, added 1916).

An investigation of scammony root and scammony made by Power and Rogerson (Chem. Soc. Trans. 1912, 101, 398) shows that the resins obtained from the root by the methods of incision and extraction, although similar, are not identical, while both these resins differ very considerably from that obtained from the root of *Ipomoea orizabensis*, which has also been examined by Power and Rogerson (*ibid.* 101, 1). Both of these resins are exceedingly complex in character, but consist to a large extent of glucosides and methylpentosides of jalapinic acid and its methyl ester, and, whilst the methylpentose obtained by the hydrolysis of the resin of scammony root appears to be identical with rhamnose, that from the resin of *Ipomoea orizabensis* yields a crystalline tetra-acetyl derivative not hitherto described. The resin from the last-mentioned source also contains small proportions of hentriacontane and cetyl alcohol, which are not present in the resin from scammony root; also, differences are observed in extracting with various solvents both the crude resins and the products of their alkaline hydrolysis. In particular the true resin is almost completely soluble in ether (the U.S.P. demands that at least 95 p.c. should dissolve) whereas of Mexican scammony only about 70 p.c. is soluble.

According to Seoville (J. Ind. Eng. Chem. 1919, ii., 335) several botanical species, closely allied, furnish scammony or scammony substitutes, among them, a Mexican plant, *Resina drastica*.

Jalapinic acid $C_{15}H_{30}(OH)CO_2H$ was first obtained by Mayer (Annalen, 95, 149) from 'jalapin,' the name given to that portion of the resin of *Ipomoea orizabensis*, which is soluble in ether. Jalapinic acid, subsequently investigated by Kromer (J. pr. Chem. [ii.] 57, 448), has been studied by Power and Rogerson (*loc.*). It forms silky needles, m.p. 67°–68°, and is slightly dextrorotatory. The methyl ester boils at 220° (20 mm.) and crystallises in laminae, which melt at 47°–48°.

For an account of the characteristics of scammony resin, its substitutes and adulterants, see also Bourdier (J. Pharm. Chim. 1912, 5, 251). The microscopic differences between true and Mexican scammony, together with some colour reactions, are given by Ballard (Pharm. J. 1912, 34, 285). For the earlier investigations on scammony resin and on the sugars obtained by its hydrolysis see the above-quoted papers by Power and Rogerson, and their paper in J. Amer. Chem. Soc. 32, 112. G. B.

GUMS. Gums are amorphous substances, composed of carbon, hydrogen, and oxygen, which are characterised by the property of either dissolving in water, or of taking up enough of that solvent to become glutinous and form a mucilage. They are either derived from plants by spontaneous exudation, or are extracted by means of solvents. The gum usually contains some inorganic matter and occasionally a small proportion of nitrogen (*cf.* Stevens, Amer. J. Pharm. 77, 255). For a long time the gums

were considered to be carbohydrates. It is now known, however, from the researches of O'Sullivan on gum arabic (Chem. Soc. Trans. 45, 41; 57, 59), Gedda gum (*ibid.* 59, 1029), and gum tragacanth (*ibid.* 79, 1164), that the gums are acids of high molecular weight, composed of an acid nucleus to which is attached a number of residues of various hexoses, pentoses, and bioses by means of ethereal oxygen linkings; the principal sugars obtained in hydrolysis are galactose and arabinose.

The proportions of the sugars united to the nucleus acid to form the natural complex gum acid, and the proportions of the complex acids in the mixture that constitute the natural gum, appear to vary in different seasons, since investigations have shown that the properties of the gum of a given plant are not always the same.

The finer gums are used in pharmacy in the preparation of emulsions and pastilles, and as a constituent of emollient medicines, whilst the commoner qualities are used in the arts as adhesive agents, in the finishing of cloth, in the preparation of ink, of water colours, and in calico printing.

Many drugs, known as gums in commerce and not included in this article, will be found by reference to BALSAMS or GUM RESINS.

One of the most important factors in determining the quality of a gum is the viscosity of the solution it forms with water, and as no standard method is yet in use the results recorded by different investigators are usually not comparable. The simplest method of determining the viscosity is to allow a quantity of the solution (say of 10 p.c.) to flow by its own weight out of a tube, provided with a capillary orifice, and to note the time of flow. The results obtained by this method are of little value, since the pressure under which the liquid flows varies continuously, but the method is still in use as affording a rough comparison of viscosities. For more accurate work, recourse may be had to the use of a viscometer, such as that described by Ostwald (Physico-Chemical Measurements, 162).

In addition to the viscosity determination, it is generally necessary to ascertain the percentage of moisture present in a sample of gum, the acidity, the amount of ash, the colour, taste, odour, and character of the solution it forms with water. The amount of moisture present should be merely enough to prevent the gum being excessively friable; as a rule it varies between 12 and 16 p.c. The ash should be merely that due to the bases combined with the natural gum acid and in good samples is generally about 3 p.c. The solution should be free from marked taste or odour and not very dark in colour.

In the early part of the 19th century, a good many gums were known, and the work then done resulted in the description of the properties of a few gum substances to which the names *bassorin*, *cerasin*, and *arabin* were given; and chemists, dominated by the idea that the number of organic compounds was only small, on investigating a gum, identified its constituents with one or more of these substances. It now appears that the number of gum compounds is very considerable, and it cannot be safely inferred that the arabin, or cerasin, &c., found in

one gum, is the same substance as the compound, given the same name, found in another natural product. For further particulars, see Robinson (Brit. Assoc. Reports, 1906, 227; and the Imperial Institute Bulletin, 6, 29), from which much of the information embodied in this article has been obtained.

ACACIA AND ALLIED GUMS.

Acacia gum. *Gum arabic*; *Acaciæ gummi*, B.P.; *Acacia*, U.S.P.; *Gomme arabique*, Fr.; *Arabisches Gummi*, Ger. *Acacia* gum is the exudation from the stems and branches of various species of acacia, notably the *A. Senegal* (Willd.), which inhabit Africa from Senegambia in the West to Kordofan, Southern Nubia, and the region of the Athara in the East (Bentl. a. Trim. 94; Höhnel, Pharm. J. [iii.] 18, 1089; Flück. a. Hanb. 233). The drug has been known from the earliest times, having been a article of Egyptian commerce in the 17th century B.C.

The most esteemed variety is *Picked Turkey* or *white Senaar gum*. This gum, also known as *Sudan* or *Kordofan gum*, is collected from the grey barked acacia tree, *Acacia Senegal* (Willd.), known locally as 'hashab.' In Kordofan, the gum is obtained both from gardens of acacia trees which are private property and from wild trees. In the gardens, the gum is obtained by artificially incising the trees soon after the end of the rainy season, the bark is removed in strips from the principal branches of all trees which are three years old or upwards; the strips should be 1 to 3 inches wide, according to the size of the branch, and 2 to 3 feet in length. The incision should not penetrate into the wood, and a thin layer of the inner bark should be left. About 60 days afterwards, the first collection of gum is made, and after that the gum is collected every fourth day until the rains recommence and new leaves appear; at this stage the exudation ceases. The gum obtained from the wild or uncultivated trees is slightly darker in colour and of less value than that derived from trees under cultivation. It exudes naturally from the wild trees and usually dries into pear-shaped pieces which vary in size, according to the length of time between successive collections. Young hashab trees, 8 to 10 feet high and 6 to 8 inches in girth, will produce gum, and the limits of age for this purpose may be taken as 3 to 15 or 20 years; probably trees of from 8 to 12 years old are the most productive. The gum consists of lumps of various sizes, sometimes as large as a walnut, and of a white or nearly white colour. The unbroken masses are rounded in shape, and traversed by numerous minute fissures. They are brittle and break with a vitreous fracture, exposing a transparent and in the finer varieties quite colourless interior.

Suakin, Talca, or Talha gum is derived from the 'red' and the 'white' barked acacia trees, both of which are varieties of *Acacia Seyal* (Delile). It is collected chiefly in the forests of the Blue Nile. The red talha tree is more abundant than the white and consequently most of the talha gum is derived from that variety. The trees are said not to be barked or wounded by the collectors, who gather the gum they find exuding. Talha gum is so brittle that commercial specimens have usually, for the most

part, fallen to powder. The particles exhibit a great variety of colour.

Senegal gum, collected in the French colony of Senegal, is obtained almost entirely from the same species of acacia which yields the Kordofan gum, but it is probable that the poorer qualities are procured from other species. The gum exudes naturally through fissures produced by the rapid and unequal desiccation of the barks of the trees by the hot winds experienced immediately after the wet season, but in recent years incisions have been made. Senegal gum is much darker in colour than the Sudan gum, and the surface of the lumps is unbroken by cracks or fissures. It is chiefly imported into France. A considerable quantity of this is however, exported to other European countries.

Morocco, Mogador, or Brown Barbary gum is exported from Morocco. It is stated to be obtained from *Acacia arabica* (Willd.), and *Acacia gummiifera* (Willd.), but according to some authorities, much of the gum now exported is merely Senegal or Sudanese gum, brought to Morocco by caravans from the interior. It consists of light dusky brown tears or vermiform pieces; they show numerous superficial fissures.

Cape gum is the product of the *Acacia horrida* (Willd.), a native of Cape Colony. Its colour is amber-brown.

Aden and East Indian gum is produced in Abyssinia and Somaliland and is exported from the towns on the Somali coast principally to Aden and Bombay. From these two ports, it is reshipped to Europe as 'Aden gum' and 'East Indian gum' respectively. The source of the gum is not known with certainty but some of it is doubtless collected from *Acacia abyssinica* (Hochst.) and *Acacia glaucophylla* (Steud.), which are known to occur in those regions. It consists of tear-shaped masses, often as large as an egg, and of a pale amber or pinkish hue. The best qualities approach the better classes of Kordofan gums in appearance, solubility, and other characters, but these gums are usually darker in colour.

Australian or Wattle gum, the product of several Australian species of *Acacia* known locally as 'Wattles,' occurs in large hard globular tear-like masses or lumps, varying in colour from deep yellow to deep reddish-brown (*v.* Maiden, Pharm. J. [iii.] 20, 86; *cf.* Flück. a. Hanb.).

Gum arabic is not much more soluble in hot than in cold water. In alcohol it is insoluble. The aqueous solution is precipitated by basic lead acetate, but not by neutral acetate; 10 c.c. of a 10 p.c. solution gives a precipitate with 0.1 c.c. of basic lead acetate solution (U.S.P.). It is also thickened or rendered turbid by the addition of solutions of borates or ferric salts or alkaline silicates. Salts of mercury or silver have no action on the solution, neither is it coloured blue by iodine. Gum arabic yields about 3 p.c. of ash, consisting of calcium magnesium and potassium carbonates. For analytical distinctions between pure gum arabic and gums with which it may be associated, *v.* Hager (Zeitsch. anal. Chem. 11, 350; Pharm. Centh. 1885, 388); Schlosser (Chem. News, 20, 120); Roussin (J. Pharm. Chim. [iv.] 7, 251); Elwood (Pharm. J. [iii.] 19, 339); Hefelmann (Zeitsch. öffentl. Chem. 11, 195); Palladino (Bull. Soc.

chim. [iii.] 9, 578); Vamvakus (Ann. Chim. anal. 12, 12). Methods of valuation of gum arabic are given by Fromm (Zeitsch. anal. Chem. 40, 143) and Dieterich (*ibid.* 40, 408).

Gum arabic contains an oxidase (*e.g.* Reinitzer; Zeitsch. physiol. Chem. 1909, 61, 352), tragacanth does not. Hence, when a drop of hydrogen peroxide is added to a mixture of equal volumes of a cold 1:30 aqueous gum solution and tincture of guaiacum, a brown colour results with gum arabic; tragacanth remains colourless (Allen's Comm. Org. Analysis, 1911, vol. iv., p. 444).

Starch is detected by iodine; dextrin by a method due to Roussin (*l.c.* and Allen, *l.c.* p. 439); gelatin by tannic acid, *cf.* also Trillat (Compt. rend. 127, 724). The quantitative estimation is described by Waters and Tuttle (J. Ind. Eng. Chem. 1916, 8, 413). They precipitate with an ammoniacal copper acetate solution in 50 p.c. alcohol, wash the precipitate with alcohol, dry at 105°, weigh and subtract the copper oxide left on ignition.

The chief constituent of gum arabic is *Arabin*, *Arabic acid*, or *Gummic acid*, combined with calcium and also perhaps with magnesium and potassium. The crude acid is precipitated when alcohol is added to an aqueous solution of gum arabic previously acidified with hydrochloric acid. By successively redissolving in water and reprecipitating, the product can be obtained pure. Arabic acid is amorphous, soluble in water and insoluble in alcohol. Heated to 100° it is converted into insoluble *meta-arabic acid* (Neubauer, J. 1854, 624; Annalen, 102, 105; Gelis, J. 1857, 496), or the same change may be effected by treatment with concentrated acid (Fremy, J. 1860, 503). *Meta-arabic acid* is readily changed back again to soluble arabic acid by the action of alkalis. Heat of combustion, *v.* Stohmann (J. pr. Chem. [ii.] 31, 298). Action of light, *v.* Eder (*ibid.* 19, 299).

The constitution of arabin has been investigated by O'Sullivan (*l.c.*) who showed that it contains the acid nucleus, $C_{23}H_{38}O_{22}$, to which he gave the name *λ-arabinosic acid*, but afterwards unfortunately called it *arabic acid*, the name already given to the naturally occurring gum acid, arabin, which is a compound of arabinosic acid with the sugar residues, arabinan and galactan, the termination 'an' indicating the anhydride of the corresponding sugar. On complete hydrolysis, arabin yields arabinose, galactose, and arabinosic (arabic) acid.

When oxidised with ordinary nitric acid, gum arabic yields oxalic, mucic, tartaric, and racemic acids (Guerin, Annalen, 4, 255; Liebig, *ibid.* 113, 4; Kiliani, Ber. 15, 35; Hornemann, J. 1863, 391; Maumene, Bull. Soc. chim. [iii.] 9, 138; Béchamp, *ibid.* [iii.] 7, 587).

Gums from *Acacia pycnantha* (Australia), *A. horrida* (S. Africa), *A. arabica* (Africa, Arabia, India), and *Melia Azadirachta* (Deccan, Ceylon, Malay Archipelago) have been examined by Meininger (Arch. Pharm. 1910, 248, 171).

Allied gums. The gum known in commerce as *Gedda gum*, in appearance very similar to the inferior kinds of gum arabic, has also been examined by O'Sullivan. He found that it is a mixture of several gum acids, which are constituted of the radicles of galactose and of

arabinose or arabinan, attached in considerable numbers to a nucleus acid to which the name geddic acid is given. Geddic acid is an isomeric acid of arabic acid, $C_{23}H_{35}O_{22}$. *Chagual gum* is obtained from Chile, where it is produced by the *Puya lanuginosa* (Schult.). It is partly insoluble in water. Chagual gum has been investigated by Winterstein (Ber. 31, 1571). *Feronia* or *wood apple gum* is derived from the Indian tree *Feronia elephantum* (Correa) (cf. Flück. a. Hanb. 239). *Ghati gum* is the name given in India to gum produced in India itself, as distinguished from East Indian gum of exotic origin. In European commerce, however, the name 'Ghatti' or 'Gatty' is practically restricted to the partially soluble and viscous gum derived from *Anogeissus latifolia* (Wall.) and certain other species. It is derived from various trees and no attempt is made to keep the products of the different species separate. The result of this is that the gum may differ considerably in properties. *Hog* or *Doctor gum* consists of reddish tears. It is derived from the *Rhus Metopium* (Linn.), or perhaps the *Moronobea grandiflora* (Choisy), natives of South America. This gum is quite distinct from the Hogg or Kuteera gum of India (cf. *Tragacanth*). Plants containing gums similar to acacia (v. Gm. 15, 195). *Para* and other gums (Pharm. J. [iii.] 18, 623, 745, and 1009).

TRAGACANTH AND ALLIED GUMS.

Tragacanth. *Tragacantha*, B.P.; U.S.P. *Gomme adragante*, Fr.; *Traganth*, Ger. A gummy exudate consisting in part of altered cells obtained either spontaneously or by means of incisions from the stems of various species of *Astragalus*, some of which occur in South Western Europe, while others are found in Greece and Turkey. The largest number, however, are indigenous in the mountainous regions of Asia Minor, Syria, Armenia, Kurdistan, and Persia. The tragacanth of commerce is produced in the last-named countries. In July and August, the shrubs are stripped of their leaves and short longitudinal incisions or slits are made in the trunks. The gum flows out, and, drying spontaneously, is ready for gathering in three or four days. If the weather is fine during the drying process, the 'white leaf' form of gum is obtained which is the most prized variety. If, however, rain falls or the wind rises, particles of dust collect on the surface of the gum which thereby loses its whiteness and becomes the 'yellow leaf' form, the second quality. The form of the pieces is determined by the shape of the incision; longitudinal incisions produce 'leaf' or flake tragacanth, punctures yield 'thread' tragacanth, while irregular shaped incisions give knob-like masses, generally coloured, and of relatively low value. Another form, known in Persia as 'Arrehbor,' exudes from branches which have been cut by a saw (Imp. Inst. Reports, 1909, No. 63).

When tragacanth is treated with water, one part dissolves and the other swells up, absorbing water, to the extent of even fifty times the weight of the gum used, the whole forming a thick mucilage. This may be diffused through more water when, on filtering, a soluble gum

passes through, and there remains on the filter a slimy non-adhesive mucilage, *bassorin*, *tragacanthin*, or *adraganthin*. In presence of alkalis, the whole of the gum dissolves readily in water (Flück. a. Hanb. 178; Sandersleben, Phytochem. Untersuch. Leipzig, 1880, 90; Frey, J. 1860, 504). On hydrolysis of three samples of white tragacanth, Widtsoe and Tollens (Ber. 33, 132) obtained fucose and arabinose, whilst fucose and xylose were obtained from two samples of brown tragacanth. Five different samples of tragacanth examined by Helger and Dreyfus (Ber. 33, 1178) were found to contain 9.4 to 15.4 p.c. of water; 3.1 to 2.7 of ash, also 15.1 to 22.4 p.c. of galactose (estimated as mucic acid) and 30 to 42 p.c. of arabinose (estimated as furfuraldehyde phenylhydrazone). A specimen of vermicelli tragacanth contained 4 p.c. of cellulose and 3 p.c. of starch. The samples obtained by artificial incision contain the larger proportions of water and ash.

Tragacanth gum, investigated by O'Sullivan, was found, like Gedda gum, to be a mixture of several gum acids. It can be separated into a group of acids which remain in solution in dilute alcohol, and an insoluble portion, for which the name *bassorin* is appropriated; cf. also von Fellenberg (Chem. Zentr. 1914, ii. 943) who finds that bassorin alone contains methoxyl (=5.38 p.c. MeOH); the soluble portion is methoxyl free. The acids of the soluble group were found to be built up on a nucleus acid, very similar if not identical with geddic acid, by its union with galactose and arabinose residues. The constitution of the insoluble portion has not been completely worked out; but it yields a nucleus acid of the formula $C_{14}H_{20}O_{13}$, to which the name *bassoric acid* is given, and also intermediate acids formed of bassoric acid united to the residues of xylose, and of a new pentose sugar, *tragacanthose*.

Allied gums. *Bassora*, *Kuteera*, or *Carmania gum*, *Hogg gum* *tragacanth*, consists of yellow or brown waxy masses. It comes from Persia, where it is said to be derived from almond and plum trees, and is employed in Smyrna in the adulteration of tragacanth (Flück. a. Hanb.). The *Cochlospermum Gossypium* (D.C.), a small deciduous tree growing abundantly in India, furnishes a gum which occurs in irregular rounded translucent lumps of a pale buff colour. The gum is sold in the Indian bazaars as a substitute for tragacanth, which it closely resembles. This gum has the property of slowly giving off acetic acid when exposed to moist air, a property also possessed by the gum of *Sterculia urens* (Roxb.) (Gurbour, Pharm. J. 15, 57). This may be utilised for the detection of adulterants in gum Tragacanth. The material is treated with dilute phosphoric acid and steam distilled. Indian gum then gives about 7 times as much acetic acid as pure gum Tragacanth (Ann. Report Bureau of Chemistry, U.S. Dept. of Agriculture, Pharm. J. 1912, 34, 353; Emery, J. Ind. Eng. Chem. 4, 374; Fuller, Amer. J. Pharm. 1912, 84, 155). For the detection of acacia see gum arabic, above, and Frey (Apoth. Zeit. 1913, 28, 787). A stable acid, *gondic acid*, $C_{23}H_{35}O_{21}$, has been obtained from the gum of *Cochlospermum Gossypium* (D.C.) in the same manner as the arabic and geddic acids of O'Sullivan. On hydrolysis, the gum

yields 18 p.c. of acetic acid, calculated on the dry and ash-free substance, and is thus an acetyl derivative. Xylose and a hexose are among the other products (Robinson, Chem. Soc. Trans. 89, 1496). *Cashew gum* is the exudation of the *Anacardium occidentale* (Linn.), a small tree indigenous to tropical America. *Cherry tree gum* behaves towards water in a similar manner to tragacanth. The insoluble portion consists of *cerasin*, combined with metals of the alkalis or alkaline earths (Fremy, J. 1860, 504). For hydrolysis of cherry tree gum, v. Hauers and Tollens (Ber. 36, 3306). *Linseed, marshmallow, and fleaseed gums* closely resemble tragacanth (Schmidt, Annalen, 51, 50; Frank, J. pr. Chem. [ii.] 95, 494; Kirchner and Tollens, Annalen, 175, 215; Hilger, Ber. 36, 3197). *Persian gum* (v. Pharm. J. [3] 20, 793) is of a hard glassy type, and its solutions in water are intermediate in character between those of tragacanth and gum arabic. The trade in this gum is considerable, but the commercial value is lower than that of either tragacanth or fine gum arabic (Imp. Inst. Report). *Wood gum* has been extracted from various woods, straw, loofah, and similar materials. It resembles cherry tree gum. On hydrolysis it yields xylose, and in some cases arabinose (Th. Thomsen, J. pr. Chem. [ii.] 19, 146; Pommardé and Figuer, Annalen, 64, 338; J. Soc. Chem. Ind. 1890, 335; Wheeler and Tollens, Ber. 22, 1046; 23, 137; Annalen, 254, 320; Allen and Tollens, *ibid.* 260, 289; Bader, Chem. Zeit. 19, 55; Johnson, Amer. Chem. J. 18, 24; Browne and Tollens, Ber. 35, 1457; Salkowski, Zeitsch. physiol. Chem. 34, 162).

OTHER GUMS.

Agar agar, Agar, U.S.P. (admitted 1916; it is not in the British Pharmacopœia), *Bengal* or *Japanese isinglass*, is the dried jelly of *Gracilaria* (*Sphaerococcus*) *lichenoides*, Grev., *Gelidium corneum*, Lam., *G. cartilagineum*, Gaill., and other Red Algæ (*Rhodophyceae*) from China, Japan, Formosa, &c. (see Takao, J. Pharm. Chim. 1917, 15, 175). It consists mainly of a carbohydrate, *d-galactan* ($C_6H_{10}O_5$)_x, less correctly termed *gelose*, which is hydrolysed by acids to galactose, and is insoluble in cold water, alcohol, dilute acids, and alkalis. Agar yields on hydrolysis also small amounts of arabinose and fructose; on oxidation mucic acid is formed (Takao, *l.c.*). 1 part in 500 of boiling water forms a jelly on cooling (Morin, J. 1880, 1010; Porumbara, J. 1880, 1011; Bauer, J. pr. Chem. [ii.] 30, 375) (v. AGAR AGAR). 0.1 gram dissolved in 100 c.c. boiling water should give no precipitate on adding tannic acid (absence of gelatine) and should not be coloured blue by iodine (absence of starch). According to Takao (*l.c.*) the mucilage of some species, however, is coloured blue. 1 gram boiled with 100 c.c. of water for ten minutes, should set on cooling to a stiff jelly (U.S.P.). The material generally contains characteristic diatom skeletons, best recognised microscopically after ignition. Those of *Arachmodiscus Ehrenbergii* are figured in Allen's Comm. Org. Analysis, 1911, vol. iv. p. 438. Agar (the Malayan plural is formed by repeating the singular) is used for preparing culture media in bacteriology, for making emulsions, for thickening ice-creams,

and medicinally in chronic constipation. Its action in the latter case is purely mechanical; it passes through the intestine almost unchanged. (Trade names, Regulin, Agarase.) *Galactin*, a very similar gum to gelose, is found in the seeds of the *Leguminosæ* (Muntz, Bull. Soc. chim. 37, 409).

Amyloid gums. These are distinguished from most gums by being coloured blue by iodine. The more important are: *Amyloid* (distinct from that derived from cellulose), the soluble gum of the cotyledons of the tamarind and other plants; *Quince gum*, which breaks up into cellulose, gum, and sugar when heated with dilute sulphuric acid; and *Salep gum*, derived from the bulbs of orchids (Frank, J. pr. Chem. [ii.] 95, 479; Hilger, Ber. 36, 3197).

Animal gum. A gummy substance having the composition $C_{11}H_{22}O_{10} \cdot 2H_2O$ has been isolated from the secretions of the salivary glands, from the brain, pancreas, kidneys, and other parts of the body. It is unaffected by the digestive ferments, but is converted into sugar by dilute acids. It reduces ammoniacal silver nitrate solution with formation of a mirror. With water, it gelatinises, forming a mucilage. It is insoluble in alcohol and ether (Landwehr, Zeitsch. physiol. Chem. 8, 122; 9, 367; 13, 122; Zeitsch. anal. Chem. 23, 601; 24, 640; Pouchet, Compt. rend. 20, 21; Folin, Zeitsch. physiol. Chem. 23, 347).

Fermentation gum. This gum, *Dextran* or *Viscose*, which occurs in the unripe sugar beet (Scheibler, Wag. J. 1875, 790), is formed in the lactic fermentation of cane sugar by the action of the bacterium *Streptococcus* (*Leuconostoc*) *mesenteroides* (van Tieghem, Jahresb. Agrik. Chem. 1879, 544; Béchamp, J. Th. 1881, 85; Brüning, Annalen, 104, 197). Formed also in mucic fermentation (Nägeli, J. pr. Chem. [ii.] 17, 409). *Dextran* $C_6H_{10}O_5$ is amorphous, soluble in water and precipitated therefrom as an elastic thread-like mass by alcohol. By treatment with dilute sulphuric acid, sugar is obtained, and when oxidised with nitric acid, oxalic but no mucic acid.

Dextrin v. DEXTIN.

Iceland moss gum. Two gums have been isolated from the jelly of Iceland moss, *Cetraria islandica* (Acharius). According to Hesse (J. prakt. Chem. 1916, [ii.] 93, 254) this lichen contains in the air-dry condition 80 p.c. of carbohydrate and 13–14 p.c. of water, and may be used for human food and fodder. The bitter taste is removed by 1 p.c. potassium carbonate. On hydrolysis with 6–8 p.c. sulphuric acid Iceland moss yields three times as much sugar (chiefly dextrose) as potatoes. Of the gums, *lichenin* $C_6H_7Ac_3O_5$ is unaffected by iodine, while the other, *isolichenin*, is coloured blue by that reagent. *Lichenin* is a transparent brittle mass which dissolves in hot water, the solution gelatinising on cooling. It is soluble in solution of ammonio-copper sulphate; combines with bases; is converted by dilute acids into sugar; oxidised by nitric acid, it yields oxalic acid, and it reacts with glacial acetic acid, forming *triacetyl lichenin* $C_6H_7Ac_3O_5$ (Knop and Schnedermann, Annalen, 55, 165; J. 1847–8, 831; Errera, L'naug. Dis. Brussels, 1882, 18; Mulder, Annalen, 28, 279; Helger and Buchner, Ber. 23, 461). *IsoLichenin* is soluble in water, and unlike

lichenin forms no acetyl derivative, nor is it soluble in ammonio-copper sulphate solution (Berg. J. 1873, 848; Errera; Hönl, Monatsh. 8, 452).

The lichen, *Evernia Prunastri* (Ach), contains a gum resembling lichenin, *everniin* $C_6H_{14}O_7$ (Stüde, Annalen, 131, 241).

Irish moss gum. Irish moss or carrageen, *Chondrus crispus* (Linn.), contains a gum which is soluble in water, insoluble in ammonio-copper sulphate, is not coloured blue by iodine and yields mucic acid when oxidised with nitric acid (Blondeau, J. 1865, 659; Flückiger and Obermeyer, J. 1868, 805; Painter, Pharm. J. [iii.] 18, 362). This seaweed is included in the U.S.P. (*Chondrus*). 1 part, boiled with 30 parts of water and strained, sets to a thick jelly on cooling. The dried plant contains about 64 p.c. of carbohydrate and 7 p.c. of protein. Hot water extracts the calcium salt of a colloidal ethereal sulphate; the calcium is freely ionised, but sulphate ions cannot be demonstrated until after hydrolysis (Haas, Bio-chem. J. 1921, 15, 469).

Sterculia gum, derived from various species of *Sterculia* (v. Maiden, Pharm. J. [iii.] 20, 381), v. gums allied to *tragacanth*, *supra*.

Sugar beet gum. Several forms of gum have been separated from the juice of the sugar beet. *Arabic* or *meta-arabic acid* (cf. gum *acacia*), *dextran* (cf. *fermentation gum*, *pararabin* (Reichardt, Ber. 8, 808), and *laevulan* (v. Lippmann, *ibid.* 14, 1509). Pararabin is a powder which forms a jelly with water of quite a different appearance from that obtained with meta-arabin. It is soluble in dilute acid solutions from which alkalis or alcohol precipitate it. Laevulan is a by-product in the extraction of crystallisable sugar from beet sugar molasses. When anhydrous, it is insoluble in water, but in its hydrated form it dissolves readily. When oxidised by nitric acid it yields mucic acid, and heated with dilute sulphuric acid it is entirely converted into fævulose.

Wine gum (v. Béchamp, J. 1875, 987; Chancel, J. 1875, 987; Neubauer, Zeitsch. anal. Chem. 15, 194).

Yeast gum (v. Hessenland, Zeit. Ver. Rübenzuck-Ind, 1892, 671; Salkowski, Ber. 1894, 27, 497, 925, 3325; Zeitsch. physiol. Chem. 1910, 69, 466; *ibid.* 1911, 73, 314; von Euler and Fodor, *ibid.* 1911, 72, 339; Meigen and Spreng, *ibid.* 1908, 55, 48; Harden and Young, Chem. Soc. Trans. 1912, 101, 1928). The preparation is more particularly described by Harden and Young; purification is best done as copper precipitate (Salkowski). Adherent glycogen is precipitated by saturation with ammonium sulphate; the filtrate is dialysed and the gum is then precipitated by alcohol. $[\alpha]_D$ is given from $+66.76^\circ$ to $+91.1^\circ$ by various authors; the higher figure is probably the most correct. On hydrolysis mannose and dextrose are formed, rather more of the former than of the latter. G. B.

GUMMITE. An amorphous hydrated uranium oxide ($UO_3 \cdot 61-75$ p.c.) with some lead, calcium, silica, &c. It occurs as an alteration product of uraninite (pitchblende), and forms yellow to reddish-brown gum-like masses, sometimes enclosing a nucleus of the unaltered parent mineral, and at times showing the external form of the original crystal. It is found together with other secondary uranium minerals at Johanngeorgenstadt, Schneeberg, and Annaberg, in Saxony, in the Elias mine (eliasite) at Joachimsthal in Bohemia, and rather abundantly in the Flat Rock and Deake mines in Mitchell Co., North Carolina.

Thorogummite ($UO_3 \cdot 3ThO_2 \cdot 3SiO_2 \cdot 6H_2O$) from Llano Co., Texas, pilbarite

($UO_3 \cdot ThO_2 \cdot PbO \cdot 2SiO_2 \cdot 4H_2O$)

from Western Australia, and yttrougummite, an alteration product of cleveite from Norway, are related minerals. L. J. S.

GUTTA PERCHA is the product obtained by coagulating the latex of certain species of *Palauquium* and *Payena*, belonging to the natural order *Sapotaceæ*, which are natives of the Malay Peninsula and Archipelago. The name is derived from two Malay words: *getah* and *percha* or *pertja*. The word *getah* is applied to any exudation from a tree, whilst *percha* or *pertja* refers either to the local name of the tree which was erroneously thought at first to furnish the product, or to the Malay name for Sumatra 'Pulau Percha.'

The introduction of gutta percha into commerce dates from 1843, when specimens were forwarded to London independently by two doctors resident in Singapore, Dr. William Montgomerie and Dr. José D'Almeida, and the remarkable properties of the material at once attracted attention. In 1847 the principal tree yielding gutta percha was described and named by Sir W. J. Hooker, and in the same year Dr. Ernst Werner von Siemens employed the material for insulating underground telegraph wires.

The principal trees yielding gutta percha of the best quality are *Palauquium Gutta*, Burck, *P. oblongifolium*, Burck, and *P. borneense*, Burck. *P. oblongifolium* is considered by some botanists to be only a variety of *P. Gutta*; the common name for both in the Malay peninsula is Taban. A number of other species of *Palauquium* furnish gutta percha of second quality, the chief of these being *P. obovatum*, King (Taban puth), *P. Main-gayi*, King and Gamble (Taban simpor), and *P.*

oxleyanum, Pierre (*Dichopsis pustulata*, Hemsley), which is variously known as Taban sutra, Taban putih, and Taban chaier in different parts of the Malay peninsula. *Payena Leerii* (Hook. and Benth.); and *P. Havilandii* (King & Gamble), furnish the white gutta percha known as Getah sundek or soondie.

There has been considerable confusion regarding the botanical identity of the trees yielding gutta percha, which has been increased by the fact that the same native name is frequently applied to distinct species in different districts.

Palaquium Gutta is a large forest tree which usually attains a height of about 60 feet and has a straight cylindrical trunk. Trees up to 150 feet or more in height and 4 to 5 feet in diameter have been recorded. The tree is easily recognised by its leaves, which are a beautiful coppery gold colour on the under surface and dark glossy green on the upper. They vary considerably in size, the leaves of mature trees being about 2 inches long, whereas those of young trees are much longer.

The geographical distribution of the trees which furnish gutta percha is curiously restricted, as they only occur naturally in a small area comprising the southern portion of the Malay peninsula, Sumatra, Banca, Borneo, Celebes, the Susu Islands, and the Philippines. The trees are not indigenous in Java but have been introduced and are now being cultivated there.

The latex is contained in isolated sacs which occur chiefly in the inner layers of the bark and also in the leaves. On making incisions in the bark the latex exudes and quickly coagulates, so that only a small yield of gutta percha can be obtained at one tapping. In consequence of this fact the Malays have adopted the destructive method of felling the trees in order to collect the gutta percha. The tree is cut down and incisions extending right round the trunk are made at intervals of 9 to 12 inches or even less. In the case of the best kinds of gutta percha, the latex exudes into the incisions where it quickly coagulates, and in about half an hour can be rolled off on a stick or scraped off with a knife. The latex of the inferior varieties does not coagulate so rapidly; it is collected in vessels placed underneath the incisions, and is afterwards coagulated by gentle heating. The gutta percha is subsequently boiled in water and made into blocks of various shapes.

The amount of gutta percha obtained per tree by the native method has been very variously stated, but it seems probable that the average return from 15 to 20 year old trees is not above 14 ozs. Large forest trees have, however, been known to yield over 2 lbs. of gutta percha, and a tree 160 feet high, in the Philippines, is stated to have furnished 8½ lbs.

In view of the serious destruction of the trees which is involved in the native method of obtaining the gutta percha, attempts are now being made in Perak and in Java to collect the product by tapping the standing trees. The average yield by this method is not yet definitely determined, but in Perak a tree 59½ inches in girth has yielded 1 lb. 3¾ ozs. of gutta percha in 21 tappings extending over 6 weeks. Gutta percha is also being extracted by mechanical

processes from the leaves of the trees. The older methods, involving the use of solvents, which were first employed for this purpose, have been abandoned, as it was found that the chemical treatment adversely affected the durability of the gutta percha when exposed to air and light.

Gutta percha resembles rubber in consisting essentially of a hydrocarbon, having the formula $(C_{10}H_{16})_n$, associated with resinous substances. It differs widely, however, from rubber in its physical properties. At ordinary temperatures it is hard, very tenacious, and cannot be stretched like rubber. On immersion in hot water it becomes soft and plastic so that it can be readily moulded; on cooling, it retains the shape given to it when soft and becomes hard but not brittle. When heated in the air, gutta percha decomposes and then takes fire, burning with a luminous smoky flame and giving off a characteristic odour resembling that of burning rubber. When submitted to destructive distillation, it yields a mixture of liquid hydrocarbons, including isoprene, similar to those obtained by the distillation of caoutchouc.

Gutta percha is not affected by weak mineral acids, strong hydrochloric or acetic acids, or strong alkalis, but is readily attacked by strong nitric or sulphuric acid. It is partially soluble in ether, alcohol, acetone, and cold petroleum spirit, which dissolve the resin; and completely soluble in carbon disulphide, chloroform, carbon tetrachloride, and hot petroleum spirit.

The hydrocarbon present in gutta percha, known as *gutta*, is the essential constituent and exhibits in an enhanced degree the characteristic properties of the product. When dissolved in chloroform and treated with chlorine, bromine, or iodine, *gutta* forms addition products, with some evolution of the halogen acid; and by the action of nitrogen oxides, nitrosites resembling those obtained from caoutchouc are formed.

Gutta percha slowly absorbs oxygen when exposed to air and light, and in the process the *gutta* is converted into a brittle resin. Gutta percha is, however, not energetically attacked by ozone like caoutchouc. Harries has shown that if gutta is dissolved in chloroform and treated with ozone, an ozonide $C_{10}H_{16}O_6$ is formed which, when decomposed by steam, gives a mixture of lævulic aldehyde and acid and lævulic aldehyde peroxide like the corresponding ozonide prepared from caoutchouc, but in different proportions. Harries concludes that the hydrocarbons of rubber and gutta percha are identical, both being probably 1:5 dimethylcyclooctadiene (Ber. 1905, 38, 3985).

The resinous bodies associated with the gutta are oxygenated substances. They were separated by Payen in 1852 into two portions: (1) a crystalline white resin, soluble in hot but insoluble in cold alcohol, which he named *albane*; and (2) an amorphous yellow resin, soluble in cold alcohol, which he named *fluavile*. It seems probable from recent investigations that these substances are mixtures and not single compounds. In 1892 Oesterle discovered in gutta percha a fourth constituent, which he named *guttane* and found to contain C 86.4 p.c. and H 12.0 p.c. For information on the composition and chemical properties of

gutta percha *see* papers by Ramsay, Chick, and Collingridge, and by Caspari in *J. Soc. Chem. Ind.* 1902, 21, 1367; 1905, 24, 1274.

In the analysis of crude gutta percha, it is customary to determine the moisture, the resin, the gutta, and the insoluble matter (dirt). The moisture is usually determined by heating a weighed quantity in an air or water oven, or *in vacuo*, until no further loss in weight occurs; sometimes the water given off is collected and weighed. The resins are determined by extraction with hot acetone in a Soxhlet apparatus, or by ether or petroleum spirit in the cold; the solvent is distilled off and the resin weighed.

The residue left after removal of the resin is treated with chloroform which dissolves the gutta leaving the insoluble matter; the latter is removed by filtration, washed with chloroform, dried, and weighed. The gutta may be weighed after distilling off the chloroform, or it may be precipitated from the chloroform solution by the addition of alcohol and then dried and weighed.

The composition of several representative specimens of gutta percha, derived from trees belonging to a single species, which have been examined at the Imperial Institute, and by Obach, is given in the following table:—

Variety of gutta percha	Botanical source	Gutta	Resin	Dirt	Moisture	Ash
Getah taban merah ¹	<i>Palaquium Gutta</i> . . .	70.6	13.9	0.7	14.8	0.95
Getah taban putih . . .	Uncertain " . . .	68.3	13.4	8.1	10.2	0.89
Getah taban chaier . . .	" " . . .	35.6	49.5	7.4	7.5	0.72
Getah simpur . . .	" " . . .	52.0	43.4	3.4	1.2	1.61
Getah taban sutra ² . . .	<i>Palaquium Maingayi</i> . . .	44.9	45.5	8.4	1.2	2.13
Getah sundek ² . . .	<i>Palaquium oblongifolium</i> . . .	84.3	10.7	3.7	1.3	—
	<i>Payena Leerii</i> . . .	43.9	37.6	5.1	13.4	—

¹ Obtained by tapping standing trees.

² Analyses by Obach.

The commercial brands of gutta percha vary very considerably in composition and quality. They are usually designated by the names of the countries in which they are produced or of the ports from which they are shipped. Obach has classified the 12 principal brands into four groups as follows:—

I. First quality—genuine from *P. Gutta* or *oblongifolium* and allied species: (1) Pahang from the Malay peninsula, (2) Bulongan red, and (3) Banjer red from Borneo;

II. Second quality—Soondie from *Payena* spp.: (4) Bagan goolie soondie, (5) Goolie red soondie, both from Borneo, and (6) Serapong goolie soondie from Sumatra;

III. Third quality—white, botanical source not definitely known: (7) Bulongan white, (8) Mixed white, (9) Banjer white, all from Borneo;

IV. Fourth quality—mixed and reboiled: (10) Sarawak mixed, (11) Padang reboiled, and (12) Banca reboiled.

Obach has given the average results of 571 analyses of these varieties, representing 2282 tons of raw gutta percha (*see* Cantor Lectures on Gutta Percha, published by the Society of Arts, Appendix v. 90–92). The figures for the genuine varieties may be given for comparison with those recorded above:—

	Quantity represented by analyses		Percentage composition			
	Lots	Tons	Gutta	Resin	Dirt	Water
Pahang . . .	93	233	57.0	13.3	11.5	18.2
Bulongan red . . .	37	60	51.8	18.2	10.8	19.2
Banjer red . . .	91	232	40.7	20.0	17.4	21.9

The treatment which crude gutta percha undergoes in the factory previous to its technical

use may be briefly described. The lumps, after slicing if necessary, are softened by immersion in hot water and are then freed from impurities by treatment in a washing machine with hot water. The washed gutta percha while still soft is forced by pressure through wire gauze in order to remove any solid impurities which have not been eliminated in the washing process. The strained product is usually rewashed and is then transferred to the masticator or kneading machine, where the mechanically enclosed water and air are eliminated and the material rendered homogeneous. It is afterwards passed through a rolling mill and formed into sheets from $\frac{1}{8}$ to $\frac{1}{4}$ inch thick, which are cut into convenient lengths and stored in cellars until required for use. If it is desired to mix various kinds of gutta percha in order to obtain a product of a required composition, or to incorporate pigments, &c., the operation is conducted by means of a mixing machine fitted with specially shaped rollers which can be heated by steam.

In certain cases the crude gutta percha is washed with a hot 5 p.c. solution of sodium hydroxide in order to improve the colour. After treatment in this way, the product must be thoroughly washed with water to remove all trace of alkali.

The loss which results on cleaning raw gutta percha (*i.e.* the quantity of dirt and water present) is considerable, usually amounting to from 30 to 40 p.c. and sometimes to as much as 50 p.c.

For some purposes a very hard gutta percha is required, and this can be obtained by removing the resin from the ordinary material by extraction with solvents.

The physical and mechanical properties of gutta percha depend very largely on the proportions of gutta and resin present. Thus the temperature at which it softens; the time required to harden on cooling; the tensile strength; and the degree of elongation before

breaking are all related to the value of the ratio gutta : resin.

The electrical properties, *i.e.* the insulation resistance, the inductive capacity and the dielectric strength, depend principally on the nature of the gutta and on the amount of water present, and are affected very little by the removal of the resin. (For determinations of the electrical properties of gutta percha, see Obach, *l.c.* 62-65.)

Gutta percha is employed for a variety of purposes, the chief of which are the insulation of submarine cables, and the manufacture of the covers of golf balls.

The amount of gutta percha which has been used in the cable industry forms a very large percentage of the total consumption. It was stated by Obach that of the 71,933 tons of raw gutta percha used in the United Kingdom from 1845 to 1896, at least two-thirds, and probably more, had been utilised for electrical purposes. The gutta percha employed for cable manufacture has to be specially selected for the purpose, as the insulating power of the different commercial brands varies enormously.

The gutta percha used for the covers of golf balls is 'hardened' by removal of the resin in order to render it as tough and elastic as possible.

Gutta percha is also utilised for the manufacture of driving belts; rings, valves, &c., for pumps and hydraulic presses; boot soles; tubes, funnels, bottles, buckets, &c., for use with acid liquids; for cements (such as Chatterton's compound); for taking casts; and for surgical and many other minor purposes.

H. B.

GUVACINE, GUVACOLINE *v.* **ARCEA** NUT.

GUYACAN. *Casalpinia melanocarpa*, Griseb, a small tree of the family *Leguminosæ* growing in Argentina, yielding seed pods used locally as tanning agents. Guyacan resembles divi-divi. Its tannin gives a blue-black colour with iron-alum, and no precipitate with bromine water. It gives a pale yellow leather, plump, soft, and pliable.

GYNOCARDIC ACID. A term applied to the acids contained in the oil expressed from the seeds of *Gynocardia odorata*. Erroneously considered as identical with chaulmoogra oil (*cf.* Power and Gornall, Chem. Soc. Trans. 1904, 85, 838).

GYNOCARDIN *v.* **GLUCOSIDES**.

GYNOVAL *v.* **SYNTHETIC DRUGS**.

GYPSUM (*Fr.* *Gypse*; *Ger.* *Gyps*; *Ital.* *Gesso*). A common mineral composed of hydrated calcium sulphate $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$, crystallising in the monoclinic system. The name *selenite* is sometimes applied to the clear crystallised variety, *satin-spar* to the finely fibrous variety, and *alabaster* (*q.v.*) to a compact, marble-like variety used for carving. The low degree of hardness (No. 2 on the scale) is a very characteristic feature; the mineral can be readily scratched with the finger-nail. Sp.gr. 2.32. The mineral is usually white, but sometimes greyish, yellowish, or reddish; and the glistening cleavage surfaces are usually conspicuous on a broken surface. The crystals possess a highly perfect cleavage in one direction parallel to the plane of symmetry; on the smooth, bright cleavage surfaces the lustre is pearly, and coloured bands (Newton's rings) are often to be

seen. Cleavage flakes are flexible but not elastic (thus differing from mica), and when bent a fibrous cleavage is developed parallel to the faces of a pyramid: this fibrous cleavage is seen as silky striations on the principal cleavage, and is a very characteristic feature of gypsum.

Single crystals of gypsum, with a rhomb-shaped outline, are of common occurrence, embedded in clays. Fine groups of water-clear crystals are found in the sulphur mines of Sicily, the salt mines of Bex in Switzerland, and at many other localities. Enormous crystals, a yard in length, have been found in a cave in Wayne Co., Utah. Various types of twinned crystals are of common occurrence. The deposits of massive gypsum, such as are mined for economic purposes, occur as thick beds and nodular masses in sedimentary rocks of various geological periods. Those of the midlands of England are interbedded with the red marls and sandstones of Triassic age; those worked near Battle, in Sussex, belong to the later Purbeck beds; many of the deposits of the United States are of Palæozoic (Silurian, Devonian, and Carboniferous) age; whilst the important deposits in the Paris basin are of Tertiary (Eocene and Oligocene) age. These more extensive deposits of gypsum have been formed by the evaporation of water in inland lakes and seas; and they are often associated with beds of rock-salt. The mineral has, however, in many cases originated by the action of water containing sulphuric acid and soluble sulphates (produced by the weathering of iron-pyrites and other sulphides) on limestone and other calcareous rocks. It is also formed by the action of volcanic vapours on the surrounding rocks.

The output of gypsum in England amounts to about a quarter of a million tons per annum; about half of this amount is mined in Nottinghamshire, considerable quantities in Staffordshire, Sussex, and Cumberland, and less in Derbyshire, Yorkshire, Westmoreland, and Somersetshire. The value ranges from 6 to 10 shillings per ton. In France, the output reaches $1\frac{1}{2}$ million tons per annum, and about the same amount is produced in the United States. Nova Scotia and New Brunswick are also large producers. The French gypsum is remarkable in containing some admixed calcium carbonate and soluble silica, and for this reason it makes a harder plaster.

The principal use of gypsum is for the manufacture of plaster of Paris, stucco, and various kinds of wall-plasters and cements. Hence the popular name 'plaster-stone.' The employment of plaster of Paris for making the moulds in the potteries has given rise to the name '*potter's stone*' for gypsum. In the tin-plate industry gypsum is used for polishing the plates; and it is added to water to give permanent hardness in brewing. The coarser grades of material are used as fertilizers (land plaster). Alabaster is used for carvings for inside decorations; and satin-spar is cut as beads and other small personal ornaments. Under the names '*terra alba*,' '*annaline*,' and '*satinité*,' ground gypsum is used for adulterating paints and as a mineral loading in the manufacture of paper (*v.* CALCIUM).

Mines, 1911, Pub. No. 84. L. J. S.

GYROPHORIC ACID $C_{16}H_{14}O_7$ is found in

Umbilicaria pustulata (Hoffm.), *Gyrophora vellea* [(Linn.) Ach.], *Gyrophora spodochroa* [(Ehrh.) Ach.] and other lichens. It crystallises in needles from ether or dilute alcohol, melting at 202° with decomposition. Very easily soluble in acetone and alcohol. The alcoholic solution has an acid reaction, and gives a violet colour with ferric chloride. Is soluble in alkali to a yellow solution; boiling acetic acid converts it into orsellinic acid and boiling alcohol into orsellinic acid and its ethyl ester (Stenhouse, *Annalen*, 70, 218; Hesse, J. pr. Chem. [ii.] 58, 475; 62, 462; 63, 522; 68, 1; Zopf, *Annalen*, 300, 330; 313, 322; 317, 110; 338, 35; 340, 276; 346, 82).

H

"H" ACID. 1-Amino-8-naphthol-3:6-disulphonic acid.

HAALEM BLUE. *Antwerp blue v. Pigments.*

HÆMATEIN v. LOGWOOD.

HÆMATIN v. BLOOD.

HÆMATITE or HEMATITE. A mineral consisting of ferric oxide (Fe_2O_3), crystallising in the rhombohedral system, and an important ore of iron (Fe, 70 p.c.). According to whether it is crystallised, massive, or earthy, it varies considerably in external appearance. In all cases, however, the mineral gives a characteristic brownish-red streak or powder; and it is on account of this colour (resembling that of dried blood) that the mineral receives its name hæmatite, meaning, in Greek, blood-stone. The sp.gr. of the crystals is 5.2, but of the compact and earthy varieties it may be as low as 4.2; hardness 6 (except in the soft, earthy varieties).

The crystals are iron-black with a brilliant metallic lustre, and they vary from rhombohedral to tabular in habit. This variety is distinguished as *iron-glass*, or *specular iron*; or, when the crystals are thin and scaly, as *micaceous iron-ore*. The compact varieties are distinguished as *red iron-ore* or *red hæmatite*. These sometimes exhibit a fibrous or columnar structure and a nodular surface, being then known as *kidney-iron-ore*; or, when the fibrous structure is so marked that the mineral breaks into rods, as *pencil-ore*. In these cases the material is often dark-red with a dull surface, but sometimes it may be iron-black with a sub-metallic to metallic lustre. Earthy, ochreous varieties are brighter red in colour, and are often mixed with clay and other impurities; these are known as *reddle*, *ruddle*, and *red iron-froth*.

Hæmatite occurs under a variety of conditions. The best crystals are found in connection with metamorphic silicate rocks and in mineral-veins; whilst the extensive masses of red iron-ore occur as bedded deposits in sedimentary rocks, often in association with limestone. The deposits on the east coast of the island of Elba, which have been extensively worked since the time of the Romans, consist of specular iron; whilst those of west Cumberland and north Lancashire, filling large irregular cavities in limestone, consist of red iron-ore and kidney-iron-ore.

Besides being used as an ore of iron, hæmatite, in its harder, compact varieties, is used, to a limited extent, as a gem-stone, and it was the material employed for some of the ancient Babylonian cylinder-seals. The pencil-ore of Cumberland is cut and polished for mounting on scarf-pins, &c., and for the burnishing tools used by jewellers and bookbinders. Ochreous varieties are used as a polishing material, and for making red paint and red pencils.

L. J. S.

HÆMATOGEN, HÆMOL. Trade names for albuminates of iron used in the treatment of anæmia.

HÆMATOXYLIN v. LOGWOOD.

HÆMOGLOBIN v. BLOOD.

HAIDINGERITE v. CALCIUM.

HALFA. *Alfa, alva.* Arabic name for *Stipa tenacissima* (Linn.); especially applied to the Esparto grass from Algeria.

HALITE or ROCK-SALT (Fr. *Sel gemme*; Ger. *Steinsalz*). Sodium chloride NaCl, crystallised in the cubic system. Although known as a mineral since remote times and of very wide distribution, the name halite (from *hals*, salt) is comparatively recent (E. F. Glocker, 1847). Well-developed crystals with the form of simple cubes are not uncommon, but those of octahedral habit are quite rare. The faces of the cube sometimes show sunken depressions, though not so marked as in the hopper-shaped crystals produced artificially. Small square pits or etched figures are readily produced on the cube faces by solution. Silky, fibrous masses also occur. But most frequently the mineral is found as granular or sparry masses with bright cleavage surfaces. This perfect cleavage, parallel to the faces of the cube, is an important character. In addition, the crystals sometimes break along surfaces (glide-planes) parallel to the rhombic-dodecahedron. This effect is, however, secondary, and is only produced after the crystal has been subjected to pressure, either naturally by earth movements or by artificial means. If a cleavage cube of salt be placed diagonally in a vice so that two cube edges are held by the jaws, it can be broken in this direction. The plastic deformation of rock-salt and the percussion-figure (a four-rayed star with the rays parallel to the diagonals of the cube face, which is produced

on a cleavage surface by a smart blow with a blunt point) also depend on the presence of these planes of gliding.

Crystals are usually colourless and transparent, but occasionally they are of a deep blue or violet colour. This colour disappears when the salt is dissolved in water or when heated; and it can be produced artificially by the vapour of alkali metals or by the action of cathode or radium rays. It has been variously ascribed to the presence of metallic sodium, subchloride Na_2Cl , sulphur, or as an optical effect produced by thin cavities. Sp.gr. of pure crystals, 2.17; H. $2\frac{1}{2}$. Specific heat, 0.219. The mineral is a non-conductor of electricity and is highly diathermanous. It is therefore used as blocks and lenses for experiments on radiant heat. The best crystallised material is obtained from Stassfurt in Prussia, and from Wieliczka and Kalusz in Poland; good, clear cleavage blocks have been found at Meadowbank in Cheshire. Crystals are very nearly pure sodium chloride, and mixed crystals with potassium chloride (sylvite) do not occur. Massive material contains impurities of various kinds (*v.* SODIUM CHLORIDE). A variety known as *huantajayite*, containing AgCl 11 p.c., is found as small cubes at Huantajaya near Tarapaca in Chili.

Rock-salt is most frequently found as bedded deposits in sedimentary rocks, such as sandstone, shale, clay, and less often limestone, and is frequently associated with beds of gypsum and anhydrite, and sometimes with petroleum. Such deposits have evidently been formed in inland seas and lakes under desert conditions; they are of world-wide distribution and are met with in formations of all geological periods, as indicated below:

Geological formations	Localities
Recent . . .	Dead Sea, Caspian Sea, Great Salt Lake of Utah, California, &c.
Pliocene . . .	Volterra in Tuscany, Parajd in Transylvania.
Miocene . . .	Wieliczka and Kalusz in Poland, Bukovina, Minglanilla in Spain.
Oligocene . . .	Eastern Carpathians in Transylvania, Wittelsheim in Alsace.
Eocene . . .	Cardona near Barcelona, Caucasus, Roumania.
Cretaceous . . .	Unna in Westphalia, Medea in Algeria, Texas, Louisiana, Peru.
Jurassic . . .	Bex in Switzerland, Rodenburg in Hesse-Nassau, Peru.
Triassic— Keuper . . .	Cheshire, Worcestershire, Lancashire, north-east Yorkshire, Durham, Isle of Man, Antrim, Pyrenees, Lorraine, Celle in Hanover, Berchtesgaden in Bavaria, Hall in Tyrol, Hallein in Salzburg, Ischl and Hallstatt in Upper Austria, Aussee in Styria.
Muschelkalk . . .	Friedrichshall in Württemberg, Ernsthall in Thuringia.

Geological formations	Localities
Triassic: <i>contd.</i> Bunter . . .	Schöningen in Brunswick, Arnshall in Thuringia.
Permian . . .	Stassfurt, Halle, &c., in Prussian Saxony, Artern in Thuringia, Spereberg near Berlin, Segeberg in Holstein, Inowrazlaw in Posen, Orenburg in Russia, Kansas.
Carboniferous . . .	Pennsylvania, Virginia, West Virginia, Michigan, Ohio, New Brunswick, Nova Scotia.
Devonian . . .	Westphalia, Baltic provinces of Russia, Siberia, China.
Silurian . . .	New York, Michigan, Ohio, Ontario.
Cambrian . . .	Salt Range in Punjab.

In addition to these bedded deposits of rock-salt, which are the only deposits of economic importance (*v.* SODIUM CHLORIDE), mention may be made here of some other modes of occurrence. The microscopic cavities present in vast numbers in the quartz of granitic igneous rocks often contain minute cubes of halite together with water and liquid carbon dioxide. The saline encrustations of active volcanoes (*e.g.* Vesuvius), produced either by direct sublimation or by the action of acid vapours on the scoria, contain sodium and potassium chlorides, usually in a powdery form, but occasionally as distinct crystals of halite and sylvite.

References.—For a detailed *résumé* of the mineralogical characters and occurrence of halite, *v.* C. Hintze, *Handbuch der Mineralogie*, Leipzig, 1911, vol. i. pp. 101–231; on the deposits worked commercially, *v.* J. O. von Buschman, *Das Salz, dessen Vorkommen und Verwertung in sämtlichen Staaten der Erde*, 2 vols. Leipzig, 1906–9. A. F. Calvert, *Salt in Cheshire*, London, 1915. L. J. S.

HALLOYSITE. An uncrystallised clay-mineral with approximately the composition of kaolinite (*q.v.*) but containing rather more water (about 19 p.c.). It forms compact masses with a slight greasy feel and lustre, and may be white, grey, or shades of various colours; sp.gr. 2.0–2.2; H. 1–2. It occurs as beds in sedimentary rocks and as masses in mineral-veins, and has sometimes been observed as a decomposition product of granite and other rocks containing felspar. Possibly the minute amorphous granules of china-clay and some other clays may be referable to this species. (*See* H. Ries, *Clays, their Occurrence, Properties, and Uses*, 2nd ed. 1908.) L. J. S.

HÄLLEFLINTA *v.* HORNSTONE.

HALOGEN. A term originally applied by Berzelius to the group of non-oxygenated electro-negative radicles, simple and compound, which combine with metals to form salts known as *haloid salts*. Usually restricted to the four elements—Fluorine, Chlorine, Bromine, and Iodine.

HALOGEN ACETIC ACIDS. Derivatives of acetic acid in which the hydrogen of the methyl group is partly or wholly replaced by a halogen,

CHLOROACETIC ACIDS.

Monochloroacetic acid $\text{CH}_2\text{Cl}\cdot\text{COOH}$. Prepared by passing chlorine into acetic acid alone (Hoffmann, *Annalen*, 102, 1), or in the presence of iodine (Müller, *ibid.* 133, 156), sulphur (Auger and Béhal, *Bull. Soc. chim.* [iii.] 2, 145), or red phosphorus (Russanow, *J. Russ. Phys. Chem. Soc.* 23, 222); by the action of chlorine on acetyl chloride in the presence of iodine (Jazukowitsch, *Zeitsch. Chem.* 1868, 234); by the interaction of chlorine, glacial acetic acid, and acetic anhydride at 100° (Hentschel, *Ber.* 1884, 17, 1286); together with acetyl chloride by the action of chlorine on acetic anhydride at 100° (Gal, *Annalen*, 122, 374); by the interaction of ethylene and chlorine peroxide (Fürst, *ibid.* 206, 78); by heating trichloroethylene with sulphuric acid containing a small amount of water (Simon and Chavanne, U.S. Pat. 1304108; *J. Soc. Chem. Ind.* 1919, 35, 553A).

Crystallises in two modifications, α -prisms, m.p. 61.8° ; β -plates, m.p. 56.01° . By evaporating an aqueous solution or by melting the solid substance, the β -modification is produced; this changes to the α -form on the addition of a crystal of the latter (Pickering, *Chem. Soc. Trans.* 1895, 665, 670; cf. Tollens, *Ber.* 1884, 17, 665; Tanatar, *J. Russ. Phys. Chem. Soc.* 24, 694); b.p. 185° – 187° , 104° – $105^\circ/20$ mm. (Sudborough and Lloyd, *Chem. Soc. Trans.* 1899, 476); sp.gr. 1.3978 at 64.5° ; hydrates (Colles, *ibid.* 1906, 1252); heat of solution (Pickering, *l.c.*; Luginin, *Ann. Chim. Phys.* [v.] 17, 251; Tanatar, *l.c.*); heat of combustion 171.0 Cals. (Berthelot, *ibid.* [vi.] 28, 567); electrical conductivity (Kortright, *Amer. Chem. J.* 18, 368); magnetic rotation (Perkin, *Chem. Soc. Trans.* 1896, 1236); esterification constant (Sudborough and Lloyd, *l.c.*; cf. Lichty, *Amer. Chem. J.* 1895, 17, 27; 1896, 18, 590). Readily soluble in cold water, but on heating the solution decomposes into hydrochloric and glycollic acids (Buchanan, *Ber.* 1871, 4, 340, 863; Thomson, *Annalen*, 200, 75; Bevan, *Proc. Camb. Phil. Soc.* 1906, 13, 269; Senter, *Chem. Soc. Trans.* 1907, 460). Metallic hydroxides of the type R'OH decompose it, yielding glycollic acid, whilst those of the type R''(OH) yield diglycollic acid (Schreiber, *J. pr. Chem.* [ii.] 13, 346). By heating salts of chloroacetic acid with water in a sealed tube glycollic acid is produced (Kastle, *Amer. Chem. J.* 1892, 14, 586; Kastle and Keiser, *ibid.* 1893, 15, 471; cf. Euler, *Ber.* 1906, 39, 2726). On distilling the acid *in vacuo* with phosphorus pentoxide, the anhydride

is produced, whilst by distilling the acid through a heated tube, carbon monoxide, hydrogen chloride, *sym*-dichloromethyl ether and trioxymethylene are the products (Grassi-Cristaldi, *Gazz. chim. ital.* 27, i. 502). On heating with 4 parts of phosphorus pentachloride, it yields carbon tetrachloride and other products (Michael, *J. pr. Chem.* [iii.] 35, 96); with ammonia glycine is produced. By interaction with sodium sulphide and sulphur in alkaline solution a dithioglycollic acid is produced, which on reduction, yields thioglycollic acid (Kalle & Co. D. R. P. 180875; *Chem. Soc. Abstr.* 1907, i. 1008). By the electrolysis of the potassium salt acetic acid, carbon dioxide and chlorine are

formed, hydrogen not being evolved until the potassium salt is completely decomposed (Lassar Cohn, *Annalen*, 251, 335; cf. Bunge, *J. Russ. Phys. Chem. Soc.* 24, 690). By heating the dry silver salt, silver chloride and glycollic acid are produced (Beckurts and Otto, *Ber.* 1884, 14, 576). The sodium salt or the ethyl ester react with potassium cyanide to yield the corresponding derivatives of cyanacetic acid (Phelps and Tillotson, *Amer. J. Sci.* 1908, [iv.] 26, 267, 275). For interaction with tertiary amines to yield betaines, v. Reitzenstein, *Annalen*, 1903, 326, 305; with aniline, v. Vallée, *Bull. Soc. chim.* 1905, [iii.] 33, 966; with hydroxylamine, v. Rivals, *Compt. rend.* 1896, 122, 1489; with thiocyanic acid or its salts, v. Nencki, *J. pr. Chem.* [ii.] 16, 1; Jäger, *ibid.* 17; with phenols, v. Saarbach, *ibid.* 21, 151; with nitrogen sulphide, v. Francis, *Chem. Soc. Trans.* 1905, 1839.

Methyl ester. Prepared by passing chlorine into methyl acetate at 110° – 120° (Censi, *Bull. Soc. Ind. Mulhouse*, 70, 311), and as ethyl ester (*q.v.*); b.p. 115° (Censi, *l.c.*), 130° at 740 mm. (Schreiner, *Annalen*, 197, 8; cf. P. Meyer, *Ber.* 1875, 8, 1152); sp.gr. 1.2352 at 19.2° (Henry, *J.* 1885, 1329).

Ethyl ester. Prepared by the interaction of chloroacetyl chloride and alcohol (Willm, *Annalen*, 102, 109), or by the action of alcohol on monochloroacetic acid in the presence of sulphuric acid (Conrad, *ibid.* 188, 218); b.p. 144.5° – 144.9° at 754.2 mm.; sp.gr. 1.1585 at $20^\circ/4^\circ$ (Brühl, *ibid.* 203, 209). Condensation products are formed with ethyl sodiomalonate (Michael, *Ber.* 1905, 33, 3217); benzylamine (Mason and Winder, *Chem. Soc. Trans.* 1894, 628); phenylhydrazine (Reissert, *Ber.* 1895, 28, 1231; Busch, Schneider and Walter, *ibid.* 1903, 36, 3877; Meussdörffer, *J. pr. Chem.* 1907, [ii.] 75, 121); substituted ureas (Dixon, *Chem. Soc. Trans.* 1897, 628); magnesium ethyl bromide (Stüsskind, *Ber.* 1906, 39, 225); magnesium phenylamine iodide (Bodroux, *Compt. rend.* 1905, 140, 1597).

Dichloroacetic acid $\text{CHCl}_2\cdot\text{COOH}$. Prepared by chlorinating acetic acid (Maumené, *Annalen*, 133, 154; Müller, *ibid.* 159); by the interaction of chloral and potassium cyanide (Wallach, *Ber.* 1873, 6, 114; *Annalen*, 173, 295; Kötze, *Chem. Soc. Abstr.* 1910, i. 151); by passing chlorine into phloroglucinol (Hlaziwetz, *Annalen*, 155, 132; Zincke and Kegel, *Ber.* 1889, 22, 1476); by the interaction of perchlorethylene and sodium ethoxide at 120° (Geuther and Fischer, *J.* 1864, 316); of hexachlorotriketohexylene and water (Zincke and Kegel, *l.c.*); of pyrrol and sodium hypochlorite (Ciamician and Silber, *Ber.* 1885, 18, 1764); of trichloroacetic acid and sodium or barium hydroxides (Pinner, *ibid.* 757); by hydrolysing the ethyl ester (*q.v.*).

Colourless liquid, m.p. -10.8° (Pickering, *Chem. Soc. Trans.* 1895, 667); b.p. 189° – 191° ; sp.gr. 1.5724 at 13.5° ; mag. rot. (Perkin, *ibid.* 1896, 1236); esterification constant (Sudborough and Lloyd, *Chem. Soc. Trans.* 1899, 476). Slowly decomposed by heating with water in a sealed tube at 100° , more rapidly with sodium or barium hydroxides (cf. Timoféeff, *J. Russ. Phys. Chem. Soc.* 1904, 36, 255). By heating with silver oxide and a small quantity of water silver chloride and glyoxylic acid are produced (Beckurts and Otto, *Ber.* 1881, 14, 583). On electrolysis of an aqueous solution hydrogen,

carbon monoxide, carbon dioxide, and an oil containing chlorine are produced (Troeger and Ewers, J. pr. Chem. [ii.] 58, 125). The potassium salt yields potassium chloride, trichloroacetic acid, and other products on dry distillation (Friedrich, Annalen, 206, 244). Dichloroacetic acid reacts with phosphorus pentachloride (Michael, Amer. Chem. J. 9, 215); aniline and its homologues (Cech and Schwebel, Ber. 1877, 10, 179; Heller, Annalen, 1904, 332, 247; 1908, 358, 349; Ber. 1908, 41, 4264; Ostromisslensky, *ibid.* 1907, 40, 4972; 1908, 41, 3019; Heller and Aschkenasi, Annalen, 1910, 375, 261); thiourea (Dixon, Chem. Soc. Trans. 1893, 816); nitrogen sulphide (Francis, *ibid.* 1905, 1838).

Methyl ester, b.p. 142°–144° (Wallach, Annalen, 173, 299); sp.gr. 1.3808 at 19.2° (Henry, *l.c.*).

Ethyl ester. Prepared by chlorinating alcohol (Altschul and Meyer, Ber. 1893, 26, 5757); by the interaction of chloral, alcohol, and potassium cyanide (Wallach, *ibid.* 1876, 9, 1212; 1877, 10, 1526); or of dichlorinated vinyl ethers and alcohol (D. R. PP. 209268, 210502, 212592; Chem. Soc. Abstr. 1909, i. 453, 694, 873); b.p. 157.7° at 754.6 mm. (Schiff, Annalen, 220, 108); sp.gr. 1.2821 at 20.4° (Brühl, *ibid.* 203, 22). With sodium or silver it yields maleic ester (Tanatar, Ber. 1879, 12, 1563).

Trichloroacetic acid CCl_3COOH . Prepared by chlorinating acetic acid in the sunlight (Dumas, Annalen, 32, 101); by the oxidation of chloral with fuming nitric acid (Kolbe, *ibid.* 54, 183; Clermont, Ann. Chim. Phys. [vi.] 6, 135; Judson, Ber. 1870, 3, 782; Thurnlackh, Annalen, 210, 63; Tommasi and Meldola, Chem. Soc. Trans. 1874, 314), chromic acid (Clermont, Compt. rend. 76, 774), or potassium permanganate (Clermont, *ibid.* 86, 1270).

M.p. 57° (Sudborough and Lloyd, Chem. Soc. Trans. 1899, 476); sp.gr. 1.6298 at 60.6°; heat of combustion (const. press.) 92.8 Cals. (Berthelot, Ann. Chim. Phys. [vi.] 28, 569); electrical conductivity (Rivals, Compt. rend. 125, 274; Ostwald, Zeitsch. physikal. Chem. 1, 100; 3, 177; Carrara, Gazz. chim. ital. 27, i. 207); esterification constant (Sudborough and Lloyd, *l.c.*; Kailan, Monatsh. 1908, 29, 799); mag.rot. (Perkin, Chem. Soc. Trans. 1896, 1236). At 300° it decomposes into triacetyl chloride, carbon dioxide, and hydrogen chloride (Engler and Steude, Ber. 1893, 26, 1443), whilst the silver salt yields the anhydride, silver chloride, carbon monoxide, and carbon dioxide (Beckurts and Otto, Ber. 1881, 14, 576); for sodium salt, cf. Henry, *ibid.* 1879, 12, 1844. At 200° with iodine trichloride perchloromethane, hydrogen chloride, and carbon dioxide are produced (Krafft, *ibid.* 1876, 9, 1049). Chloroform and carbon dioxide are produced by heating the acid with water or alkalis (Dumas, *l.c.*; Otto, Ber. 1871, 14, 589; Seubert, *ibid.* 1875, 18, 3342), potassium cyanide (Bourgoin, Compt. rend. 94, 448), aniline (Goldschmidt and Braier, Ber. 1906, 39, 109), tertiary bases (Silberstein, *ibid.* 1881, 17, 2664), antipyrine (Stollé, Ber. Deut. pharm. Ges. 1910, 20, 371), or with resorcinol or cresol, but phenol or thymol yield hydrogen chloride, carbon monoxide, and phosgene (Anselmino, *ibid.* 16, 390). Reduction with potassium amalgam or hydriodic acid gives

acetic acid. The sodium or zinc salt yields on electrolysis trichloromethyl trichloroacetate (Elbs and Kratz, J. pr. Chem. [ii.] 55, 502). For compounds with aldehydes and ketones, v. Koboseff, J. Russ. Phys. Chem. Soc. 1903, 35, 652; Plotnikoff, *ibid.* 1904, 36, 1088; 1905, 37, 875; Ber. 1906, 39, 1794).

Methyl ester. B.p. 152.3°–152.5° at 765.3 mm. (Schiff, Zeitsch. physikal. Chem. 1, 379; cf. Anschütz and Haslam, Annalen, 253, 124); sp.gr. 1.4892 at 19.2° (Henry, J. 1885, 1329).

Ethyl ester. Prepared by the interaction of trichloroacetic acid and alcohol with sulphuric acid (Clermont, Compt. rend. 1901, 133, 737), or with hydrogen chloride (Spiegel, Ber. 1907, 40, 1730); b.p. 164°; sp.gr. 1.369 at 15° (Claus, Annalen, 191, 58; Brühl, *ibid.* 203, 22; Schiff, *ibid.* 220, 108). With ammonia it yields the amide; with sodium ethoxide, orthoformic ester, sodium ethyl carbonate, and sodium chloride are the products (Klein, Chem. Soc. Trans. 1877, i. 291).

BROMOACETIC ACIDS.

Monobromoacetic acid CH_2BrCOOH . Prepared by the action of bromine on acetic acid, either alone (Perkin and Duppa, Annalen, 108, 106) or in the presence of carbon disulphide (Michael, Amer. Chem. J. 5, 202), or of sulphur (Genvresse, Bull. Soc. chim. [iii.] 7, 364); by the interaction of chloroacetic and hydrobromic acids at 150° (Demole, Ber. 1876, 561); by the oxidation of ethylene dibromide with fuming sulphuric acid (Kachler, Monatsh. 2, 559), or of monobromoacetylene in alcoholic solution by air (Glöckner, Annalen, Suppl. 7, 115).

M.p. 49°–50°; b.p. 117°–118°/15 mm. (Sudborough and Lloyd, Chem. Soc. Trans. 1899, 477), 196° (Lassar-Cohn, Annalen, 251, 342). On heating an aqueous solution of the acid it is slowly decomposed into glycollic acid (Senter, Chem. Soc. Trans. 1909, 1828). Electrical conductivity (Ostwald, Zeitsch. physikal. Chem. 3, 178; Kortright, Amer. Chem. J. 18, 368). By heating the acid with silver powder at 130°, succinic acid is formed, whilst with silver nitrate silver glycolate is produced (Senter, Chem. Soc. Trans. 1910, 346). Nitrogen sulphide yields bromoacetamide and bromodiacetamide (Francis, *ibid.* 1905, 1839). The sodium salt heated *in vacuo* yields glycolide. The potassium salt gives on electrolysis acetic acid, bromine, and carbon dioxide, no hydrogen being evolved until the potassium salt is completely decomposed (Lassar-Cohn, *l.c.*). Monobromoacetic acid has been used as a reagent for detecting albumin in urine (Boymond, J. Pharm. Chim. [v.] 20, 482).

Methyl ester. Prepared by heating methyl alcohol and monobromoacetic acid in sealed tubes at 100° (Perkin and Duppa, Annalen, 108, 109); b.p. 144°.

Ethyl ester. Prepared as methyl ester, or together with other products by the interaction of sodium ethoxide and bromine (Sell and Salzmann, Ber. 1874, 7, 496); b.p. 159°. It undergoes numerous condensations: with magnesium it yields ethyl acetoacetate and ethyl γ -bromoacetoacetate (Stollé, Ber. 1908, 41, 954); with ethyl oxalylacetate, ethyl citrate (Lawrence, Chem. Soc. Trans. 1897, 458); with ethyl sodioacetoacetate, ethyl acetosuccinate (Sprankling, *ibid.* 1165); with ethyl dimethylacetoacetate,

ethyl $\alpha\beta$ -trimethyl- β -hydroxyglutarate (Perkin and Thorpe, *ibid.* 1178).

For other esters, *v.* Clarke, *ibid.* 1910, 428; Steinlen, Bull. Acad. roy. Belg. [iii.] 34, 101; Kuncell and Scheven, Ber. 1898, 31, 172).

Dibromoacetic acid $\text{CHBr}_2\cdot\text{COOH}$. Prepared by the action of bromine on acetic acid alone (Perkin and Duppa, Annalen, 110, 115), or in the presence of sulphur (Genvresse, Bull. Soc. chim. [iii.] 7, 478); by the hydrolysis of the ethyl ester (*q.v.*); m.p. 48° ; b.p. $232^\circ\text{--}234^\circ$; esterification constant, *v.* Sudborough and Lloyd, Chem. Soc. Trans. 1899, 477. The silver salt, heated with water, yields silver bromide, glyoxylic acid, and dibromoacetic acid (Perkin, *ibid.* 1877, i. 91).

Ethyl ester. Prepared by the action of bromine on ethyl acetate at 160° ; by passing bromine into alcohol (Schäffer, Ber. 1871, 4, 368); by the interaction of 4 parts of bromal hydrate with 1 part of alcoholic potassium cyanide (Remi, J. Russ. Phys. Chem. Soc. 7, 263); b.p. 192° .

Tribromoacetic acid $\text{CBr}_3\cdot\text{COOH}$. Prepared by the oxidation of bromal with fuming nitric acid (Schäffer, Ber. 1871, 4, 370; Gal. Compt. rend. 77, 786) or by heating an aqueous solution of malonic acid with bromine (Petrie, Ber. 1875, 8, 730). Monoclinic plates, m.p. 131° (Sudborough and Lloyd, Chem. Soc. Trans. 1899, 477; *cf.* Gal. Annalen, 129, 56); electrical conductivity, *v.* Swartz, Chem. Zentr. 1898, ii. 703. On heating at 245° bromine and hydrogen bromide are evolved. By heating an aqueous solution of the acid or its salts, bromoform is produced. For compounds with aldehydes and ketones, *v.* Koboseff, J. Russ. Phys. Chem. Soc. 1903, 35, 652; Plotnikoff, *ibid.* 1908, 40, 64, 1238).

Ethyl ester. Prepared by passing hydrogen chloride into a cooled alcoholic solution of tribromoacetic acid (Broche, J. pr. Chem. [ii.] 50, 98); b.p. 225° .

CHLOROBROMOACETIC ACIDS.

Chlorobromoacetic acid $\text{CHClBr}\cdot\text{COOH}$. Prepared by heating monochloroacetic acid (1 mol.) with bromine (1 mol.) in sealed tubes at 160° (Cech and Steiner, Ber. 1875, 8, 1174). Pungent smelling liquid, b.p. 201° ; *ethyl ester*, b.p. $160^\circ\text{--}163^\circ$; *amide*, m.p. 126° .

Monochlorodibromoacetic acid $\text{CClBr}_2\cdot\text{COOH}$. Prepared by heating monochlorodibromoacetaldehyde with fuming nitric acid (Neumeister, Ber. 1882, 15, 603); rhombic plates, m.p. 89° ; b.p. $232^\circ\text{--}234^\circ$, with decomposition. Potassium hydroxide converts it, on heating, into monochlorodibromomethane.

Dichloromonobromoacetic acid $\text{CCl}_2\text{Br}\cdot\text{COOH}$. Prepared by heating dichloromonobromoacetaldehyde with fuming nitric acid (Neumeister, *l.c.*); prisms, m.p. 64° ; b.p. 215° with decomposition; readily soluble in water or alcohol. Potassium hydroxide converts it, on heating, into dichloromonobromomethane.

IODOACETIC ACIDS.

Mono-iodoacetic acid $\text{CH}_2\text{I}\cdot\text{COOH}$. Prepared by decomposing the ethyl ester (*q.v.*) with baryta water (Perkin and Duppa, Annalen, 112, 125); by heating acetic anhydride with iodine and iodic acid (Schützenberger, Zeitsch. Chem.

1868, 484). Prismatic needles, m.p. 82° ; electrical conductivity (Walden, Zeitsch. physikal. Chem. 1892, 10, 647); esterification constant (Sudborough and Lloyd, Chem. Soc. Trans. 1899, 478).

Methyl ester. Prepared in the same manner as the ethyl ester (Aronstein and Kramps, Ber. 1881, 14, 604); b.p. $169^\circ\text{--}171^\circ$.

Ethyl ester. Prepared by the interaction of ethyl chloro- or bromoacetate, potassium iodide, and alcohol (Perkin and Duppa, *l.c.*); together with other products by heating di-iodoacetylene with excess of alcoholic potassium hydroxide (Nef, Annalen, 298, 348). Colourless oil with a penetrating smell; b.p. $69^\circ/12\text{ mm.}$; $75^\circ\text{--}78^\circ/16\text{ mm.}$ (Tiemann, Ber. 1898, 31, 825).

Di-iodoacetic acid $\text{CHI}_2\cdot\text{COOH}$. Prepared by the interaction of 1 part of malonic acid with 1 part of iodic acid in 4 parts of water; carbon dioxide is evolved, the solution is cooled, filtered, and allowed to stand. After 2 or 3 days crystals of tri-iodoacetic acid separate; these are filtered off and, after heating the filtrate, the di-iodo compound separates on cooling; m.p. 110° (Angeli, Ber. 1893, 26, 596).

Ethyl ester. Prepared by the interaction of ethyl dibromoacetate and potassium iodide in alcoholic solution (Perkin and Duppa, Annalen, 117, 351), or of ethyl dichloroacetate and calcium iodide (Spindler, *ibid.* 231, 273). Yellow liquid, which cannot be distilled unchanged under atmospheric pressure.

Tri-iodoacetic acid $\text{CI}_3\cdot\text{COOH}$. For preparation, *v.* di-iodoacetic acid. Yellow plates, m.p. 150° with decomposition. By heating with acetic acid iodoform and carbon dioxide are produced.

HALAZONE. Trade name for *p*-sulphon-dichloramine benzoic acid

Used for the sterilisation of drinking water.

HALOTRICHITE. An iron-alum

occurring naturally as silky, fibrous, efflorescent masses of a yellowish-white colour; named from ἥλς, salt, and θρίξ, τριχός, hair. It results by the action of the products of decomposition of iron-pyrites on surrounding aluminous rocks, as at Hurler and Campsie near Glasgow; and also by the action of volcanic gases on rocks, as at the Solfatara di Pozzuoli near Naples, and in Iceland, where a variety called 'hversalt' is found. A large deposit occupies the crater of an extinct volcano near the source of the Gila river in Grant Co., New Mexico. At Urmia in Persia the mineral has been used for making ink.

L. J. S.

HAMAMELIN. A preparation from the witch-hazel *Hamamelis virginiana* (Linn.), either green or brown in colour, depending upon whether the leaves or bark have been used.

HAMAMELIS. The dried bark (*Hamamelidis Corter*, B.P.) and leaves (*Hamamelidis Folia*, B.P.) of *Hamamelis virginiana* (Linn.), or witch-hazel, are used in pharmacy in tinctures, liquid extracts, solutions, and ointments.

HARDENED or HYDROGENATED OILS.

The conversion of fluid oils into solid fats on a commercial scale is, perhaps, the most important development of recent years in the oil industry. Prior to the introduction of hydrogenation processes various methods of hardening oils had been tried. One of these was based on Varentrapp's reaction, according to which oleic acid is converted into palmitic acid by fusion with potassium hydroxide, but in practice the process was found to yield material of a bad colour, whilst the large amount of hydrogen liberated in the reaction was a source of danger.

Schmidt's process of heating oleic acid with zinc chloride at 185° requires a distillation of the product, and this is attended by partial decomposition of the β -hydroxystearic acid formed in the reaction, into oleic and iso-oleic acids. Better results were obtained by methods in which oleic acid was treated with sulphuric acid at a low temperature, and the resulting sulphonated compound decomposed by means of water into hydroxystearic acid and free sulphuric acid. By distillation of the hydroxystearic acid a mixture of oleic acid and its solid isomeride iso-oleic acid was obtained, the latter being of commercial value as a candle material. It is probable that this process has now been completely superseded by processes in which the oil is hydrogenated in presence of a catalytic agent.

In 1897 Tissier (Fr. Pat. 263158, 1897) claimed a process of converting oleic acid into stearic acid by means of the nascent hydrogen liberated when fats are heated with water and finely divided zinc in an autoclave, but Freundlich and Rosauer (Chem. Zeit. 1900, 566) found that the process did not produce the results claimed for it.

Electrolytic methods of hydrogenating oleic acid are claimed in the patents of Magnier, Brangier, and Tissier (Eng. Pat. 3363, 1900) and of Hemptinne (Eng. Pat. 1572, 1905). According to the latter, oleic acid is spread in a thin layer, on metallic plates, between which is passed an electric current, whilst the air in the vessel is replaced by hydrogen. Under these conditions hydrogen is absorbed, with the formation of a considerable proportion of stearic acid and other substances of higher m.p., and the process is repeated until about 20–30 p.c. of the oleic acid has been converted. The solid products are then separated by chilling and filtering the mixture.

Better yields were obtained in Böhrlinger's process (D. R. PP. 187788, 189332, 1906) in which the cathodes consisted of platinum coated with a layer of spongy platinum, or palladium coated with palladium black.

Development of Hydrogenation Processes. The modern methods of catalytic hydrogenation are based on the investigations of Sabatier and Senderens (Compt. rend. 1900, 130, 723; 131, 187), who showed that the unsaturated bonds in organic compounds could be made to absorb hydrogen, by treating the substances with the gas in the presence of a catalyst such as finely divided platinum.

A German patent for the hydrogenation of oils on these lines was taken out in 1902 by Le Prince and Siveke, whilst in 1903 Normann (Eng. Pat. 1515, 1903) claimed a process of

catalytically hydrogenating oils either in the form of vapour or as liquid. He stated, for example, that by suspending nickel powder in oleic acid heated in an oil bath, and passing a current of hydrogen or of a gaseous mixture rich in hydrogen, through the liquid, the oleic acid could be completely converted into stearic acid.

In Day's process (U.S. Pat. 826089, 1906) catalytic hydrogenation of hydrocarbon oils is employed to effect deodorisation, palladium black being preferably used as the catalyst.

An apparatus claimed by Schwoerer (D. R. P. 199909, 1906) consists of a vessel containing a helical trough the underside of which is coated with asbestos impregnated with nickel. The oily substance, e.g. oleic acid, is brought into a fine state of division by means of superheated steam, and passed, together with hydrogen, into the vessel, where the mixture is heated to 250°–270°. Under these conditions the hydrogen is absorbed, and the stearic acid deposited to a large extent in the trough. Bedford's process (Eng. Pat. 9112, 1908) is also concerned with the hydrogenation of oleic acid in vaporised form, the mixture of acid and hydrogen being made to pass through two separated layers of catalytic material in a vertical tower, the internal temperature of which is maintained at about 200°. The upper outlet of this tower delivers into a condenser connected with a receiver and a vacuum pump.

In his processes described in D. R. PP. 211669, 221890, 1907, Erdmann claims several modifications of a method of hydrogenating oils in the form of a fine spray in presence of a nickel or other catalyst. Thus the oil may be finely divided by means of a jet of hydrogen in a chamber containing a rotating cylinder covered with a layer of the catalytic agent, and is then made to pass through a bed of pumice impregnated with nickel. Or the oil may be introduced as a spray into a tower nearly filled with porous catalytic material, and there meet a current of hydrogen from another inlet, the temperature being maintained at 170°–180°. The solid product is preferably purified by distillation with steam under reduced pressure.

In the Kayser process, which is stated to be employed on a large scale in the United States, an inert powder such as kieselguhr is used as the carrier for a nickel catalyst, the oil being agitated with this at about 150°–160°. One form of apparatus used for effecting an intimate admixture of oil and catalyst consists of a horizontal cylinder in which revolves a paddle wheel the skeleton blades of which are covered with wire gauze. Hydrogen under pressure is introduced at one end of the cylinder, and the unabsorbed gas is drawn off at the other end.

Hydrogenation under pressure is also a feature of Testrup's process (Eng. Pat. 7726, 1910), the mixture of finely divided oil and catalyst being pumped into a vessel containing an atmosphere of hydrogen. For example, a mixture of oil and palladium may be heated to about 160° in a jacketed chamber provided with a stirring device, and then forced through nozzles into a second chamber, where the temperature is maintained at about 100°, and into which a current of hydrogen is passed under pressure. If still harder products are

required, the process may be repeated in another chamber into which hydrogen is admitted at a still lower pressure, or a whole series of connected vessels may be used. (See Fig. 1.)

The use of autoclaves for hydrogenating oils has the advantage that the conversion is effected at a relatively lower temperature (100° – 160°) thus obviating the risk of injury by over-heating. In Wilbuschewitz's process (Fr. Pat. 426343, 1910) an intimate mixture of the oil and catalyst is pumped or injected into a series of connected autoclaves, through which circulates a current of hydrogen in the opposite direction. The gas may be admitted in such a way that it disperses, in the form of a spray, the oily mixture accumulating in the bottom of the vessel, so that it can be pumped into connected autoclaves, where

the process is repeated until the product has the desired m.p.; or the hydrogen may be introduced into the last autoclave, and the reduction continued in the succeeding autoclaves, with the aid of a reduction valve, and with a corresponding diminution in the pressure.

In the process claimed by Bedford and Williams (Eng. Pat. 29612, 1910) about 1 p.c. of a metal oxide catalyst is added to the oil, which is heated by means of a steam coil, in a closed vessel, to about 250° , while hydrogen is introduced through a perforated pipe at the bottom of the vessel. By using a mixture of hydrogen and oxygen in place of pure hydrogen, hydroxy fatty acids, or their compounds, may be produced by this process.

In order to effect the hydrogenation in stages

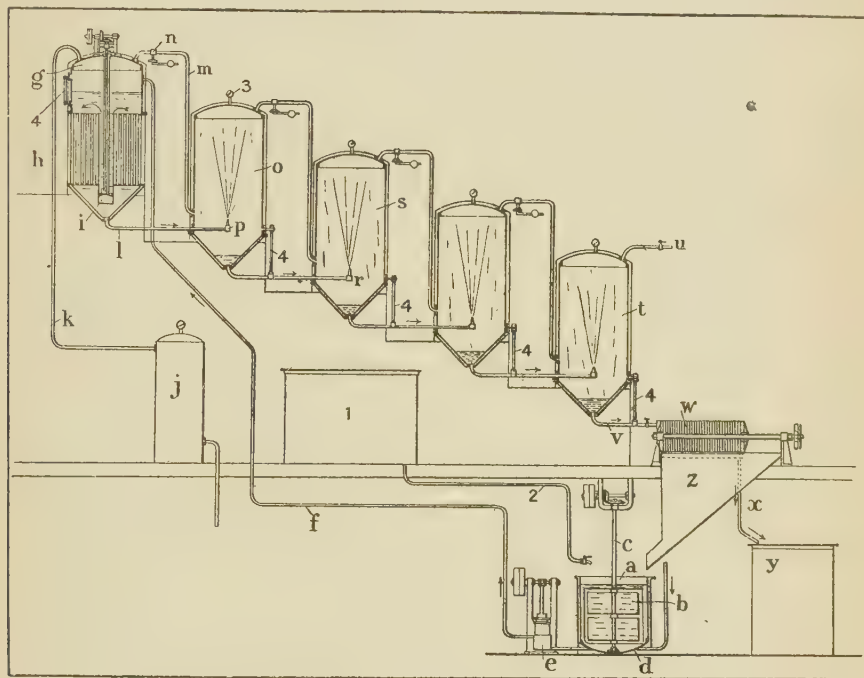

FIG. 1.

at different temperatures Ellis has devised a method whereby the mixture of oil and metal catalyst is made to pass in a continuous stream through a long tube divided into a series of compartments, and encounters a current of hydrogen travelling in the opposite direction. A different temperature is maintained in the different compartments, e.g. 150° in the first, 165° in the second, and 180° in the last (Eng. Pat. 24084, 1912). In Pictet's process (Fr. Pat. 472080, 1913) the oil, with or without the addition of a catalyst, is made to pass by gravitation through a series of communicating tubes, the walls of which are composed of catalytic metal. Hydrogen is introduced in suitable proportion, and the oil is finely divided and brought into intimate contact with the gas by means of rotating devices which brush continually against the walls of the tubes.

In order to obtain a large surface of catalytic material Dewar and Liebmann (Eng. Pat. 15668, 1914) distribute the catalyst over fibrous material such as yarn, which for strength may be enclosed between sheets of wire gauze. Or the fibrous material may be supported on frames attached to the agitator, or wound round the blades of the agitator in the hydrogenating apparatus.

In Calvert's hydrogenation process the oil is mixed with the catalyst and treated with hydrogen in a closed vessel containing a comb-shaped rotating agitator to subdivide the oil, whilst a centrifugal propeller at the base flings the mixture upwards to be beaten again.

The method of effecting minute subdivision of the oil adopted by Moore (U.S. Pat. 1121860, 1914) is to pass it together with the hydrogen through catalytic material which may be

contained in a diaphragm porous to the oil and gas, but not to the catalyst.

Lane's apparatus (Eng. Pat. 968, 1915) consists of a vertical cylindrical vessel which is heated by means of a steam jacket or otherwise. Beaters rotating horizontally round a central shaft alternate with annular sloping shelves on the sides of the vessel, so that the oil and catalyst, entering at the top, are alternately sprayed outwards to the sides and guided to the centre of the beaters next below; and so on, until they reach the bottom and are then pumped again to the top. The hydrogen enters by a pipe at the base of the apparatus (Fig. 2). In Walker's

FIG. 2.

process (U.S. Pat. 1123962, 1915) the melted fatty acids or glycerides are sprayed by means of hydrogen under pressure against heated, finely divided, catalytic material, in presence of an electric discharge.

The essential features of the process of Birkeland and Devik (U.S. Pat. 1125259, 1915) are that the oil is mixed with the catalyst and a portion forced from a jet into an atmosphere of hydrogen, and thence downwards into the body of the oil, whereby hydrogen is conveyed by suction to the bottom of the vessel and is absorbed on rising through the oil.

McElroy (U.S. Pat. 1157993, 1915) claims the use of an emulsifying process. Freshly reduced nickel is mixed with the oil, and hydrogen is made to circulate through the liquid in minute ascending bubbles in a special form of apparatus, in such a way as to produce a gas-liquid emulsion.

In the process patented by Richardson (U.S. Pat. 1177896, 1916) an electric arc is pro-

duced between nickel electrodes which are immersed in the oil, with the result that part of the metal is disintegrated and becomes incorporated with the oil. After hydrogenation the disintegrated metal is separated from the oil.

The apparatus devised by Maxted and Ridsdale (Eng. Pat. 109903, 1916) consists of a vertical column provided with baffle plates, so arranged that a mixture of oil, catalyst, and hydrogen, projected into the top of the vessel, is rotated alternately first in one direction and then in the other on its passage to the bottom.

A process for the simultaneous neutralisation and hydrogenation of oils is claimed by Schlinck and Co. (D. R. P. 334659, 1916), consisting in the addition of glycol and a catalyst before introducing hydrogen at a high temperature. The apparatus of the Soc. Anon. l'Oxyhydrique Française (Eng. Pat. 143848, 1920) contains tubular filtering devices of asbestos or biscuit porcelain, which serve for the introduction of the hydrogen in a fine state of division, and the separation of the catalyst from the oil.

The essential feature of the process of Wells (U.S. Pat. 1338887, 1921) is the vigorous agitation of the reaction mixture by the introduction of a stream of hydrogen from beneath.

Catalysts for Hydrogenation. In the original investigations on catalytic hydrogenation by Sabatier and Senderens finely divided platinum or palladium was used as the catalytic agent, but as nickel is a much less expensive catalyst than those metals it is now generally employed for the hydrogenation of oils and fats. Palladium is still used, however, in some works owing to its effecting the hydrogenation at a lower temperature (80° – 90°) and in a shorter time. According to Paal (Ber. 1908, 41, 2282) colloidal palladium effects very rapid hydrogenation of vegetable and animal oils and fats, whilst platinum black is much less effective than palladium for the purpose. The use of other metals such as cobalt, iron, and copper, as catalytic agents has also been claimed in several of the patent processes of hydrogenation.

In preparing a nickel catalyst the usual method is to precipitate nickel hydroxide from a solution of a salt such as nickel sulphate, in the presence of inert material such as kieselguhr, to dry the sludge and to reduce it in a current of hydrogen at a temperature of 300° – 325° .

In Lane's process (Engineer, 1917, 511) solutions of nickel sulphate and of sodium carbonate are prepared in separate tanks provided with steam jets, and are transferred into a third tank provided with a mixing apparatus and containing indifferent material, such as kieselguhr. The mixture of precipitated nickel carbonate and kieselguhr is dried, ground up, and roasted to convert the carbonate into oxide, after which it is heated in a current of hydrogen.

One form of apparatus used for this purpose is a vertical vessel provided with external means of heating, and containing a series of reciprocating grids. The powdered material is introduced at the top and falls on to the successive grids, the movement of which exposes fresh particles to the current of hydrogen, which is admitted at the base, and rises through the grids to the outlet at the top of the apparatus. The reduced material falls into a vessel containing oil of the same kind as is to be hydrogenated,

and, after being thoroughly mixed, the oil mass is ground until of the desired consistency.

The method of preparing the catalyst has a considerable influence on its activity and its resistance to external influences. For example, nickel which has been reduced at as low a temperature as possible is more effective than that reduced at a higher temperature, but, on the other hand, is also more sensitive to the action of catalytic 'poisons.' Ellis (J. Soc. Chem. Ind. 1912, 31, 1163) gives 300° – 325° as a suitable temperature for the reduction. According to Kelber, however (Ber. 1916, 49, 1868), a catalyst prepared by reducing basic nickel carbonate with hydrogen at 450° is more sensitive to poisons than one prepared at 310° . A catalytic agent prepared by reducing a mixture of nickel salt with an inert inorganic medium at 450° proved remarkably resistant to the action of hydrocyanic acid, hydrogen sulphide, and carbon disulphide.

Reduced iron, sodium chloride, sodium sulphate, and sodium nitrate have no influence on the activity of nickel catalysts, but sodium sulphide gradually impairs the efficiency, and sulphur destroys it immediately (Moore, Richter, and Van Arsdell, J. Ind. Eng. Chem. 1917, 9, 451). Nickel may also be rendered inactive by traces of chlorine and of decomposition products in the oils undergoing hydrogenation. For this reason low-grade oils, such as whale and fish oils, may speedily render a nickel catalyst inactive. Heating and agitating the oil with freshly-precipitated copper hydroxide has been found an effective means of removing the poisonous constituents from such oils, especially after a preliminary treatment with sodium carbonate solution (Ellis and Wells, J. Ind. Eng. Chem. 1916, 8, 886). In some cases, however, it is necessary to hydrogenate the oil in two stages, filtering off the catalyst after it has become inactive. Veno (J. Chem. Ind., Tokyo, 1918, 21, 898) has shown that powdered metals (not reduced by hydrogen), such as nickel, tin, zirconium and copper, have but little injurious action on catalytic hydrogenation, but that iron, zinc, lead and mercury act as poisons.

The efficiency of a catalytic metal is considerably increased by distributing it over a porous non-catalytic medium such as charcoal, powdered pumice, or kieselguhr, and the method of impregnating the medium with the metal forms the subject-matter of numerous patents. In Crosfield's process (Eng. Pat. 30282, 1910) an inert medium, such as asbestos or kieselguhr, is impregnated with a solution of nickel sulphate, and then treated with a solution of an alkali hydroxide. The mass, which now contains nickel hydroxide, is washed, dried, and heated in a current of hydrogen, and the resulting product should contain about 30 p.c. of metallic nickel.

Kayser (U.S. Pat. 1004034, 1911) saturates the porous medium with a solution of a nickel salt, and incorporates it in molecular proportions with powdered sodium carbonate. The mixture is then treated with boiling water, dried, and the nickel salt reduced. In a later patent (U.S. Pat. 1001279, 1911) Kayser claims a method of preparing a catalyst which may be exposed to the air for several days without undergoing oxidation and losing its catalytic

activity. In this process nickel oxide is reduced at about 500° – 600° , and a current of carbon dioxide passed through the material until the gas leaving the apparatus is no longer inflammable.

In order to accelerate the speed of reduction Wilbuschewitsch (U.S. Pat. 1016864, 1911) heats the material in a rotating drum at about 500° in the presence of hydrogen. In a later patent (U.S. Pat. 1022347, 1912) Wilbuschewitsch claims a method of recovering spent nickel catalysts, in which the material is first extracted with petroleum spirit, then treated with alkali solution, acidified, treated with sodium carbonate solution, and reduced.

In the case of fats containing substances which act as catalytic poison, Ellis (U.S. Pat. 1078136, 1913) dilutes the material, prior to hydrogenation, with a pure oil or fat. The same inventor claims the use of a catalyst consisting of a porous substance such as 'active charcoal' coated but not materially impregnated with the metallic agent (U.S. Pat. 1060673, 1913).

In Bolton and Lush's process (Eng. Pat. 162382, 1920) the poisoning of the catalyst through the formation of nickel soap is prevented by adding mono- or diglycerides to the oil. These combine with any free fatty acids present and so prevent the nickel being attacked. Bolton has also claimed a method of restoring the activity of the catalyst by washing it in the apparatus, first with hot oil to remove soap and then with a solvent to remove the oil (Eng. Pat. 162370, 1920).

In Higgins' patent (Eng. Pat. 18282, 1912) hydrogenation is accelerated by adding 1–2 p.c. of formic or other volatile organic acid to the catalytic material; whilst Lessing (Eng. Pat. 18998, 1912) claims the use of a catalyst composed of nickel carbonyl or other metallic compound which undergoes decomposition at the temperature of hydrogenation.

Reduction of nickel formate in the oil itself is described in a process of Brochet (Bull. Soc. Chim. 1920, 27, 899).

Bedford and Erdmann (Eng. Pat. 27718, 1912) make use of metallic oxides in a form suitable for catalytic agents. They assert (J. pr. Chem. 1913, 87, 425) that nickel oxides are much less sensitive than metallic nickel to external influences, and that they effect more rapid hydrogenation. In the case of the higher oxides of nickel they state that, during the hydrogenation, reduction to metallic nickel does not take place, the reduction stopping at the formation of a nickel suboxide, which is the active catalytic agent. The activity of the catalytic action is increased by the presence of the oxides of other metals. In carrying out the process the oil is heated to 180° in a cylindrical copper vessel fitted with an agitator, while a slow current of hydrogen is passed through it. A small quantity of nickel oxide is introduced, the temperature raised to 255° – 260° , and, after the addition of more catalyst, the supply of hydrogen is increased. It is claimed that the hydrogenated product is free from hydroxy acids, and that nickel soap is formed only to a very limited extent.

Erdmann and Rack also attribute any activity of nickel borate to the formation of nickel oxides at 260° . Contrary to the claim of

Schönfeld, they find that nickel borate does not convey hydrogen to unsaturated fats at 175°. Normann, however, attributes the catalytic activity of nickel borate to the formation of metallic nickel reduced by the hydrogen during the hydrogenation process, and finds that there is no positive evidence of the presence of nickel suboxide.

Meigen's experiments (J. pr. Chem. 1915, 92, 390) are also opposed to the views of Erdmann and Bedford, that an oxide or suboxide of nickel is the catalytic agent. He concludes that while it is conceivable that their view may be correct, it is a hypothesis which is lacking in experimental proof.

In Byron's method of preparing a stable catalyst (Eng. Pat. 13382, 1913) the solution of a salt of a catalytically active metal, such as nickel sulphate, is treated with a solution of an alkali silicate, and the precipitate dried, and, if desired, reduced in a current of hydrogen.

Catalysts which do not lose their activity on exposure to the air are prepared by Higgins (Eng. Pat. 23873, 1913) by heating the fatty acid salts of catalytic metals, such as the formates of nickel, cobalt, iron, or copper, until carbonisation begins, preferably in an atmosphere of nitrogen.

Richardson (U.S. Pat. 1151718, 1915) claims the use of an oleate of nickel or other metal; whilst Bacon and Nicolet (U.S. Pat. 1152591, 1915) prepare a catalyst containing nickel hydroxide and aluminium hydroxide, in which the nickel has been rendered active by reduction with hydrogen. Catalysts composed of aluminates of nickel or other heavy metals have also been patented by De Nordiske Fabriker Deno-fa Akt. (Eng. Pat. 140371, 1920).

A catalytic agent claimed by Ellis (U.S. Pat. 1156068) is prepared by incorporating hydrated nickel hydroxide $\text{Ni}(\text{OH})_2 \cdot \text{H}_2\text{O}$, with an oily medium, reducing the nickel compound with hydrogen, and removing moisture from the product. In another process, also patented by Ellis (U.S. Pat. 1159480, 1915), a basic compound of nickel is partially reduced with hydrogen to obtain a catalyst consisting of nickel and a lower oxide of nickel.

Other catalysts described by Ellis (U.S. Pats. 1378336-7-8, 1921) are prepared by incorporating organic salts of nickel, etc., with an oily medium, and heating the mixture at reduced pressure; by reducing nickel from nickel oleate in the absence of reducing gases; and by reducing mixtures of metallic salts of nickel, copper and cobalt in an oily medium.

With the object of obtaining a more stable catalyst the Bremen-Besigheimer Oelfabriken (Eng. Pat. 4023, 1915) calcine organic compounds of metals, such as nickel benzoate, either alone or in admixture with carbon or substances containing carbon, until a mixture of the metal or metallic oxides with carbon is obtained. This product is immediately introduced into oil or other inert medium to protect it from atmospheric oxidation. It is claimed that by means of this catalyst oils can be hardened at 150°-200°, whilst the carbon has a deodorising and bleaching effect. In Kimura's process (Eng. Pat. 118323, 1917) a powdered nickel salt is mixed with non-combustible non-catalytic material, such as powdered pumice or asbestos,

and the mixture dried and heated in a current of ammonia gas or vaporised ammonium compound such as ammonium chloride. Advantages claimed for the catalysts thus produced are that they act at a relatively low temperature and that any nickel salt can be used in their preparation.

Grote (Seifensied. Zeit. 1920, 47, 713) describes a form of catalyst prepared by treating an aqueous solution of a nickel salt with a solution of an aluminium or magnesium salt, washing the precipitate, and reducing it in hydrogen.

Hydrogen for Catalytic Processes. One of the main essentials for the successful hydrogenation of oils is a supply of pure hydrogen. The gas must be free from sulphur, chlorine, arsenic, and phosphorus, and contain only negligible quantities of oxygen or oxides of carbon.

In some of the larger works (Siemens-Schuckert, Ateliers Oerlikon) a very pure hydrogen, containing as impurity only 0.2 p.c. of oxygen, is prepared by the electrolysis of alkaline distilled water. In other works water gas or producer gas are used as the source of hydrogen. The methods of Linde-Frank-Caro and of the Soc. de l'Air Liquide are based on a fractional distillation of the liquefied components of water gas. The resulting hydrogen is of 97-98 p.c. purity, and is brought to 99-99.5 p.c. by being passed over soda lime heated to 180°.

In Lane's process steam is decomposed by means of reduced iron, and the resulting iron-oxide is reduced by the elements of water gas. Spathic iron ore (ferrous carbonate) is used as the original source of iron. This, when heated, yields a porous mass of ferrous oxide, which is packed into a retort, where it is alternately reduced and oxidised. The cost of hydrogen made by this process was about 4s. 2d. per 1000 cubic feet (Ellis, J. Soc. Chem. Ind. 1912, 31, 1164). Purified water gas is also used by the Soc. Lyonnaise du Gaz and the Griesheim Elektron Co., the decomposition being effected by means of a mixture of lime and iron. These methods yield hydrogen of 97.5-98.5 p.c. purity.

Where petroleum is readily obtainable the method of Rincker-Wolter is used, in which the hydrocarbons of oil gas are decomposed at a high temperature into carbon and hydrogen.

Prior to the war, the relative costs of preparing hydrogen by the different methods were given by Bontoux (Les Matières Grasses, 1914, 7, 4194) as follows: An installation for the production of electrolytic hydrogen cost about £4400 for 1590 cubic feet per hour, and about £9100 for 3530 cubic feet per hour. With electric power at 0.3d. per kilowatt-hour the gas cost about 6s. 3½d. per 1000 cubic feet, including labour. An installation for water gas cost about £7900 for 50 c.m. per hour, and the hydrogen produced cost about 3s. 4½d. per 1000 cubic feet.

Technology of Hydrogenation. From a consideration of the foregoing outlines of patent processes it will be seen that the main conditions for successful hydrogenation are a suitable temperature, fine state of subdivision of the oil, an active catalyst, and the absence of injurious substances.

Under ordinary atmospheric pressure the temperature most suitable for hydrogenation (over 250°) is liable to cause discoloration of the oil. Hence, in Lane's process, full details of which have been published (Engineer, 1917, 511, 546) a lower temperature is employed (170°–180°) and the pressure increased to about 70–80 lbs. per square inch.

For this purpose the apparatus typified in the patent description (Fig. 2) is constructed as an autoclave, and is surrounded by an outer jacket of firebricks so as to form a flue for heating gases from an external furnace.

The oil is dried first in heating vessels provided with agitators, and subsequently in vacuum pans containing a heating coil and provided with a stirring device.

The mixture of oil and nickel catalyst, which has been prepared as described, is introduced into the top of the autoclave, whilst pure hydrogen is admitted through a pipe at the base. When the gas enters the apparatus the pressure first rises and then becomes stationary at a point depending upon the temperature.

The mass of oil and catalyst is brought into contact with the hydrogen by means of a series of square beaters and cone distributors, and the process is continued until a sample drawn from a tap at the base shows the required degree of hardening.

In practice it has been found that the oil suffers from continual contact with the heated walls of the vessel, and later forms of the apparatus have therefore been constructed with a beater or paddle in the lower part of the vessel.

After sufficient hardening, the oil is drawn off, cooled slightly, and filtered through a press. The residual catalytic material is then washed free from oil, broken up, and prepared for use with a further quantity of oil.

The cost of hydrogenating a ton of linseed oil by means of a plant capable of dealing with one ton per hour was estimated in 1917 at about £2, the main items being the hydrogen (16s.) and loss of catalyst (14s. 2d.).

Properties of Hydrogenated Oils. The degree of hardening depends upon the extent to which the hydrogenation process has been carried, so that products ranging from the consistence of a soft butter to a hard tallow may be obtained from the same oil. In general, the solidified products derived from whale and fish oils are only used for technical purposes such as the manufacture of soap, as claimed by Crosfield and Sons (Eng. Pat. 13042, 1907).

Fish oils and whale oils are deodorised during hydrogenation owing to the conversion of the clupanodonic acid (to which, as Tsujimoto has shown, the odour is mainly due) into stearic acid. To obtain a product yielding a soap in which the odour does not readily reappear it is necessary to continue the hydrogenation until the iodine value is lower than fifty.

Hydrogenated oils are also suitable for use as lubricants, either alone or in admixture with other oils. For edible purposes the chief oils hydrogenated are cotton seed, maize, soya bean, and coconut oils, though any edible oil is suitable for the process. Products such as margarine and artificial lard, which formerly consisted of a vegetable oil mixed with sufficient

oleostearin to give a semi-solid mass, are now prepared from an oil such as cotton-seed oil hydrogenated to a sufficient extent to give the required consistence. In the opinion of Ellis (J. Soc. Chem. Ind. 1912, 31, 1165) this method of preparation is preferable to that used by some manufacturers of bleaching hydrogenated oils with untreated oils, since the resulting product has a better flavour and keeps better.

The objection to the use of hydrogenated fish oils or whale oils for food is that the characteristic odours are liable to reappear (Klimont and Mayer, Zeitsch. angew. Chem. 1914, 27, 645), although in other respects they appear to be as digestible as other hardened oils (Offerdahl, *l.c.*).

In Germany, prior to 1914, a technical product termed *candelite* was made from whale oil, and an edible fat *talgol* from vegetable oils, and the factories where the two classes of products were manufactured were kept distinct. With regard to the effect of hydrogenation on oils it has been found that the acid and saponification values are not materially affected, but that the refractive index and iodine value are lowered and the m.p. is raised to an extent corresponding with the degree of hydrogenation. The reduction in the refractive index is shown by the following examples given by Ellis (J. Ind. Eng. Chem. 1914, 6, 117): Maize oil, 1.4514; whale oil, 1.4550; soya bean oil, 1.4538; coconut 'olein', 1.4425; linseed oil, 1.4610; palm oil, 1.4517; and arachis oil, 1.4547.

The acetyl value of hydroxylated oils such as castor oil is lowered by hydrogenation at the usual temperatures, but Jurgens and Meigen have shown when esters of ricinoleic acid are hydrogenated below 200°, practically only the double bond is saturated.

Experiments on the hydrogenation of cotton-seed oil by Moore, Richter, and Van Ardel (J. Ind. Eng. Chem. 1917, 9, 451) have shown that linolin is hydrogenated more rapidly than olein at 200° and upwards, so that olein tends to accumulate in the fat. To obtain a hardened product with the same iodine value as another but containing, relatively, more saturated glycerides and linolin, it is necessary to effect the hydrogenation under conditions of a lower temperature, greater pressure, more vigorous agitation, and a larger proportion of catalyst.

Marine animal oils yield a much smaller proportion of insoluble bromides after hydrogenation, and the distinctive colour reactions of the original oils are either modified or no longer obtained.

Bellier's reagent (nitric acid sp.gr. 1.4 and resorcinol in benzene) also gives different colour reactions with hardened sesamé, cotton-seed, and arachis oils from those given by the original oils. The Baudouin test for sesamé oil is intensified by hydrogenation, but Halphen's test for cotton-seed oil is inhibited, the chromogenic substance giving the reaction being destroyed after hydrogenation for fifteen minutes with a nickel catalyst at 150°–160°.

The amount of phytosterol is not materially reduced by hydrogenation at 200°, but cholesterol is resinified at 200°, and after treatment at 250° will no longer yield a crystalline derivative (Marcusson and Meyerheim, Zeitsch. angew. Chem. 1914, 27, 201).

Arachidic acid may still be detected in hardened arachis oil, but a modification of the usual test is necessary.

Leimdörfer (Chem. Zentr. 1914, 1, 304) has shown that the stearic acid formed in the hydrogenation of oils is chemically identical with natural stearic acid, but that the stearin of

hydrogenated oils differs in crystalline form and other physical characters from the stearin of ordinary fats.

Typical hydrogenated oils prepared from whale oil in Germany, and intended as ingredients of margarine, were examined by Sandelin with the following results:—

	Melting point	Solidification point	Acid value	Saponification value	Iodine value	Reichert-Meißl value	Mol. weight of insol. fatty acids	M.p. of the arachidic acid
Original whale oil	Fluid	Fluid	9.50	192.2	144.8	0.27	287.7	—
Artificial tallow	47.5°	38.1°	9.88	183.7	56.9	0.25	296.4	75.5°
Artificial stearine	54.3°	47.3°	7.80	187.7	11.7	0.14	297.0	74.1°
Hydrogenated whale oil	41.9°	31.9°	5.30	190.9	57.8	0.18	282.0	76.0°

Nickel in Hydrogenated Fats. The presence of a trace of the metallic catalyst was at one time of frequent occurrence in hydrogenated fats, especially those of continental origin. Thus Bömer (Chem. Rev. Fett. Ind. 1912, 19, 221) found 0.01 p.c. of ash with 0.006 p.c. of nickel oxide in hydrogenated sesame oil, and 0.006 p.c. of ash with 0.0045 p.c. of nickel oxide in hardened whale oil. Hence, the detection of nickel in a fat indicates the presence of a hardened oil, although a negative result in the test does not necessarily prove that such products are absent, since means, such as treatment with dilute hydrochloric acid, are often employed to remove the residual metal. In experiments to ascertain the effect of traces of nickel upon the human system, Offerdahl (Ber. Deut. pharm. Ges. 1913, 23, 558) found that 0.5 gram of nickel could be taken daily without any injurious effect, 99.8 p.c. of the metal being rapidly excreted from the system.

For the detection of traces of nickel the dimethylglyoxime test may be used (see Knapp, Analyst, 1913, 38, 102), but it is necessary to take into account the fact that certain untreated oils, free from nickel, may show a similar coloration in this test (Prall). A still more sensitive reagent for nickel is *d*-benzildiacetyldioxime, as suggested by Atack (Analyst, 1913, 38, 316).

To obtain products relatively free from nickel Ellis (J. Soc. Chem. Ind. 1912, 31, 1165) lays stress upon the importance of using the catalyst in metallic form rather than in the form of oxide, since metallic nickel will not readily combine with free fatty acids to form a soap in the presence of free hydrogen. Too rapid hydrogenation should also be avoided, so as to prevent decomposition of the fat, with liberation of water, which might cause hydrolysis of the fat and liberation of free fatty acids.

For the mechanism of the addition of hydrogen to unsaturated glycerides in the presence of nickel, see Thomas (J. Soc. Chem. Ind. xxxix. 1920, 10 T.); and for a study of the relation between the occlusive power of palladium for hydrogen, and its activity in catalytic hydrogenation, see Maxted (Chem. Soc. Trans. 1921, 119, 1281). C. A. M.

HARDWICKIA RESIN v. OLEO-RESINS.

HARMALA. The seeds of the wild rue, *Pe-ganum Harmala* (Linn.), or harmal seeds, have been employed from the earliest times in Eastern

medicine as a stimulant, anthelmintic, or even as a narcotic. They are said to be the source of a red dye produced in Southern Russia, and they have been used in the manufacture of oil. Wild rue is an odoriferous herbaceous plant, 1–3 feet high, and inhabits Southern Europe, Asia Minor, Egypt, North-western India, and Southern Siberia (Flückiger, Pharm. J. [iii.] 2, 229).

Harmal seeds contain about 4 p.c. of two alkaloids (probably in combination with phosphoric acid), which are found for the most part in the outer portions of the seed. The first of these, *harmaline* $C_{13}H_{14}N_2O$, was discovered by Göbel (Annalen, 38, 363), the second, *harmine* $C_{13}H_{12}N_2O$, by Fritzsche (*ibid.* 64, 360; J. 1847–8, 639; Annalen, 68, 351; 68, 355; 72, 306; 88, 327; 88, 328; 92, 330; J. 1862, 377), who studied both alkaloids, and obtained numerous derivatives. Fritzsche extracts the seeds with water containing acetic or sulphuric acid, and saturates the solution obtained with common salt, which causes the alkaloids to precipitate in the form of hydrochlorides. The precipitate is dissolved in water, decolorised by treatment with animal charcoal, and the solution obtained is fractionally precipitated by ammonium hydroxide at 50°–60°. The first portion of the precipitate is harmine, and the last portion harmaline. The crude harmaline is best purified by recrystallisation from methyl alcohol (O. Fischer and Täuber, Ber. 18, 400). From methyl alcohol harmaline crystallises in small tables, or from ethyl alcohol in rhombic octahedra. It melts with decomposition at 238°. It is very slightly soluble in cold water or ether, but readily dissolves in hot alcohol. It forms a well-defined crystalline *hydrochloride*

hydrocyanide $C_{13}H_{14}N_2O.HCN$; *platinichloride* $(C_{13}H_{14}N_2O.HCl)_2PtCl_4$; *methiodide*

chromate $(C_{13}H_{14}N_2O)_2H_2CrO_4$; and *nitro derivative* $C_{13}H_{13}(NO_2)N_2O$. Both the hydrocyanide and the nitro derivative are bases, and combine with acids to form crystalline salts. Nascent hydrogen converts harmaline into a *dihydride* $C_{13}H_{16}N_2O$ (O. Fischer, Ber. 22, 638). Harmaline is shown by Fischer (*ibid.* 28, 2481) to be *dihydro-harmine*, and it can be converted into harmine by oxidation, which is

best effected by potassium permanganate in dilute sulphuric acid solution. By oxidation with chromic acid in boiling acetic acid solution or by nitric acid both harmaline and harmine are converted into *harminic acid* $C_{10}H_8N_2O_4$. By the action of hydrochloric acid on harmaline, Fischer and Täuber obtained a brick-red crystalline powder *harmalol* $C_{12}H_{12}N_2O$, which melts at 212° with decomposition. This compound also occurs naturally in harmal seeds, and has been isolated from them by Fischer (Chem. Zentr. 1901, i. 957).

Harmine exists in harmal seeds in much smaller proportion than harmaline. It may, however, be prepared from the latter by simple oxidation, either by the action of heat on the dry chromate, or by heating an alcoholic solution of harmaline nitrate to which hydrochloric acid has been added. Harmine crystallises in four-sided prisms (Schabus, J. 1854, 525). It melts with decomposition at 257° – 259° . It is very slightly soluble in water or alcohol, and slightly soluble in ether. The salts of harmine are crystalline and colourless, and in acid solution exhibit an indigo blue fluorescence. The more important are the *hydrochloride*

the *platinichloride* $(C_{13}H_{12}N_2O \cdot HCl) \cdot PtCl_4$; the *methiodide* $C_{13}H_{12}N_2O \cdot MeI$ (F. and T.); and the two *sulphates* $(C_{13}H_{12}N_2O)_2 \cdot H_2SO_4 \cdot H_2O$, and $C_{13}H_{12}N_2O \cdot H_2SO_4$. Fritzsche prepared the following halogen and nitro derivatives of harmine all of which are bases and form crystalline salts: *dichloroharmine* $C_{13}H_{10}Cl_2N_2O$; *nitroharmine* $C_{13}H_{11}(NO_2)N_2O$; *chloronitroharmine* $C_{13}H_{10}Cl(NO_2)N_2O$; and *bromonitroharmine* $C_{13}H_{10}Br(NO_2)N_2O$. A *tetrabromide*

has been obtained by Fischer.

When harmine is treated with concentrated hydrochloric acid at 140° , Fischer and Täuber find that it breaks up into methyl chloride and a new phenolic compound *harmol* $C_{12}H_{10}N_2O$, which crystallises in needles and melts at 321° . When harmol is fused with potash it yields a compound possessing both basic and acid properties, *harmolic acid*, $C_{12}H_{10}N_2O_5$, which melts at 247° (Fischer, Ber. 22, 637). Fischer and Täuber, by acting on harmine in acetic acid solution with chromic acid, obtained dibasic *harminic acid* $C_8H_6N_2(COOH)_2$. It forms silky needles, melting at 345° , at which point it decomposes into carbon dioxide and a crystalline basic sublimate of *apoharmine* $C_8H_8N_2$, m.p. 183° , from which Fischer obtained a well-defined gold salt. A *tetrabromide* $C_8H_8N_2Br_4$, and a *dihydride* $C_8H_8N_2H_2$, were also obtained. Other derivatives of harmine are described by Fischer and Buck (Ber. 38, 329).

Perkin and Robinson (Chem. Soc. Trans. 1912, 101, 1775; 1919, 115, 933, 967) have established the formula

for harmine. In harmaline the pyridine ring contains two, and in tetrahydroharmine it contains four additional hydrogen atoms.

Harman, obtained by zinc dust distillation of harmalol, has the formula

and is identical with a base obtained by Hopkins (J. Physiol. 1903, 29, 451) from tryptophane by oxidation; it is further identical with the alkaloid aricine of *Arariba rubra*, Mart. (Späth, Monatsh. 1919, 40, 351).

Harmine and harmaline cause convulsions, increase of saliva, interference with respiration, and depression of temperature in warm-blooded animals (Gunn, T. E. 1910, 47, 245; Flury, Arch. expt. Path. Pharm. 1910, 64, 105). In Turkey peganum seeds are used as an anthelmintic, and Flury (*loc.*) ascribes this action to the paralysis of the musculature of the parasites caused by harmaline. G. B.

HARMALIN. *Fuchsin v. Triphenyl Methane* COLOURING MATTERS.

HARMALINE, HARMALOL, HARMINE, HARMINIC ACID, HARMOL and HARMOLIC ACID. *v. HARMALA.*

HARTIN *v. RESINS.*

HARTITE *v. RESINS.*

HAUERITE. *Manganese disulphide* MnS_2 , *v. MANGANESE.*

HAUSMANNITE. A manganese oxide, Mn_3O_4 , crystallised in the tetragonal system, and the richest ore of manganese (Mn 72 p.c.). It forms pyramidal crystals with a good basal cleavage, and with very much the aspect of regular octahedra. They are opaque with a sub-metallic lustre and a dark brownish-black or black colour; the streak is chestnut-brown. Sp.gr. 4.7–4.8; H. 5–5½. Well-developed crystals are found at Ilmenau in Thuringia, Ilfeld in the Harz, Långban in Sweden, Bigrigg in Cumberland, and Miguel Burnier in Brazil. The massive black ores of manganese consist of mixtures of various manganese oxides, and doubtless hausmannite is often present, though not readily recognisable in the massive condition. L. J. S.

HAÜYNITE *v. LAPIS-LAZULI.*

HAZELINE. Trade name for a fragrant essence obtained from the fresh bark of *Hamelis virginiana* (Linn.) or witch-hazel. Is probably analogous to eucalyptol. Is a colourless oil, possessing a pleasant pungent smell and sweet astringent taste. Is used in the treatment of eczema, ulcers, burns, &c., and as a substitute for arnica.

HAZELNUT OIL. The kernels of the seeds of the hazelnut tree *Corylus avellana* (L.), yield about 55 p.c. of a bright yellow oil having the characteristic odour of the nuts. The oil, which is mainly used as a lubricant for fine machinery, such as watch-springs, is said to be liable to adulteration with olive oil, which it resembles in many of its physical and chemical characters. The following values for genuine specimens of the oil have been recorded: sp.gr. at 15° , 0.9164–0.9170; saponification value, 191.4–193.7; and iodine value, 86.2–90.2. Hazelnut oil behaves like olive oil in the claidin test, but differs from that oil in its low solidification point (-18° to -20°). The presence of

olive oil would, therefore, be suggested by the formation of a deposit on chilling the oil.

C. A. M.

HEATHER or **CALLUNA VULGARIS**. In former times the common heath or heather, until recently named *Erica vulgaris*, was used as a dyestuff for producing a yellow colour on woollen goods (Crookes, Dyeing and Calico Printing, 1874, 511). Although now almost superseded, it was until recently employed in the home industries of outlying districts, such as the Highlands of Scotland. Bancroft (Philosophy of Permanent Colours, 1813, 2, 108) states that all five species of the *ericca* or heather found in Great Britain are, he believes, capable of giving yellows much like those obtained from dyer's brown. According, however, to the experiments of J. J. Hummel the *E. tetralix* (bell heather) and *E. cinerea* contain only traces of yellow colouring matter. Leuchs (Farben u. Färbekunde, 2, 320) refers to the tanning property of heather, and notes that the effect resembles in character that given by oak bark. H. R. Procter found it to contain 6.4 p.c. of tannin. The colouring matter was isolated by Perkin and Newbury (Chem. Soc. Trans. 1899, 75, 837) from an aqueous extract of the green portion of the plant, in which it appears only to reside, by precipitation with lead acetate in the usual manner. It proved to be identical with the *quercetin* of quercitron bark. The dyeing properties of heather, though distinctly weaker, are so similar in character to those given by quercitron bark as to require no special description. Experiment showed that 36 parts of the heather were necessary to obtain as good a result as that given by 10 parts of quercitron bark.

A. G. P.

HEAVY SPAR. Native barium sulphate *v.* BARYTES and BARIUM.

HEBBAKHADÉ *v.* GUM RESINS.

HECLA POWDER *v.* EXPLOSIVES.

HECTINE. Trade name for sodium benzo-sulpho-*p*-aminophenylarsinate.

HERDERAGENIN, HEDERIC ACID *v.* Ivy, art. GUM RESINS.

HEDERIN. A poisonous glucoside $C_6H_{10}O_{13}$ found in ivy. Dextro-rotary $[\alpha]_D^{16-27}$. By hydrolysis yields rhamnose and *hederidine* $C_{26}H_{40}O_4$, crystallising in rhombic prisms, m.p. 324° , and subliming without decomposition. Hederine acts as a powerful cathartic (Houdas, Compt. rend. 128, 1463; Joánin, *ibid.* 128, 1476).

HEREDRO-TANNIC ACID *v.* Ivy, GUM RESINS.

HEDGE-MUSTARD OIL. An oil manufactured, from the so-called hedge-mustard or bank-creases (*Raphanus Raphanistrum* [Linn.]) cultivated in Hungary, and used as a substitute for rape-seed oil. The oil is brought to the market either by itself or mixed with rape-seed oil, and is occasionally sold under this latter name. The siliquous fruit of the plant mentioned bears little seeds which contain 30-35 p.c. oil. This can be for the most part obtained by pressing. It has a dark olive-green colour, and an odour and taste very similar to rape-seed oil; its density and faculty for saponifying with alkali is also nearly the same, so that it is difficult to recognise it in a mixture of the two oils. Valenta has tested the two oils as regards their behaviour with the usual reagents.

On acting upon them with acids of different strength, such as sulphuric and nitric acids, a mixture of these, *aqua regia*, phosphoric acid, &c., as well as with oxidising mixtures, as potassium dichromate and sulphuric acid, or concentrated nitric acid saturated with nitric oxide, various colours are produced with both oils, by the shade and intensity of which they can be fairly readily distinguished. The following reaction is most characteristic for hedge-mustard oil; about 5 grams of the oil are saponified with potassium hydroxide and spirit with warming, and the soap thus obtained is filtered from the unchanged oil, which is golden-yellow, and almost odourless and tasteless. On adding a large excess of hydrochloric acid to the concentrated filtrate, it assumes a distinct green colour if a somewhat large portion of hedge-mustard oil be present (J. Soc. Chem. Ind. 11, 181).

HEDIORITE. Syn. for the lactone of α -glucoheptonic acid.

HEDONAL *v.* SYNTHETIC DRUGS.

HEGONON. A combination of albumose and ammonio-silver nitrate.

HEINTZITE, HINTZEITE, *v.* KALIBORITE.

HELCOSOL. *Bismuth pyrogallate v.* BISMUTH, ORGANIC COMPOUNDS OF; and SYNTHETIC DRUGS.

HELIANTHIC ACID $C_{14}H_{18}O_8$. An acid found in sunflower seeds (Ludwig and Kromayer, Arch. Pharm. [ii.] 99, 1285).

HELIANTHIN *v.* AZO-COLOURING MATTERS.

HELICON. Syn. for acetyl salicylic acid.

HELINUS OVATUS (E. Meyer, nat. ord. *Rhamnaceæ*) is a climbing shrub indigenous to S. Africa. According to Goodson (Chem. Soc. Trans. 1920, 117, 140), it contains aconitic acid, quercetin, a saponin, and scyllitol, a substance first isolated from certain plagiostomous fishes, but found also in a number of plant products, e.g. acorns of the common oak and the leaves of *Cocos plumosa* and *C. nucifera* (cf. J. Müller, Ber. 1907, 40, 1821; H. Müller, Chem. Soc. Trans. 1907, 91, 1767; 1912, 101, 2383).

HELIOCHRYSIN *v.* NAPHTHALENE COLOURING MATTERS.

HELIOTROPE *v.* AZO-COLOURING MATTERS. Quartz.

HELIOTROPINE is a crystalline, volatile, poisonous alkaloid of bitter taste contained in *Heliotropium Europeanum* (Linn.), and *H. Peruvianum* (Linn.) (Battandier, Répert de Pharm. 1876, 4, 648). The name is also applied to a perfume (*v.* PIPERONAL).

HELIUM. Sym. He. At. wt. 3.99 (Watson); 4.002 (Heuse); 4.001 (Taylor). This element is the lightest member of the group of inert gases discovered by Rayleigh and Ramsay. Its place in the periodic classification is before lithium.

History.—During the solar eclipse of 1868 Janssen observed in the spectrum of the solar chromosphere a line in the yellow, nearly coincident with the sodium lines D_1 and D_2 , which was not attributable to any terrestrial substance. Lockyer and Frankland supposed it to be due to the presence in the sun of a new element to which they gave the name 'helium' ($\eta\lambda\iota\omicron\varsigma$, the sun).

Palmieri (Gazz. chim. ital. 1882, 12, 556) observed that the helium spectrum could be obtained from certain volcanic rocks and lavas.

Hillebrand found that the gas evolved from the mineral *uraninite* gave a fluted spectrum,

by him attributed to nitrogen, but afterwards proved to be due to helium (Bull. U.S. Geol. Survey, 1889, 78, 43).

The discovery of terrestrial helium was made by Ramsay when searching for argon, &c., in the gases evolved from the mineral *cleveite*, and its presence in the atmosphere was first noticed by Kayser (Chem. News, 1895, 72, 89), who detected the helium line in the air-spectrum. For a bibliography and account of the earlier investigations on helium, see Ramsay, Ann. Chim. 1898, [vii.] 13. A classified bibliography of the literature of helium has been compiled by E. R. Weaver, of the American Bureau of Standards (J. Ind. Eng. Chem. 1919, 11, 682). Soddy, in 1903, showed that helium is formed by the disintegration of radio-active bodies (*v. infra*).

Occurrence.—It is now known that helium is very widely distributed, though it occurs only in minute quantities. It is present in air in the proportion of 0.000056 p.c. by weight or 0.00040 p.c. by volume, *i.e.* about 1 volume of helium in 250,000 vols. of air (Ramsay, Proc. Roy. Soc. 1908, 80, A, 599). Helium also occurs in many minerals, of which the chief are *cleveite*, *bröggerite*, *samaraskite*, *uraninite*, and *fergusonite*, and it has been detected in the gases of many mineral springs, *e.g.* Bath; in those of the Pyrenees (Bouchard, Compt. rend. 121, 392); of Wildbad (Kayser, Chem. Zeit. 19, 1549); and of Maizières, the gas from the latter containing 5.34 p.c. of helium (Moureu, Compt. rend. 121, 819).

The gas obtained from minerals usually consists principally of helium with about 10 p.c. of nitrogen and smaller amounts of argon, &c. In view of the chemical inertness of helium it is of interest to know in what state it exists in minerals. Ramsay and Travers have found that, by the action of heat alone, almost exactly half the total helium in the mineral is evolved, whilst by heating with sulphuric acid the whole is obtained. The evolution of gas is also in some cases accompanied by an evolution of heat, suggesting that the helium is present as an endothermic compound (Proc. Roy. Soc. 1898, 62, 325). Gray has investigated the conditions under which helium is liberated on grinding minerals, and finds that its evolution begins when the particles have a diameter of 10μ and attains a practical limit when the diameter is 3μ , 28 p.c. of the helium content being then liberated. He concludes that the helium is contained in a structure which is large compared with the molecular structure (Proc. Roy. Soc. 1909, 82, A, 301).

Strutt has investigated the accumulation of helium in rocks in geological time (Proc. Roy. Soc. 1908, 81, A, 272), and concludes that it is due to unknown favourable circumstances, as the rate of loss of helium from minerals under experimental conditions is much greater than the rate of production from radioactive emanations (*v.i.*) (Proc. Roy. Soc. 1909, 82, A, 166).

Helium occurs in the natural gas of Kansas and of Fort Worth, Texas: 1.84 p.c. was found in the gas at Dexter, Cowley Co. (Cady and McFarland, J. Amer. Chem. Soc. 1907, 29, 1523). A plant was erected at Calgary (Canada) for the separation of helium from the natural gas of the Alberta fields. During the European War about 200,000 cubic feet of helium were

produced in the United States. The gas contained 92.5 p.c. of pure helium. It was stored in steel cylinders at a pressure of a ton per square inch. Each cylinder containing 200 cubic feet when exposed to atmospheric pressure (Chem. Abst. Amer. Chem. Soc. 1919, 13, 2258). For a description of the mode of extraction and purification, see McLennan (Chem. Soc. Trans. 1920, 117, 923). It has also been found occluded in meteoric iron (Ramsay and Travers, Proc. Roy. Soc. 60, 442).

The following table of mineral springs from which gas, containing a large percentage of helium, is evolved, is given by Moureu and Lepape (Compt. rend. 1912, 155, 197):—

Location of Spring	Helium p. c. in natural gas	Yield in litres per year of	
		Natural gas	Helium
Santenay (Côte-d'Or)— Source Lithium	10.16	51,000	5182
„ Carnot	9.97	179,000	17,845
„ Fontaine-Salée	8.40	—	—
Maizières (Côte-d'Or)— Source Romaine	5.92	18,250	1080
Grisy (Saône-et-Loire)— Source d'ys	2.18	—	—
Bourbon Lancy (Saône et-Loire)— Source du Lymbé	1.84	547,500	10,074
Néris (Allier)— Source César	0.97	3,504,000	33,990
La Bourboule (Puy-de- Dôme)— Source Choussy	0.1	30,484,800	3048

If the helium be assumed to come in the first place from radioactive disintegrations, it may be looked upon either as nascent helium evolved immediately it is produced or as dissolved, or ancient helium evolved by the disintegration of minerals in which it has been absorbed. The quantities are, however, too large for the former view, and it is more probable that the immediate source is dissolved helium. It is to be noted also that most of the above stations, as well as other sources of radioactive gas, are grouped in the neighbourhood of a line drawn through the towns of Moulins, Dijon, and Vesoul (J. Soc. Chem. Ind. 1912, 31, 720).

Preparation and purification.—The preparation of helium always involves its separation from a mixture with nitrogen, argon, krypton, &c. The mixed gases may be obtained by any of the following methods:—

(1) From 'atmospheric' nitrogen, by passing the gas over heated magnesium (Ramsay and Travers, Proc. Roy. Soc. 64, 183); or a heated mixture of magnesium and lime (Maquenne, Compt. rend. 121, 1147), when the nitrogen is absorbed and the inert gases can be collected.

(2) By fractional distillation of liquid air, according to the method of Ramsay and Travers (Phil. Trans. 1901, 197, 47). Claude has designed an apparatus for producing considerable quantities of the lighter constituents of the atmosphere (Compt. rend. 1908, 147, 624).

(3) From certain mineral springs (*v.s.*). (For methods of collecting the gases see Travers' Study of Gases, chap. iv., and Proc. Roy. Soc. 60, 442.) The gases from King's well, Bath, contain 0.12 p.c. of helium by volume, and have been used as a source of the gas by Rayleigh (Proc. Roy. Soc. 1896, 59, 198), the oxygen and nitrogen being separated as from air. It is calculated that this well produces about 1000 litres of helium annually.

The Wildbad springs contain 0.71 p.c. of helium. For determinations of the amount of helium in various natural gases, see McLennan (*l.c.*).

(4) By heating certain minerals alone, or with dilute sulphuric acid or acid potassium sulphate. This is probably the best method of preparing helium, and may be carried out as follows:—

The mineral in fine powder is introduced into a wide tube of hard glass or iron sealed at one end and connected by a rubber joint with a manometer and a reservoir, in which the gas can be collected over mercury. The whole apparatus is completely evacuated and the tube slowly heated to redness. When, after some hours, the evolution of helium becomes very slow, the heating is stopped and the gas is pumped out of the reservoir (Travers' Gases, 111). Fusion with an equal weight of acid potassium sulphate in a hard glass tube gives a larger yield, but much frothing takes place, and a preferable method is to heat with dilute sulphuric acid in an evacuated flask (Travers, Proc. Roy. Soc. 1898, 64, 131). This is a comparatively cheap method of production as 1 gram of cleveite yields over 3.2 c.c. of helium, and a kilog. of the mineral can be obtained for £1.

From the mixture of gases thus obtained pure helium may be isolated by one of the following processes:—

Jacquerod and Perrot have found that quartz is permeable to helium at 1000°–1200°; therefore by surrounding a quartz tube with impure helium at that temperature and pumping away the gas from the interior it can be obtained free from nitrogen and other inert gases (Compt. rend. 1907, 144, 135). Watson has shown that this process is not practicable with some kinds of fused quartz (Chem. Soc. Trans. 1910, 812). Ramsay's method consists in introducing the impure gas into a vacuum tube containing charcoal at the temperature of liquid air (Proc. Roy. Soc. 1905, A, 76, 111). Under these conditions all gases except helium and neon are completely condensed, and the vapour pressure of neon is so much less than that of helium, that by systematic repetition of the process a perfectly pure product can be obtained (Watson, *l.c.*).

For a continuous flow apparatus for the purification of impure helium mixtures, see Edwards and Elworthy (Trans. Roy. Soc. Canada, 1919, 13, [iii.] 47). Helium containing at least 12 p.c. of impurity can readily be purified by passing in a continuous stream over charcoal at the temperature of liquid air or oxygen. The helium is not absorbed. The rate of flow can be increased to at least 10 litres per hour without decreasing the efficiency of the absorption. By the use of two or more sets of charcoal tubes in parallel the process may be

made continuous, as the charcoal may be revived without disturbing the flow.

Properties.—Helium has so far resisted all efforts to cause it to combine with other elements. It appears, however, to be absorbed to some extent by the finely divided platinum deposited on the walls of a vacuum tube with platinum electrodes by the continued passage of an electric discharge (Travers, Proc. Roy. Soc. 60, 449). This affords a method of separating small amounts of helium and argon, as the latter is only slightly absorbed under these conditions. Cooke has found that zinc vaporised in helium has a vapour density 12 p.c. greater than when vaporised in nitrogen at the same temperature (Zeitsch. physikal. Chem. 1906, 55, 537). This indicates some tendency toward combination.

There is possibly some connection between the chemical inertness of the gas and the fact that its molecules are monatomic as shown by determinations of the ratio of the specific heats. Behn and Geiger, using a modification of Kundt's method, have found the value $C_p/C_v = 1.63$, which agrees with that required by theory and found experimentally in the case of other monatomic gases, *e.g.* mercury (Ber. deut. phys. Ges. 1907, 5, 657).

The following determinations of the density of helium have been made ($O = 16$):—

Ramsay and Travers (Phil. Trans. 1901, 197, 47) $D = 1.98$

Olzewski (Ann. Physik. 1905, [iv.] 17, 997) $D = 2.00$

Schierloh $D = 1.985$

Onnes (Leyden, Comm. 1908, No. 108) $D = 2.02$

Watson (Chem. Soc. Trans. 1910, 97, 827) $D = 1.997$

According to Heuse (Ber. deut. phys. Ges. 1913, 15, 518), the weight of a normal litre of helium is 0.17856 ± 0.00008 gram. It is next to hydrogen the lightest gas known, and may be used for filling balloons for which it is preferable to hydrogen on account of its non-inflammability.

The fact that helium is both non-inflammable, non-explosive, and possesses 92 p.c. of the lifting power of hydrogen, makes it a most suitable filling for airship envelopes. By the use of helium, the engines of airships can be placed within the envelope if desired. A further advantage possessed by helium over hydrogen is that the buoyancy may be increased or decreased at will by heating and cooling the gas by electric or other means, which fact may possibly lead to considerable modifications in the technique of airship manœuvring and navigation. Moreover, the loss of gas from diffusion through the envelope is less with helium than with hydrogen to the extent of about 30 p.c. (McLennan, *l.c.*). Helium may be mixed with hydrogen to the extent of 26 p.c. without the mixture becoming inflammable (Satterly and Burton, Trans. Roy. Soc. Canada, 1919, 13, [iii.] 211; *cf.* Ledig, J. Ind. Eng. Chem. 1920, 12, 1098).

The molecular weight is taken as 4.00, and as the gas is monatomic this is also the atomic weight.

The refractive index of helium is about 1.000035 for the whole of the visible spectrum, the dispersive power being very small (Scheel and Schmidt, Ber. deut. Phys. Ges. 1908, 6,

207; Hermann, *ibid.* 1908, 6, 211, 246). The accurate value of μ for the D lines is 1.00003500 (Burton, Proc. Roy. Soc. 1908, A, 80, 390; Cuthbertson and Metcalf, *ibid.* 411).

Helium is diamagnetic (Tänzler, Ann. Physik. 1907, [iv.] 24, 931). Its coefficient of solubility in water is less than that of hydrogen, being 0.00967 at 0°, 0.00996 at 20°, and 0.0108 at 50° (Antropoff, Zeitsch. Elektrochem. 1919, 25, 269). Helium resembles hydrogen also in that the product of pressure and volume increases with the pressure, and it is therefore used in thermometry at low temperatures.

Iron, platinum, palladium, and platinum-iridium are all impervious to helium at temperatures up to 1500° (Dorn, Phys. Ztg. 7, 312). The spectrum of helium is characterised by the presence of a strong line, D₃, in the yellow ($\lambda=5876$), which has been shown to be double, and a bright-green line ($\lambda=5016$) (cf. Stark, Ber. Deut. phys. Ges. 1914, 16, 468). The colour of the glow given by the gas in a Plücker's tube varies with the pressure, being yellow at 7 mm. and green at 1–2 mm. pressure, according to the strength of one or other of these lines. This phenomenon led Runge and Paschen to assume that helium consists of two components (Nature, 1895, 52, 520). This idea has been disproved by subsequent experiments (Nature, 1897, 56, 380).

After many fruitless attempts helium was first liquefied by Onnes (Proc. K. Acad. Wetensch. Amsterdam, 1909, 11, 168; Compt. rend. 147, 421), who found that when cooled in solid hydrogen it gave the Joule-Kelvin effect on expansion through a small nozzle and could therefore be liquefied by the Linde process. From 200 litres of the gas he thus obtained over 60 c.c. of liquid helium in 3 hours.

It is a colourless mobile liquid of density 0.122, being thus the lightest liquid known. It boils at 4.5° absolute, and has a critical temperature about 5° absolute, with a critical pressure of 2.75 atmospheres. By the rapid evaporation of liquid helium a temperature within 1° or 2° of the absolute zero has been reached, but there was no indication of the formation of the solid (Onnes, Proc. K. Acad. Wetensch. Amsterdam, 1909, 12, 175; *ibid.* 1911, 14, 678). Liquid helium has a point of maximum density in the neighbourhood of 2° absolute (Onnes, Communication from Phys. Lab. of Leyden, No. 119).

A method has been described by Bordas (Compt. rend. 1908, 146, 628) for the detection of small amounts of helium by means of a Plücker tube connected with a Dewar tube containing charcoal (Dewar, Proc. Roy. Soc. 1904, 74, 127).

Methods of determining small amounts of helium and hydrogen in air by means of the Jamin interferometer have been described by McLennan and Elworthy (Trans. Roy. Soc. Canada, 1919, 13, [iii.] 19). For the application of the catharometer for the estimation of the helium content in a mixture of gases, see Murray (*idem.* 1919, 13, [iii.] 27).

Tschermak has suggested the use of a vacuum tube containing helium as a standard in spectroscopy, and as a source of light in determining refractive indices, &c. (Chem. Soc. Abstr. 1902, ii. 189). Collie has found that the spectroscopy of helium is considerably modified by

the presence of mercury vapour and recommends a helium-mercury tube containing a trace of hydrogen as a standard in spectroscopy (Proc. Roy. Soc. 1902, 71, 25).

Production of helium from radioactive elements.—The gas evolved from a solution of radium bromide is a mixture of oxygen and hydrogen with a radioactive emanation, which can be obtained pure by condensation at a low temperature. When volatilised into a closed space the emanation phosphoresces and gives a characteristic spectrum, but in the course of about four days the radioactivity disappears and the spectrum changes to that of helium (Ramsay and Soddy, Proc. Roy. Soc. 1903, 72, 204; 1904, 73, 346). During this change the volume increases to three times that of the original emanation (Dewar and Curie, Compt. rend. 1904, 138, 190; Indrikson, Physikal. Zeitsch. 1904, 5, 214; Himstedt and Meyer, Ann. Physik. 1904, 15, 184).

It is probable that helium is the final product of the disintegration of radium. The rate of production of helium is 0.37 cub. mm. per day from 70 mgm. of radium chloride, and agrees with that calculated by Rutherford on the assumption that α -particles are helium atoms carrying two ionic charges (Dewar, Proc. Roy. Soc. 1908, 81, A, 280).

Helium is also a product of the disintegration of actinium (Giesel, Ber. 1907, 40, 3011), and of thorium radioactivity (Strutt, Proc. Roy. Soc. 1907, 80, A, 56). The rate of production in this case also supports the view that the α -particle is identical with the helium atom (Soddy, Phil. Mag. 1908, [vi.] 16, 513; Physikal. Zeitsch. 1909, 10, 41).

HELKOMEN. Trade name for a basic bismuth dibromohydroxynaphthoate. Yellow odourless powder. Used as a substitute for iodoform.

HELLANDITE. Silicate of yttrium, erbium, calcium, aluminium, and manganese crystallised in the monoclinic system. One analysis showed Y₂O₃ 19.29, Er₂O₃ 15.43, Ce₂O₃ 1.01 p.c. The crystals are prismatic in habit, and when fresh are nut-brown in colour with a resinous lustre on the conchoidal fracture. Sp.gr. 3.70; H. 5½. The mineral is readily soluble in hydrochloric acid with evolution of chlorine, and it is fusible in the Bunsen flame. Usually, however, it is much altered to a yellow or white earthy material which is optically isotropic and contains much water. The crystals are found singly, in association with tourmaline, apatite, thorite, orthite, &c., embedded in the granite pegmatite-veins which are quarried for felspar in the neighbourhood of Kragerø in the south of Norway.

L. J. S.

HELLEBOREIN, HELLEBORIN, HELLEBORIN, HELLEBORETIN, v. BLACK HELLEBORE ROOT.

HELL-HOFFITE v. EXPLOSIVES.

HELMITOL. Trade name for a compound of hexamethylenetetramine (urotropine) and anhydromethylene citric acid. Known also as neurotrophine and uropurgol. A mixture with hetraline forms citramine or citraminoxyphen (*v. SYNTHETIC DRUGS*).

HEMELLITHENOL v. PHENOL AND ITS HOMOLOGUES.

HEMIMORPHITE (or Electric Calamine). Hydrated silicate of zinc, $\text{H}_2\text{Zn}_2\text{SiO}_5$, crystallising in the orthorhombic system, and an important ore of zinc. The water is expelled only at a red heat, and the formula may be written as an acid salt or as a basic metasilicate $\text{Zn}_2(\text{OH})_2\text{SiO}_3$, or as a basic diorthosilicate $\text{H}_2\text{Zn}_2(\text{ZnOH})_2(\text{SiO}_4)_2$. An important chemical character, of help in recognising the mineral, is the fact that it readily gelatinises with acids. Crystals are not uncommon, but are usually small; they are often grouped in fan-like aggregates, at the edges of which the perfect prismatic cleavage with pearly lustre may often be seen. When doubly terminated, they show a characteristic hemimorphic development, different kinds of faces being present at the two ends of the vertical axis. Connected with this polarity is the strong pyroelectric character of the crystals. The mineral also forms mamillated and stalactitic masses; or it may be massive and cavernous and cellular, being then often mixed with clayey matter or smithsonite. The colour ranges from white to yellow and brown, and is sometimes bright blue or green. Sp.gr. 3.45; H. 4½–5. Hemimorphite usually occurs in association with zinc carbonate (smithsonite) and zinc-blende and ores of lead, often as veins and beds in limestone strata. Fine large crystals are found at Santa Eulalia, Chihuahua, Mexico; and the mineral has been mined as an ore at several localities; e.g. Cumberland, Altenberg in Rhenish Prussia, Sardinia, Santander, Hungary, Rhodesia, United States, British Columbia, &c. The ambiguous name calamine (*q.v.*) is often applied to this mineral species. L. J. S.

HEMIPINIC ACIDS $\text{C}_{10}\text{H}_{10}\text{O}_6$. *n-Hemipinic acid* (3:4-dimethoxybenzene-1:2-dicarboxylic acid) is a product of oxidation of narcotine (Wöhler, Annalen, 1844, 50, 17; Blythe, *ibid.* 43); of opianic acid (Beckett and Wright, J. 1876, 806); of berberine (Schmidt, Ber. 1883, 16, 2589); of corydaline (Dobbie and Lauder, Chem. Soc. Trans. 1894, 57; *ibid.* 1895, 18; *ibid.* 1897, 657; *ibid.* 1902, 146; Martindale, Arch. Pharm. 1898, 236, 214); and of other alkaloids. It is prepared by boiling the oxide of opianic anhydride with potassium hydroxide. The solution is then acidified and extracted with ether (Goldschmidt, Monatsh. 1888, 9, 766). It crystallises with $\frac{1}{2}$ and also with 2 molecules of water.

Properties.—Both in the normal and the meta acids the m.p. varies with the rate of heating. When heated rapidly it has m.p. about 181° (Dobbie and Lauder, Chem. Soc. Trans. 1899, 678). It is sparingly soluble in cold water, readily so in alcohol; the aqueous solution gives an orange-yellow precipitate with ferric chloride, and no precipitate with silver nitrate solution. When heated with ammonia it yields an imide $\text{C}_{10}\text{H}_9\text{NO}_4$ (Kühn, Ber. 1895, 28, 809), the potassium salt of which when heated with ethyl iodide at 150° yields the characteristic *hemipinethylimide*; m.p. 92°–96° (Goldschmidt and Ostersetzter, Monatsh. 1888, 9, 762; Liebermann, Ber. 1886, 19, 2282; Freund and Heim, *ibid.* 1890, 23, 2906). When treated with phosphorus pentachloride at 140° hemipinic acid yields the anhydride, which is also obtained by the action of equal volumes of

methyl alcohol and concentrated sulphuric acid on the acid (Beckett and Wright, *l.c.*; Wegscheider, Monatsh. 1897, 18, 649).

The *anhydride* $\text{C}_{10}\text{H}_8\text{O}_5$ forms brilliant needles; m.p. 166°–167°. It reacts with hydroxyquinol, forming *dihydroxydimethoxyfluorescein* (Liebermann and Wolbling, Ber. 1902, 35, 1782), and with resorcinol, forming *dimethoxyfluorescein* (Friedl, Weizmann, and Wyler, Chem. Soc. Trans. 1907, 1584).

Lagodzinski has synthesised alizarin from hemipinic acid by treating the latter with benzene in the presence of aluminium chloride. The aluminium compound so formed is decomposed with hydrochloric acid, and the resulting product $\text{C}_{15}\text{H}_{12}\text{O}_5\cdot\text{H}_2\text{O}$ is dissolved in cold sulphuric acid and heated to 100°. The violet solution is poured on to ice and the mono-methyl ether of alizarin so obtained is decomposed with hydrogen iodide (Ber. 1895, 28, 1427).

The *methyl ester* exists in 2 modifications; m.p. 121°–122° and 138° respectively, the latter being the more stable form at ordinary temperature (Wegscheider, Monatsh. 1897, 18, 418, 589, 629).

Other esters (Wegscheider, *l.c.*; Monatsh. 1902, 23, 327, 381; Landau, Ber. 1898, 31, 2090; Cahn-Speyer, Monatsh. 1907, 28, 803); a number of metallic salts (Salzer, Ber. 1897, 30, 1102), and many other derivatives have been obtained (Goldschmidt, Monatsh. 1887, 8, 512; Mealen, Rec. trav. chim. 1896, 15, 282, 323; Claus and Predagi, J. pr. Chem. 1897, [ii.] 55, 171; Besterzycki and Fink, Ber. 1898, 31, 930; Wegscheider, *l.c.*, and Monatsh. 1903, 24, 375; Dobbie and Lauder, *l.c.*, amongst others).

On gentle nitration, hemipinic acid yields chiefly nitro derivatives, but on more energetic nitration 5:6-dinitro-2:3-dimethoxybenzoic acid is formed (Wegscheider, Monatsh. 1908, 29, 54, 557; *ibid.* 1910, 31, 709).

m-Hemipinic acid (4:5-dimethoxybenzene-2:3-dicarboxylic acid) is a product of the oxidation of papavarine (Goldschmidt, Monatsh. 1885, 6, 380); of laudanin (*ibid.* 13, 695); and of corydic acid (Dobbie and Marsden, Chem. Soc. Trans. 1897, 664). It is also obtained by the oxidation of trimethylbrazilin (Gilbody, Perkin, and Yates, Chem. Soc. Trans. 1901, 1400; *ibid.* 1902, 1045); of tetramethylhamatoxylin (*ibid.* 1061); and of 4:5-dimethoxy-*o*-toluic acid (Luff, Perkin, and Robinson, *ibid.* 1910, 1136). It can be prepared according to the following method:—

5:6-Dimethoxy-1-hydrindone (3 grams) is boiled with nitric acid (12 grams) and water (36 c.c.). The clear yellow solution is neutralised with sodium carbonate, mixed with hydrochloric acid until the solution turns Congo paper blue, evaporated to dryness, the residue mixed with sand and extracted in a Soxhlet apparatus with ether. The ethereal solution is dried over anhydrous sodium sulphate, evaporated, and the residue dissolved in hot water, and after digestion with animal charcoal and filtration, the solution is allowed to evaporate slowly in the air. It can also be obtained by the oxidation of *iso*-nitrosodimethoxyhydrindone with potassium permanganate, which gives an almost theoretical yield (Perkin and Robinson, Chem. Soc. Trans. 1907, 1083) and by heating aqueous dimethoxycarboxybenzoyl formic acid (Perkin, *ibid.* 1902, 1025; see also Perkin and Yates, *ibid.* 242).

m-Hemipinic acid crystallises with 1 and with 2 molecules of water, has m.p. about 199° (Dobbie and Lauder), and is much less soluble in water than the normal acid. Its aqueous solution gives a cinnabar orange precipitate with ferric chloride and a white precipitate with silver nitrate. On heating it forms an anhydride, m.p. 175°; when fused with potash it yields protocatechuic acid and carbon dioxide. When treated with nitric acid it gives dinitroveratrol, whilst on reduction it yields 4:5-dihydroxy-phthalic acid (Rossin, Monatsh. 1891, 12, 488). Its *ethylimide* has m.p. 228°–230°, and unlike that from the normal acid, it is very sparingly soluble in methyl alcohol. The ethyl esters have been prepared by Rossin (*l.c.*).

HEMISINE. Syn. for Adrenaline (*q.v.*); also **SYNTHETIC DRUGS.**

HEMLOCK SPRUCE RESIN *v.* RESINS.

HEMP. The name of various plants and of the fibres derived from them (*see also* BAST-FIBRES). The following list embraces these fibres under their commercial denominations, with the names of the plants which produce them:—

Common hemp	. . . <i>Cannabis sativa</i> (Linn.).
African bowstring hemp	. . . <i>Sanseveria guineensis</i> (Willd.) and others.
Bastard hemp	. . . <i>Datisca cannabina</i> (Linn.).
Bengal or Bombay hemp	. . . <i>Crotalaria juncea</i> (Linn.).
Bombay hemp (also)	. . . <i>Hibiscus cannabinus</i> .
Bowstring (of India) hemp	. . . <i>Sanseveria Roxburghii</i> and others.
Bowstring (of India) hemp (also)	. . . <i>Calotropis gigantea</i> (Rand.).
Brown hemp	. . . <i>Crotalaria juncea</i> (Linn.).
Brown (Indian) hemp (also)	. . . <i>Hibiscus cannabinus</i> (Linn.).
Florida bowstring hemp	. . . <i>Sanseveria longiflora</i> (Sims).
Indian (in America) hemp	. . . <i>Apocynum cannabinum</i> (Linn.).
Jubbulpore hemp	. . . <i>Crotalaria juncea</i> (Linn.).
Madras hemp	. . . <i>Crotalaria juncea</i> (Linn.).
Manilla hemp	. . . <i>Musa textilis</i> .
Sisal hemp	. . . <i>Agave rigida</i> (Mill.).
Sunn hemp	. . . <i>Crotalaria juncea</i> (Linn.).
Virginian or Water hemp.	. . . <i>Acrida cannabina</i> (Linn.).

Of these, *Cannabis sativa*, nat. ord. *Urticaceæ*, allied to the hop plant, furnishes the true hemp. The plant is an annual, growing ordinarily to the height of 8 or 10 feet, but sometimes exceeding that limit by several feet; and it doubtless owes its origin to some part of temperate Asia. On extending its habitat, the character of the plant changed with soil and climate, giving origin to the supposed varieties *C. chinensis* and *C. indica*, the former of which is cultivated for its bast-fibres (hemp), while the latter is grown for its narcotics.

Hemp fibre examined by the microscope resembles that of flax in being round and ribbed; it has a mean diameter of 0.2 mm., and exhibits small hairy appendages at the joints. Accord-
VOL. III.—F.

ing to Haberlandt, the breaking strain of a cord of 1 sq. mm. section is on the average 34.5 kilos. In *Manilla* hemp the fibrous bundles are oval, nearly opaque, and surrounded by a number of rectangular cells composing a dried tissue. The bundles are smooth. *Sisal* hemp forms oval fibrous bundles surrounded by cellular tissue; a few smooth ultimate fibres projecting from the bundles. It is more translucent than *Manilla*, and is characterised by the large quantity of spiral fibres in the bundle.

Hemp is cultivated (1) for its fibre; (2) for its resin; (3) for the oil contained in its seed; (4) for the seed itself. The tough, elastic, and durable fibre is better adapted for the manufacture of cordage and sail-cloth than any other known material. It is, moreover, employed for canvas, tarpaulin, and towelling. The finest qualities for these purposes are imported from Italy and Russia. The preparation of the fibre is similar to that of flax; the stems being bruised and 'retted' or fermented in water, after which they are again beaten out and finally 'scutched' and 'hackled' or combed (*v.* FLAX). The water in which hemp has been steeped produces no evil effects on the health of a district when allowed to flow into running water, but it always destroys the fish together with certain vegetable growths (Renouard, Bied. Zentr. 1880).

The resin of hemp is employed in India as *charas*, *bharg* or *siddhi*, and *gánjá*, in which form it is used for its intoxicating and narcotic properties. *Charas* is the resin itself; *bharg* or *siddhi* consists of the dried resinous leaves and stalks; it is used for smoking, for making sweetmeats along with honey and sugar, or for forming a potable infusion. *Gánjá* is composed of the resinous fruiting heads of the female plant and is similarly employed. In 'A Report on Indian Fibres and Fibrous Substances,' Spon, 1887, it is stated that *Cannabis sativa* (var. *indica*) is chiefly, if not exclusively, cultivated on account of its narcotic principle. It has been found that the narcotic-yielding plant affords only a worthless fibre, and it is presumed that the climate of India favours the production of narcotic at the expense of the fibre. To attempt an extension of its cultivation, fiscal difficulties of a very formidable character would also have to be overcome, for the Government of India would never permit a plant of which the leaves and flowers yield so pernicious a narcotic to be widely grown. According to Hunter (The Indian Empire, and its People, History, and Products, 2nd ed. 455), excise duties are levied upon these resinous products; the hemp which furnishes them is chiefly confined to a limited area in Rájsháhi district, Bengal, and to the inner valleys of the Himalayas. The use of them is a frequent cause, not only of crime, but also of insanity. Government attempts to check consumption—first, by fixing the retail duty at the highest rate that will not encourage smuggling; and secondly, by continually raising that rate as experience suggests.

The effect of hemp-resin and its compounds on the consumer is at first to exhilarate and to promote appetite. Further doses produce delirium, sleep, and sometimes catalepsy.

Hemp-resin examined by T. and H. Smith is soluble in alcohol, and has a warm, bitter, acrid taste with a slight odour. It melts between 70°

and 90°, and has a pale-brown colour. It is called *cannabin*.

The oil is obtained by expression from the seed, which yields from 25 to 30 p.c. of oil, and 70-75 p.c. of residual cake used for cattle feeding, although sparingly on account of its laxative properties.

The seeds themselves are used as food for birds, some kinds of which are inordinately fond of them. They are roundish, ovate, of a grey colour, and contain 34 p.c. of oil and 16 p.c. of albuminoids.

The essential oil of *C. sativa* was prepared by L. Valenta (Gazzetta, 10, 479-481) by distilling the fresh leaves with water and agitating the resulting milky distillate with ether. The oil dried over calcium chloride and distilled repeatedly from sodium is colourless and mobile (b.p. 256°-258°). The analysis agreed with the formula $C_{15}H_{24}$; the vapour density could not be determined, as it decomposes at 300°. The essential oil mixes in all proportions with alcohol, ether, or chloroform.

HEMP SEED OIL. The hemp plant, *Cannabis sativa* (Linn.), is cultivated in France, Belgium, Germany, Northern Italy, Algeria, North America, India, Manchuria, and Japan. A large quantity of the seed is still grown in France, where the oil is expressed for commercial purposes. The seeds yield about 33 p.c. of oil. The colour of the freshly-expressed oil is light green to greenish-yellow, which becomes brownish-yellow on keeping.

Hemp seed oil contains a few p.c. of solid glycerides, most likely palmitin, with a small amount of stearin or arachin. The liquid fatty acids in hemp seed oil consist of linolic acid, and smaller quantities of oleic, and linolenic (and isolinolenic (?)) acids.

Hemp seed oil is used as a paint oil, though less frequently in this country than on the Continent. Considerable quantities are used on the Continent for making soft soap, characterised by a dark green colour. The lower qualities of hemp seed oil are stated to be used in the manufacture of varnishes.

It is sometimes used as an adulterant of linseed oil, and may also be present accidentally, owing to admixture of the seeds prior to expression.

The following values have been recorded for genuine samples of hemp seed oil: Sp.gr. 15°/15°, 0.9280-0.9283; saponification value, 190-192; iodine value, 157-166; m.p. of fatty acids, 17°-21°. The presence of hemp seed oil in linseed oil would be indicated by the lower iodine value, and lower yield of insoluble bromides. J. L.

HENBANE. *Hyoscyamus. Jusquiame*, Fr.; *Bilsenkraut*, Ger.

Henbane, *Hyoscyamus niger* (Linn.) (Bentl. a. Trim. 194), is one of the group of poisonous plants belonging to the natural order *Solanaceae* and is nearly related to belladonna, stramonium, and duboisia. It has been employed in medicine since the 7th century and an allied species, having similar properties, *H. albus* (Linn.) was known to Dioscorides. There are two varieties of *H. niger*, one an annual and the other a biennial. Both are to be obtained in the market, but the leaves or green tops of second-year plants of the biennial variety are the official variety

and should alone be employed in medicine (*Hyoscyami folia*, B.P.; *Hyoscyamus*, U.S.P.). The seeds possess still greater activity, but they are only used in the manufacture of alkaloid. Henbane is a coarse hairy erect herb with pale-yellow flowers marked with purple veins, and the whole plant evolves an unpleasant odour. It occurs wild throughout Britain and most parts of Europe, Asia, and Northern Africa, and has been naturalised in North and South America. Henbane is employed as a sedative, anodyne, or hypnotic, and, like belladonna and stramonium, it dilates the pupil of the eye. Its activity is destroyed by the presence of free alkali, with which it should therefore not be administered (Garrod, Pharm. J. 17, 462; 18, 174).

The active constituents of henbane are two alkaloids. The one, *hyoscyamine* $C_{17}H_{23}NO_3$, was first obtained in a pure state by Geiger and Hesse (Annalen, 7, 270) and more completely studied by Höhn and Reichardt (Annalen, 157, 98); the other, present in much smaller proportion, *hyoscine* $C_{17}H_{21}NO_4$, was discovered by Ladenburg (Annalen, 206, 282). The sulphate of the former and the hydrobromide of the latter are official in the B.P. The U.S.P. has hyoscyamine hydrobromide and scopolamine (=Hyoscine) hydrobromide. The alkaloidal content of the dried leaves is very variable; in the B.P. drug 0.045-0.14 p.c.; in annual plants from Southern Europe, 0.03 p.c.; in isolated cases yields up to 0.27 p.c. have been reported (B.P. Codex). The U.S.P. demands a minimum of 0.065 p.c. The seeds contain 0.5-0.6 p.c. of alkaloid. Hyoscyamine also occurs together with atropine in belladonna and stramonium (*v.* STRAMONIUM), and 'duboisine,' the alkaloid of *Duboisia myoporoides* (R. Br.), is identical with hyoscyamine (Ladenburg and Petersen, Ber. 20, 1661). Both hyoscyamine and hyoscine, like atropine, are mydriatic alkaloids.

To obtain hyoscyamine from henbane seeds Höhn and Reichardt first deprive them of fixed oil by treatment with ether and then exhaust by means of alcohol acidified with sulphuric acid. The clear extract, after removal of the alcohol by distillation, is almost neutralised by soda and precipitated with tannic acid. The moist precipitate is mixed with lime and extracted with alcohol. The alcoholic solution is acidified, concentrated, and purified by washing with ether. The alkaloid is then set free by the addition of soda and isolated by extraction with ether. Other somewhat similar methods have been suggested by Rennard (Neues Rep. Pharm. 17, 91), Thorey (Pharm. J. [iii.] 12, 874), and Thibaut (Chem. Zentr. 1875, 565). Duquesnel (J. Pharm. Chim. [v.] 5, 131) extracts the seeds with hot 90 p.c. alcohol containing tartaric acid, and from the solution obtained removes the alcohol by distillation. There remains a residue of two layers, a lower syrupy and an upper oily layer, which latter is found to contain most of the alkaloid, perhaps in combination with a fatty acid. This is extracted by treating the oil with water acidified with sulphuric acid. The solution is nearly neutralised with potassium bicarbonate, concentrated to a syrup, and extracted with alcohol, which leaves potassium sulphate undissolved. The alcohol is removed from the solution by distillation, and the residue, diluted

with water and treated with a slight excess of potassium bicarbonate, is extracted with chloroform. The crude hyoscyamine is removed from the chloroform solution by water acidified with sulphuric acid, is purified by treatment with animal charcoal, and the solution is then concentrated to a syrup. The alkaloid is set free by an excess of calcium carbonate, and mixed with sand, is dried over sulphuric acid. Finally, treatment with chloroform extracts the hyoscyamine and yields it on evaporation in prismatic needles.

For the properties and reactions of hyoscyamine and atropine *v.* TROPEINES.

Brandes, who analysed henbane seeds, found 24 p.c. of fixed oil (Berz. J. 21, 180); a substance 'hyoscyperin,' supposed to be a glucoside, was obtained by Höhn and Reichardt; and the presence of potassium nitrate in the leaves was pointed out by Thorey and in the medicinal extract by Attfield (Pharm. J. 3, 447).

Hyoscyamus muticus (Linn.), a species of henbane occurring in certain parts of India, and particularly in Egypt and the Sudan, has been examined by Dunstan and Brown (Chem. Soc. Trans. 75, 72), who find hyoscyamine to be the only alkaloid present in any notable quantity. It may be distinguished from *H. niger* by the occurrence of characteristic, branching, nonglandular hairs on the stem and leaves. *Hyoscyamus muticus* from Egypt has of late years become the principle industrial source of hyoscyamine (atropine). G. B.

HENDECATOIC or UNDECATOIC ACIDS

1. *n*-Undecylic acid $CH_3[CH_2]_9COOH$ is a crystalline solid having a faint smell of caproic acid; it is obtained by the reduction of undecylenic acid or by the oxidation of methylundecylketone; m.p. 28.5°; b.p. 228° (160 mm.) (Krafft, Ber. 1879, 1664).

2. Methyl dibutyl acetic acid

is obtained with other products by the oxidation of isotributylene. A white crystalline solid, insoluble in water, but soluble in alcohol or ether; m.p. 66°–70°; b.p. 260°.

3. *Umbellulic acid* $C_{11}H_{22}O_2$. The nuts of the Californian bay tree (*Umbellularia Californica* [Nutt.]) contain about 60 p.c. of a fat easily soluble in ether. It is a white, hard, tallowy mass m.p. 31°. By saponification with caustic potash and decomposition with hydrochloric acid, the acid is obtained as a white solid with a faint odour and very disagreeable and irritating taste; m.p. 31°–34°; b.p. 275°–280°. Its alkyl esters are colourless mobile liquids of agreeable odour (Spillman and O'Neill, Amer. Chem. J. 1882, 206). Possibly identical with *cocinic acid* found by Saint-Evre in cocoa-nut oil, and with the *undecylic acid* of Krafft (*v. supra*).

HENDECENOIC ACID, $C_{11}H_{20}O_2$, an acid boiling at 258°–261° found in petroleum; known also as *petroleum acid*. It is obtained from the petroleum distillate, b.p. 250°–270°, by adding sodium hydroxide and then to the alkaline extract, sulphuric acid. This is treated with alcohol and hydrochloric acid, and the resulting ester fractionated and hydrolysed with alcoholic potash (Hell and Medinger, Ber. 1874, 1217; 1877, 451).

HENNA (*Al-henneh*, *Al-henna*, or *All-Kenna*).

The root and leaves of *Lawsonia alba*, an aqueous infusion of which has long been used in the East as a prophylactic against certain skin diseases. The root is considered as a specific against leprosy and the flowers are used in preparing a perfume. The fruit is employed as an emmenagogue. Used largely as a dye and for staining the hair, soles of the feet, palms of the hands and nails of an orange-red colour, and to colour the manes and tails of horses.

Lawson, $C_{10}H_6O_3$, the colouring matter contained in henna leaves is a hydroxy naphthoquinone, and is probably identical with 2-hydroxy-1.4-naphthoquinone. (Tommasi, Gazz. chim. ital. 1920, 50, I. 263) *v.* ALKANET and ALKANNA.

HEPARADEN and HEPARON *v.* SYNTHETIC DRUGS.

HEPAR SICC. *v.* SYNTHETIC DRUGS.

HEPATIC CINNABAR *v.* CINNABAR.

HEPTOIC ACIDS $C_7H_{14}O_2$.

1. *n*-Heptoic acid, *enanthylic acid*

Obtained by the oxidation of *enanthol* (Bussy, Annalen, 60, 248; Tilly, *ibid.* 67, 107; Krafft, Ber. 1882, 1717; Schorlemmer and Grimshaw, Annalen, 170, 141); also formed by the oxidation of castor-oil, of oleic acid, and of normal heptyl alcohol (Schorlemmer, Annalen, 161, 279; Tripier, Bull. Soc. chim. [iii.] 11, 99); from the normal hexyl cyanide (Franchimont, Annalen, 165, 237); and by the reduction of dextrosecarboxylic acid (Kiliani, Ber. 1886, 1130). An oily liquid; b.p. 222.4° (743.4 mm.), m.p. –10.5°, sp.gr. 0.9183, 20°.

2. *iso*Heptoic acid; *α*-methylhexoic acid

Obtained by boiling hexyl cyanide with alcoholic potash (Hecht, Annalen, 209, 309), or by the reduction of fructosecarboxylic acid (Kiliani, Ber. 1885, 3071). An oily rancid smelling liquid; b.p. 211.5° (745.8 mm.), sp.gr. 0.9138, 21°. Soluble in 278 parts water.

3. *Isoenanthylic acid* found among the products obtained by heating a mixture of sodium acetate and sodium isovalerate; b.p. 217°, sp.gr. 0.9260, 15° (Porsche, Annalen, 218, 66).

4. *iso*Amyl acetic acid; *δ*-methylhexoic acid

Obtained by the action of sodium and *iso*amyl iodide upon ethyl acetate (Frankland and Duppa, Annalen, 138, 338), or by the distillation of *iso*-amylmalonic acid (Paal and Hoffmann, Ber. 1890, 1498); b.p. 208°–210°, sp.gr. 0.9122, 13°.

5. *Methyl diethyl acetic acid; αα*-methyl-ethylbutyric acid $CH_3(C_2H_5)_2C'COOH$. Obtained by prolonged heating of methyl diethyl carbinol cyanide with strong hydrochloric acid (Schdanow, Annalen, 185, 120); b.p. 207°–208° (753 mm.); almost insoluble in water.

6. *Methyl isopropyl propionic acid; βγ*-dimethylvaleric acid

Obtained by heating sodium isovalerate with sodium ethoxide in a stream of carbon monoxide (Loos, Annalen, 202, 321); b.p. 220°.

7. *Ethylpropylacetic acid; α*-ethylvaleric acid $CH_3(CH_2)_2CH(C_2H_5)CO_2H$. Obtained by hydrolysing ethylpropylacetacetic ester with alkali (Kiliani, Ber. 1886, 227); b.p. 209.2°.

8. *Active amylic acid*; γ -methylhexoic acid $\text{CH}_3(\text{C}_2\text{H}_5)_2\text{CH}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{COOH}$. Obtained by heating active amylicmalonic acid (Welt, Ann. Chim. [vii.] 6, 132); b.p. 221° ; sp.gr. 0.9149, $20^\circ/20^\circ$.

9. *Methylisobutylacetic acid*; $\alpha\gamma$ -dimethylvaleric acid. Obtained by heating methylisobutylmalonic acid (Burrows and Bentley, Chem. Soc. Trans. 1895, 511); b.p. 204° - 205° .

iso-HEPTYLACETIC ACID v. NONOIC ACIDS.
n-HEPTYLSUCCINIC ACID

Obtained by the reduction of hexylita-, -citra- or -mesaconic acids with sodium amalgam (Fittig and Hoeffken, Annalen, 304, 337); m.p. 90° - 91° .

HERABOL. See Myrrh, art. GUM RESINS.

HERCULES METAL v. ALUMINIUM.

HERCULES POWDER v. EXPLOSIVES.

HERMOPHENYL v. SYNTHETIC DRUGS

HERNIARINE v. LACTONES.

HEROIN v. OPIUM AND SYNTHETIC DRUGS.

HERRING OIL is obtained from the several species of herring, *Clupea harengus* (North Sea), *C. Pallasi*, *C.* and *V.* (Japan). This oil is now extracted on a commercial scale in Japan, and genuine specimens of such oil have been prepared by Tsujimoto. The Japanese herring oil yields on brominating 3.82-6.5 p.c. of the octobromide of clupanodonic acid, which is a characteristic constituent of all fish oils. The herring oils produced in Europe (Norway) are not kept separate from other fish oils, and, therefore, do not represent such pure oils as those described by Tsujimoto. The iodine value of genuine herring oil ranges from 103 to 123 (Tsujimoto), whilst the commercial North Sea herring oil has a higher iodine value (about 131-142).

Like all other fish oils, herring oil is chiefly used in the leather industry. J. L.

HESPERIDIN v. GLUCOSIDES.

HESSIAN PURPLE, RED, YELLOW, v. AZO-COLOURING MATTERS.

HESSITE or TELLURIC SILVER. Silver telluride, Ag_2Te , crystallised in the cubic system and isomorphous with argentite. The silver (Ag 63.3 p.c.) is often partly replaced isomorphously by gold, forming a passage to petzite. The colour is lead-grey, and the material somewhat sectile; sp.gr. 8.3-8.9, H. 2½-3. The best crystals, though much distorted, are from Botes in Transylvania, and massive material was formerly obtained in some quantity in the Slavodinsk mine in the Altai Mountains, Siberia. The mineral has also been found in California, Colorado, and Utah. L. J. S.

HESSONITE v. GARNET.

HETEROXANTHINE, 7-methylxanthine,

occurs together with xanthine and paraxanthine as a constituent of normal human urine (Salomon, Ber. 1885, 18, 3406; Virchow's Archiv. 1891, 125, 554); 10,000 litres yielded 22.2 grams of the mixed bases, of which 11.36 grams was heteroxanthine (Salomon and Krüger, Zeitsch. physiol. Chem. 1898, 24, 364); it occurs also with xanthine in the urine of the dog (Salomon, *ibid.* 1887, 11, 410). Heteroxanthine appears to be a

product of the metabolism of theobromine and caffeine, for when rabbits, dogs, or men are dosed with these alkaloids, heteroxanthine appears in the urine (Bondzynski and Gottlieb, Ber. 1895, 28, 1113). According to Albanese (Gazz. chim. ital. 1895, 25, ii. 298) heteroxanthine is an intermediate product in the transformation that caffeine undergoes in the organism, the methyl groups being removed one by one until xanthine is obtained, and this is converted into urea and ammonia. Heteroxanthine acts as a powerful diuretic on dogs and rabbits when hypodermically injected in small doses; larger doses are toxic, an injection of 1 gram killed a dog weighing 8 kilos. in 10 days (Albanese, *l.c.*). (Cp. also Krüger and Salomon, Zeitsch. physiol. Chem. 1895, 21, 169; Schmiedeberg, Ber. 1901, 34, 2556.)

The synthesis of heteroxanthine from theobromine has been effected by Fischer (Ber. 1897, 30, 2400). When 2 : 6-dichloro-7-methyl-

action of phosphoryl chloride on theobromine, is heated at 120° - 125° with hydrochloric acid (sp.gr. 1.19), it is converted into the hydrochloride of 7-methylxanthine or heteroxanthine. Krüger and Salomon (Zeitsch. physiol. Chem. 1898, 26, 389) also obtained it by the action of nitrous acid on epiguanine, 7-methylguanine (2-amino-

and as Fischer (*l.c.*) has synthesised epiguanine, this method of preparation is also synthetical. Traube and Dudley (Ber. 1913, 46, 3845) obtained heteroxanthine by the action of nitrous acid on 1 : 7-dimethylguanine.

Heteroxanthine is a crystalline powder; when heated gradually it melts and decomposes at 341° - 342° , when heated rapidly it darkens at 360° , and melts and decomposes at 380° . It dissolves in 142 parts of boiling water (Fischer, *l.c.*), or in 7575 parts of alcohol at 17° , or in 2250 parts at the boiling temperature (Bondzynski and Gottlieb, Ber. 1895, 28, 1113). Heteroxanthine possesses both acidic and basic properties, the basic dissociation constant k_b being 3.754K ; and the acidic dissociation constant k_a being 1276K , where K is the dissociation constant of water (Wood, Chem. Soc. Trans. 1906, 1840).

Heteroxanthine forms salts with acids that are readily dissociated in water, the hydrochloride crystallises in tufts of transparent crystals, and yields a microcrystalline platinichloride; the sulphate $\text{C}_6\text{H}_5\text{O}_2\text{N}_4\cdot\text{H}_2\text{SO}_4$ is decomposed by water. Heteroxanthine forms a characteristic sodium derivative $\text{NaC}_6\text{H}_5\text{O}_2\text{N}_4\cdot 5\text{H}_2\text{O}$, crystallising in plates or prisms, melting at about 300° , readily soluble in water, sparingly so in sodium hydroxide; the potassium derivative has similar properties and a higher melting-point (Salomon, Ber. 1885, 18, 3406; Virchow's Archiv. 1891, 125, 554). Heteroxanthine yields a crystalline precipitate with mercuric chloride, and forms a crystalline derivative with silver nitrate. It is also precipitated by copper acetate, phosphotungstic acid or lead acetate in the presence of ammonia (Salomon, *l.c.*). It is differentiated from hypoxanthine, xanthine, and

guanine by the sparing solubility of its sodium derivative in sodium hydroxide; it differs from paraxanthine in being amorphous and sparingly soluble, and in not yielding a precipitate with picric acid in the presence of hydrochloric acid.

When a solution of heteroxanthine containing chlorine water and nitric acid is evaporated, the residue develops a red colour with ammonia, becoming blue on the addition of sodium hydroxide. On oxidation with potassium permanganate in concentrated sulphuric acid heteroxanthine yields three of its four nitrogen atoms as ammonia or carbamide, and the fourth as methylamine (Jolles, Ber. 1900, 33, 2126, 2120).

By electrolytic reduction in sulphuric acid solution, heteroxanthine yields 7-methyl-2-oxy-1:6-dihydropurine (Tafel and Weinschenck, Ber. 1900, 33, 3374). M. A. W.

HETOCRESOL. Trade name for cinnamyl-m-cresol. Used as a dusting powder in surgery.

HETOFORM. Formin benzoate.

HETOL. An aqueous solution of sodium cinnamate. Used in the treatment of inoperable cancer.

HETRALIN. A resorcin-hexamethylene-tetramine preparation, containing 9 p.c. of formaldehyde.

HEWETTITE. A hydrated vanadate of calcium $\text{CaO} \cdot 3\text{V}_2\text{O}_5 \cdot 9\text{H}_2\text{O}$, crystallised in the orthorhombic system. It forms mahogany-red, earthy masses, composed of minute silky needles, and occurs somewhat abundantly as an oxidation product of patronite (*q.v.*) at Minasragra, near Cerro de Pasco in Peru. The mineral fuses readily to a dark-red liquid, and is slightly soluble in water. Sp.gr. 2.55.

Meta-hewettite is identical with hewettite in composition and in crystallising in the orthorhombic system, but it differs somewhat in its optical characters and behaviour during dehydration. It is found as a dark-red, powdery impregnation in sandstone at Paradox Valley in Colorado, and over a wide area in eastern Utah. L. J. S.

HEXACYANOGEN $\text{CN} \cdot \text{C} \begin{smallmatrix} \nearrow \text{N} \cdot \text{C}(\text{CN}) \\ \searrow \text{N} : \text{C}(\text{CN}) \end{smallmatrix} \searrow \text{N}$ is obtained by heating a mixture of cyanuric tricarboxylamide and phosphoric oxide in a vacuum at 250°. Is decomposed by water with production of cyanuric acid. Is unattacked by the halogens. When strongly heated decomposes forming dicyanogen (Ott, Ber. 1919, 52 [B], 656).

HEXADECYLENEDICARBOXYLIC ACID, *Tetradecylsuccinic acid* $\text{C}_{18}\text{H}_{34}\text{O}_4$. Prepared by heating hexadecylenedibromide, potassium cyanide, and alcohol at 160°–190°, and decomposing the nitrile thus formed with alcoholic potash (Krafft and Grosjean, Ber. 1890, 2355); m.p. 121°. The anhydride melts at 89°.

HEXAHYDROXYBENZENE *v.* PHENOL AND ITS HOMOLOGUES.

HEXAL. Hexamethylenetetramine sulphosalicylate.

HEXALLT. Trade name for hexamethylenetetramine salicyl sulphonic acid.

HEXAMECOL. Hexamethylenetetramine guaicol. Used as an external disinfectant in skin diseases.

HEXAMETHYLENETETRAMINE *v.* METHYL-

HEXAMINE. Syn. for hexamethylenetetramine (*q.v.*).

HEXANATRIN. Trade name for a combination of hexamethylenetetramine and acid sodium phosphate.

HEXANEDIONE *v.* KETONES.

HEXANITRIN. Trade name for mannitol hexanitrate.

cyclo-**HEXANONE** and **HEXENONE** *v.* KETONES.

HEXOIC ACIDS *v.* CAPROIC ACIDS.

HEXOPHAN. Oxyphenylquinoline dicarbonate.

HEXOSEPHOSPHORIC ACID *v.* FERMENTATION.

HEXOSES *v.* CARBOHYDRATES.

HIBBENITE *v.* HOPEITE.

HIDDENITE. A transparent, emerald-green variety of the mineral spodumene $\text{LiAlSi}_2\text{O}_6$ (*q.v.*), used as a gem-stone. It is found with emerald in North Carolina, and has been popularly, but erroneously, known as 'lithia-emerald.' L. J. S.

HIGHGATE RESINS *v.* RESINS.

HIIROGANE. "Hiirrogane" is the name applied to a blood-red coloured metal prepared either by treatment of copper with an aqueous solution of copper sulphate and verdigris, or by heating a copper alloy with a paste containing a salt of copper, borax, and some water. Cf. SHAKUDO (S. Miyazawa, J. Chem. Ind. Tokyo, 1917, 20, 1102; J. Soc. Chem. Ind. 1918, 37, 211a).

HING *v.* GUM RESINS.

HIPPOL. Trade name for methylene-hippuric acid. Used as a urinary antiseptic.

HIPPURIC ACID, *Benzamino-acetic acid benzoylglycine* $\text{NH}(\text{C}_6\text{H}_5\text{O})\text{CH}_2 \cdot \text{CO}_2\text{H}$, an acid found in the urine of horses and cows and other herbivora and in human urine when benzoic acid is taken internally. It is prepared from urine by boiling with milk of lime, neutralising with HCl, concentrating to one-eighth original volume, and saturating with HCl; crude strongly coloured hippuric acid separates; it may be purified by passing chlorine into the hot aqueous solution, filtering while hot, and rapidly cooling the filtrate. May be prepared by action of benzoic anhydride on glyocoll (Curtius, Ber. 1884, 1663). Crystallises in large trimetric prisms, soluble in water, alcohol, and ethyl acetate; insoluble in light petroleum; m.p. 187.5°. Has a slightly bitter taste and reddens litmus. Decomposes on heating, forming benzonitrile and benzoic acid (Limpricht and Usilar, Annalen, 88, 133). Its aqueous solution boiled with mineral acids yields glyocoll (glycine) and benzoic acid. Oxidation with potassium permanganate in acid solution yields carbamide (Jolles, Ber. 1900, 2834). In presence of acetic anhydride, it reacts with thiocyanates forming 2-thio-3-benzoyl hydantoin, the yield being greatly influenced by the thiocyanate used: thus NH_4CNS gives 93.4 p.c., KCNS about 48 p.c. (Johnson, Hill and Bailey, J. Amer. Chem. Soc. 1915, 2406). Hippuric acid may be detected in urine by treating a few c.c. with sodium hypobromite, just sufficient being taken to decompose the carbamide and impart a permanent yellow colour to the solution. If hippuric acid is present, a characteristic orange- or brownish-red precipitate is formed on boiling

the solution (Dehn, J. Amer. Chem. Soc. 1908, 1508). It may be estimated by hydrolysing the hippuric acid, extracting the benzoic acid with chloroform and titrating with sodium ethylate; this method can be used for its estimation in urine (Folin and Flanders, J. Biol. Chem. Soc. 1912, 11 Proc. xxvii.).

HIPTAGIN. $C_{10}H_{14}O_5N_2 \cdot \frac{1}{2}H_2O$, a glucoside, from *Hiptage Madablotia* (Gaertn.). Forms silky needles, m.p. 110° ; $[a]_D +3.5^\circ$ in 5 p.c. acetone solution. Alkalis evolve ammonia and form hydrocyanic acid. For other reactions and probable constitution and mode of origin, see Gorter, Bull. Jard. bot. Buitenzorg. 1920, [iii.] 2, 187.

HISTAMINE. Trade name for β -Iminazolyethylamine v. ERGOT.

HISTIDINE, glyoxaline-4-alanine, l- α -amino- β -glyoxaline-4 (or 5)-propionic acid, β -iminazole- α -aminopropionic acid

was discovered by Albrecht and Kossel (Zeitsch. physiol. Chem. 1896, 22, 176) among the hydrolytic products of the protamine sturine, which contain 12.9 p.c. histidine, 12 p.c. lysine, and 58.2 p.c. arginine (Kossel, *ibid.* 1900, 31, 207). Hedin (*ibid.* 1896, 22, 191) isolated it from the bases precipitated by silver nitrate from the decomposition products of other proteins. Kutscher (*ibid.* 1898, 25, 195) found it present in antipeptone obtained by the pancreatic digestion of fibrin. Lawroff (*ibid.* 1899, 28, 388) and Abderhalden and Rona (*ibid.* 1904, 41, 278) prepared it from thymus histon; and Koch (J. Biol. Chem. 1911, 9, 121) established its presence among the hydrolytic products of the globulin from pigs' thyroids. Jones obtained 15 grams of histidine hydrochloride from 2 litres of a concentrated suspension of red blood corpuscles (J. Biol. Chem. 1918, 33, 429). Hanke and Koessler prepared 15 grams pure histidine dihydrochloride from 500 c.c. of blood corpuscle paste (J. Biol. Chem. 1920, 43, 521). Histidine occurs also with arginine and lysine among the hydrolytic products of vegetable proteins, notably in the seeds and seedlings of *Picea excelsa* (Linn.), *Pinus sylvestris* (Linn.), *Cucubita Pepo* (Linn.), *Lupinus luteus* (Linn.), and *Pisum sativum* (Linn.); in the case of conifer seeds 300 grams of the dry proteid yield 3 grams histidine hydrochloride, 19 grams arginine nitrate, and 3 grams lysine picrate (Schulze and Winterstein, Zeitsch. physiol. Chem. 1899, 28, 459, 465; 1901, 33, 547). It is present in *secale cornutum* (Fränkel, Rainer, Biochem. Zeitsch. 74, 167), in J. artichoke and salsify (Schulze and Trier, Zeitsch. physiol. Chem. 1912, 81, 53), in some of the lower fungi (Sullivan, Science, 1913, 38, 678; and Reed, J. Biol. Chem. 1914, 19, 260); see also Chapman, Chem. Soc. Trans. 1914, 105, 1895, for probable presence in hops. It is found in soils (Schreiner and Shorey, J. Biol. Chem. 1910, 8, 381; Skinner, Bied. Zentr. 1913, 42, 213, from 8th Proc. Int. Cong. Appl. Chem. 1912; Lathrop, Chem. Zentr. 1917, 11, 560), in fresh fish (Suzuki, J. Agric. Tokyo, 1912, 5, 1), and in diphtheria bacillus (Tamura, Zeitsch. physiol. Chem. 1914, 89, 295).

The constitution of histidine as α -amino- β -glyoxaline-4 (or 5)-propionic acid, has been estab-

lished by the work of Fränkel, Pauly, Knoop and Windaus, and Pyman. Fränkel (Monatsh. 1903, 24, 229) showed that histidine contains a carboxyl group, since it displaces carbon dioxide from silver and copper carbonates, and an amino group because on treatment with hypobromite or nitrous acid one nitrogen atom is removed and a hydroxyl group introduced. Fränkel, therefore, represented histidine by the partially expanded formula $\text{NH}_2 \cdot \text{C}_5\text{H}_8\text{N}_2 \cdot \text{CO}_2\text{H}$, and gave the name *histine* to the complex $-\text{C}_5\text{H}_8\text{N}_2-$, and *hydroxydeaminohistidine* or *hydroxyhistinecarboxylic acid* to the compound $\text{OH} \cdot \text{C}_5\text{H}_8\text{N}_2 \cdot \text{CO}_2\text{H}$ obtained from histidine by the action of nitrous acid. Pauly (Zeitsch. physiol. Chem. 1904, 42, 508) confirmed the presence of the carboxyl group in histidine by preparing the methyl ester, and proved that the *histine* complex $-\text{C}_5\text{H}_8\text{N}_2-$ contains an imino-group, because histidine yields a dinaphthalene- β -sulphone derivative, and forms a red dye with diazobenzenesulphonic chloride. These considerations, and the stability of the compound towards oxidising agents led Pauly to conclude that the complex *histine* contains an iminazole or glyoxaline ring, and that histidine is α -amino- β -glyoxaline-4 (or 5)-propionic acid

This conclusion has been confirmed by Knoop and Windaus (Beitr. Chem. Physiol. Path. 1905, 7, 144), who obtained *glyoxaline-4* (or 5)-propionic acid

by reducing Fränkel's hydroxydeaminohistidine, and showed that it is identical with the synthetic product prepared by the action of formaldehyde and ammonia on Wolff's glyoxypropionic acid (Annalen, 1890, 260, 79). Cf. Fränkel (Beitr. Chem. Physiol. Path. 1907, 19, 116).

Knoop (Beitr. Chem. Physiol. Path. 1907, 10, 111) also showed that by the successive oxidation of hydroxydeaminohistidine *glyoxaline-*

4 (or 5)-carboxylic acid $\begin{array}{c} \text{NH}-\text{CH} \\ | \quad \diagup \\ \text{CH}=\text{N} \quad \text{C} \cdot \text{CO}_2\text{H} \end{array}$ is ob-

tained, which, when heated at 286° , loses carbon

dioxide and yields glyoxaline $\begin{array}{c} \text{NH}-\text{CH} \\ | \quad \diagup \\ \text{CH}=\text{N} \quad \text{CH} \end{array}$

The complete synthesis of histidine from 4 (or 5)-chloromethylglyoxaline is described by Pyman (Chem. Soc. Trans. 1911, 1386). 4 (or 5)-Chloromethylglyoxaline (I), obtained from diaminoacetone (*ibid.* 668), condenses with ethyl sodiochloromalonate to form *ethyl 4* (or 5)-*glyoxalinemethylchloromalonate* (II)

This ester on hydrolysis is converted into *r*- α -chloro- β -glyoxaline-4 (or 5)-propionic acid (III), which reacts with ammonia to form *r*- α -amino- β -glyoxaline-4 (or 5)-propionic acid (IV), that is *r*-histidine

Pyman (Chem. Soc. Trans. 1916, 109, 186) also synthesised *r*-histidine from benzoyl-*r*-histidine by boiling this for four hours with 20 p.c. aqueous hydrochloric acid. *r*-Histidine can be resolved by the fractional crystallisation of the salts it forms with *d*-tartaric acid into the *d*- and *l*-isomers, and the *l*-histidine thus obtained is identical with the naturally occurring compound. *d*-*l*-histidine is partly resolved by means of yeast, the *d*-isomeride remaining unattacked (Abderhalden and Weil, Zeitsch. physiol. Chem. 1912, 77, 435; Ehrlich, Biochem. Zeitsch. 63, 379).

A possible explanation of the formation of histidine in the plant economy is afforded by the work of Knoop and Windaus (Beitr. Chem. Physiol. Path. 1905, 6, 292; Ber. 1906, 39, 3886; 1907, 40, 799) on the synthetic formation of iminazole derivatives from sugars and ammonia. These authors find that when a solution of glucose containing zinc hydroxide dissolved in ammonia is exposed to the sunlight at the ordinary temperature for some weeks, it is converted to the extent of 10 p.c. into 4- or 5-methyliminazole. It is probable that glyoxal and formaldehyde are produced as intermediate products and then react with the ammonia according to the equation

d-Mannose, *d*-fructose, *d*-sorbose, *l*-arabinose, or *l*-xylose also yield methyliminazole when similarly treated. The authors suggest that histidine may be formed naturally by the condensation of methyliminazole with glycecol and simultaneous oxidation

Histidine crystallises from water in needles or tables, m.p. 287° (corr.); the aqueous solution has a sweet taste (Fränkel, Monatsh. 1903, 24, 229; Pyman, Chem. Soc. Trans. 1911, 1397), is feebly alkaline (Hedin, Zeitsch. physiol. Chem. 1896, 22, 191), and is optically active [α]_D -39.74° (Kossel and Kutscher, *ibid.* 28, 382); [α]_D -36.7° (Pyman, *l.c.*); it racemises on heating under pressure (Abderhalden and Weil, *l.c.*).

r-Histidine crystallises in quadrilateral plates, and decomposes at 283° (corr.); *d*-histidine crystallises in monoclinic plates forming elongated hexagons; it decomposes at 287°-288° (corr.), and has [α]_D +39.3° (Pyman, *l.c.*, and 1916, 109, 197).

When histidine is administered as a food, or by intravenous injection very little (0.4 gram out of 10 grams) is recoverable as such in the urine; the urea and ammonia in the urine are largely increased, but the increase of allantoin is very slight. Pure *d*-histidine was obtained from the urine of rabbits fed on *d*-*l*-histidine (Abderhalden, Einbeck, and Schmid, Zeitsch. physiol. Chem. 1909, 62, 322; 1910, 68, 395; Kowalewsky, Biochem. Zeitsch. 1909, 23, 1; Abderhalden, *ibid.* 1910, 68, 395, and *ibid.* 1911, 74, 481; Abderhalden and Weil, *ibid.* 1912, 77, 435).

For the catabolism of histidine in the animal organism, see Dakin and Wakeman (J. Biol. Chem. 1912, 10, 499), and, as forerunner of purine bodies in animal metabolism, Ackroyd and Hopkins (Bio-Chem. J. 1916, 10, 551).

Salts. *l*-Histidine forms stable salts with acids and their solutions are dextrorotatory.

Monohydrochloride C₆H₉O₂N₃·HCl, H₂O forms large colourless rhombic crystals

$$a : b : c = 0.7965 : 1 : 1.71104$$

has [α]_D +1.74°, m.p. 80°, and loses H₂O at 140° (Albrecht and Kossel, Zeitsch. physiol. Chem. 1896, 22, 176; Hedin, *ibid.* 191; Kossel and Kutscher, *ibid.* 1899, 28, 382; Fränkel, Monatsh. 1903, 24, 229); the *di-hydrochloride* C₆H₉O₂N₃·2HCl is isomorphous with the mono-compound [$a : b : c = 0.76537 : 1 : 1.77516$], it has [α]_D +5.3° to 6.4° (Kossel and Kutscher, *l.c.*; Schwartze, Zeitsch. physiol. Chem. 1900, 29, 493). *Histidine cadmium chloride*

melts and decomposes at 270°-275° (Schenck, *ibid.* 1904, 43, 72). Histidine gives a complex copper salt Cu(C₆H₉O₂N₃)₂ (Kober and Sugiura, J. Biol. Chem. 1912-13, 13, 5), and a compound with iron (C₆H₉O₂N₃)₂Fe (D.R.P. 266522). *Histidine phosphotungstate*

crystallises without water of crystallisation (Wechsler, Zeitsch. physiol. Chem. 1911, 73, 140). *Histidine monopicrolonate*

is yellow. The *dipicrolonate*

is orange (Steudel, Zeitsch. physiol. Chem. 1905, 44, 157; Brigl, *ibid.* 1910, 64, 337); the *dipicrate* C₁₈H₁₅O₁₆N₉·2H₂O has m.p. 86° (corr.), (Pyman, Trans. Chem. Soc. 1911, 343); the pentahydrate C₆H₉O₂N₃·(C₆H₃O₇N₃)₂·5H₂O has m.p. 80° (Hugouenq and Florence, Bull. Soc. Chem. Biol. 1919, 1, 102).

l-Histidine-*d*-hydrogen tartrate

is easily soluble in water, crystallises in large well-defined prisms, and decomposes at 172°-173° (corr.); and has [α]_D +16.3°. *l*-Histidine-*l*-hydrogen tartrate is sparingly soluble in cold water, crystallises in clusters of prisms and decomposes at 234° (corr.), and has [α]_D -12.1° (Pyman, *ibid.* 1397, 1400).

d-Histidine-*d*-hydrogen tartrate is sparingly soluble, decomposes at 234° (corr.), and has [α]_D +13.3° (Pyman, *l.c.*).

r-Histidine mono-hydrochloride

has m.p. 117° – 119° (corr.); *sesquihydrochloride*

has m.p. 168° – 170° (corr.); the *dihydrochloride* has m.p. 235° – 236° (corr.); *γ-histidine monopicrate* $C_{12}H_{12}O_9N_6 \cdot H_2O$ decomposes at 180° – 181° (corr.); the *dipicrate* $C_{12}H_{10}O_{11}N_6 \cdot 2H_2O$ decomposes at 190° (corr.), (Pyman, *ibid.* 1916, 109, 196).

Derivatives. *Histidine methyl ester hydrochloride* $C_6H_5N_3 \cdot CO_2Me \cdot 2HCl$ forms flat rhombic prisms, m.p. 196° (decomp.), the free ester is an oil (Pauly, Zeitsch. physiol. Chem. 1904, 42, 508). *Chlorohistidinecarboxylic acid* (*α-chloro-β-glyoxaline-4* (or *5*)-*propionic acid*) forms thick prisms, m.p. 191° (decomp.), the corresponding *racemic* compound decomposes at 201° (corr.) (Pyman, *ibid.* 1394), the *oxalate* of the ester has m.p. 161° (Windaus and Vogt, Beitr. chem. Physiol. Path. 1908, 11, 406). *Histidine anhydride* $C_{12}H_{14}O_2N_6$ forms glittering prisms, m.p. 340° (Fischer and Suzuki, Sitzungsber. K. Akad. Wiss. Berlin, 1904, 1333); the *l-anhydride* has m.p. 328° in a closed evacuated tube, crystallises with $2\frac{1}{2}H_2O$, and has $[\alpha]_D^{20} = -66.24^{\circ}$ in normal hydrochloric acid solution; the *dl-anhydride* also has m.p. 328° , and is obtained by heating the ethyl ester of histidine at 160° (Pauly, Zeitsch. physiol. Chem. 1910, 64, 75); the *picrate* decomposes at 255° (corr.); the *hydrochloride* at 320° . The *tetraido* derivative has m.p. 240° , and is amphoteric and forms a *silver salt* (Pauly, Ber. 1910, 43, 2243). *Histidylhistidine* $C_{12}H_{16}O_3N_3$ forms a yellow *picrate*, m.p. 165° – 175° (Fischer and Suzuki, *l.c.*).

Alkyl derivatives. The direct methylation of histidine affects the glyoxaline ring. Under certain conditions *pentamethylhistidine* may be obtained which forms a stable chloride and a sparingly soluble aurichloride, $C_{11}H_{21}O_3N_3Au_2Cl_3$, m.p. 220° , but which does not respond to the diazo reaction (Engeland and Kutscher, Chem. Zentr. 1913, 1, 28).

Trimethyl histidine occurs in fungi (Winterstein and Reuter, Zeitsch. physiol. Chem. 1913, 86, 234), it has been isolated as the aurichloride $C_9H_{17}O_2N_3Au_2Cl_3$, m.p. 183 (decomp.) (Engeland, Kutscher, Chem. Zentr. 1913, 1, 28, from Zentr. physiol. 1912, 26, 569). Barger and Ewins (Bio-Chem. J. 1913, 7, 204) prove the identity of that obtained from various sources. The *mono-picrate* has m.p. 201° – 202° , the *dipicrate*, m.p. 213° . Trimethyl histidine has $[\alpha]_D +46.5^{\circ}$.

Acyl derivatives. Of the *acyl* derivatives of histidine the *benzoyl* has m.p. 249° (decomp.) (Pauly, *l.c.*; Fränkel, *l.c.*); *benzoyl-γ-histidine*, $C_{13}H_{13}O_3N_3$ (from *α-benzoylamino-β-glyoxaline-4* (or *5*) *acrylic acid* on reduction with sodium amalgam in aqueous suspension), has m.p. 248° (corr. decomp.); it crystallises in hard, glistening prisms with one molecule of water of crystallisation, which is lost at 115° . The *hydrochloride* crystallises from water in hard glistening prisms, m.p. 232° (corr. efferv.). The *picrate* crystallises in bunches of yellow feathery needles, m.p. 226° (corr.) (Pyman, Chem. Soc. Trans. 1916, 109, 195). Benzoylation of histidine methyl ester yields a tribenzoyl derivative

m.p. 219° (not sharp), which does not give the red colour with diazobenzene sulphonate; on heating the glyoxaline closes again and the product gives the characteristic colour reaction (Kossel and Edlbacher, Zeitsch. physiol. Chem. 1915, 93, 396; cf. Inouye, *ibid.* 1913, 83, 79, who points out that in order to obtain the colour reaction excess of benzoyl chloride must not be present). The *dinaphthalene β-sulphone* $C_{18}H_{12}O_2N_3(SO_2 \cdot C_{10}H_7)_2$ melts at 149° – 150° (Pauly); *p-Nitrobenzoylhistidine*

m.p. 251° – 252° (Pauly). *Benzoyldiiodohistidine*, m.p. 161° – 164° , in an evacuated tube; and *p-nitrobenzoyldiiodohistidine*, m.p. 172° (decomp.) are derivatives of the unknown diiodohistidine

they give orange-red colorations with diazobenzenesulphonic acid and sodium carbonate, and form silver salts (Pauly, Ber. 1910, 43, 2243). *d-α-Bromoisohexoyl-L-histidine methyl ester*

has m.p. 175° (corr.); *d-α-bromoisohexoyl-L-histidine* $C_{11}H_{15}O_3N_3Br$ has m.p. 118° (corr.); *l-leucyl-L-histidine*

crystallises in plates or prisms, containing H_2O , which it loses at 100° /15–20 mm., and has m.p. 178° (corr.) (decomp.), the *copper salt* forms deep violet crystals; *formyl-L-histidine* has m.p. 203° (corr.) (Fischer and Cone, Annalen, 1908, 363, 107).

Colour reactions. Histidine gives the *biuret* reaction (Herzog, Zeitsch. physiol. Chem. 1903, 37, 248). It also gives the Weidel pyrimidine reaction under the following conditions: a solution of histidine hydrochloride and a little potassium chlorate is evaporated to dryness, hydrochloric acid containing one drop of nitric acid added and the solution again evaporated; on exposing the residue to ammonia fumes an intense red colour is produced, becoming reddish-violet on the addition of sodium hydroxide (Frankel, *l.c.*). With diazobenzenesulphonic chloride in the presence of sodium carbonate histidine gives a dark cherry-red coloration, becoming orange on the addition of an acid. This is an extremely delicate test for histidine, and with the exception of tyrosine no other product of protein hydrolysis gives a similar reaction (Pauly, Zeitsch. physiol. Chem. 1904, 42, 508, and *ibid.* 1915, 94, 427; cf. Inouye, *ibid.* 1913, 83, 79, who applies the test for histidine in presence of tyrosine after addition of benzoylchloride, and Totani, Bio-Chem. J. 1915, 9, 385, who reduces the coloured solution obtained by Pauly's reaction (by means of zinc dust in presence of hydrochloric acid) and then makes it strongly alkaline with ammonia: if the original solution contained histidine it will now become a bright golden yellow). Histidine develops a yellow colour with bromine water; this disappears on warming, but after a time a pink colour appears, which afterwards deepens to a wine-red. The reaction is sensitive with solutions of 1:1000, but is destroyed by too large excess of bromine water (Knoop, Beitr. Chem. Physiol. Path. 1908, 11, 356).

A method for estimating histidine colourimetrically is based upon the Pauly diazo-reaction (Weiss, Sobolev, Biochem. Zeitsch. 1913, 58, 119): a mixture of sulphanilic acid in hydrochloric acid and sodium nitrite are added to the solution to be investigated, and then 10 p.c. sodium carbonate added. The total volume is kept constant, and the colour obtained compared with that given (under similar conditions) by a 1/10,000 histidine solution. The histidine can also be estimated volumetrically by titrating the stable histidine dye with titanium trichloride (Lautenschläger, Zeitsch. physiol. Chem. 1918, 102, 226). For the estimation of histidine in proteins by hydrolysis followed by bromination, see Thrum and Trowbridge (J. Biol. Chem. 1918, 34, 343). For a microchemical method, see Kober and Suguira, J. Amer. Chem. Soc. 1913, 35, 1546, and Van Slyke, J. Biol. Chem. 1911, 9, 185; *ibid.* 1911-12, 10, 29; *ibid.* 1912, 12, 279; *ibid.* 1915, 23, 411. For the phosphotungstate precipitate of histidine, see Wechsler, Zeitsch. physiol. Chem. 1911, 73, 141.

Decomposition. When histidine undergoes anaerobic bacterial cleavage by the action of putrefying pancreas, it is converted almost quantitatively by the loss of carbon dioxide into 4 (or 5)- β -aminoethylglyoxaline (β -iminazolyethylamine)

product (v. Ackermann, Zeitsch. physiol. Chem. 1910, 65, 504). The 4 (or 5)- β -aminoethylglyoxaline thus obtained is identical with the base prepared synthetically by Windaus and Vogt (Ber. 1907, 40, 3691) from ethyl iminazolypropionate; or by Pyman (Chem. Soc. Trans. 1911, 668) from diaminoacetone, and is also identical with one of the *ergot* bases isolated by Barger and Dale (Phil. Trans. 1910, 2592), and which is also present in Popielski's *vasodilatin* (Barger and Dale, J. Physiol. 1911, 41, 499); see Mellanby and Trout, who isolated a bacillus which splits off carbon dioxide from histidine and converts it to β -iminazolyethylamine; also Raistrick (Bio-Chem. J. 1917, 11, 71; *ibid.* 1919, 13, 446), who found that bacteria of the *Coli*-typhus group convert histidine into urocanic acid (β -iminazolyacrylic acid in certain media. *l*-Histidine is converted to the extent of 11 p.c. *l* into *d*- β -iminazolyacetic acid by the prolonged action of *Proteus vulgaris* in a protein-free nutrient media (Hirai, Act. Schol. Med. Kyoto. 1919, 3, 49). *Bacillus coli communis* transforms histidine into histamine to the extent of 50 p.c. in the presence of glycerol or dextrose and potassium nitrate or ammonium chloride (Koessler and Hanke, J. Biol. Chem. 1919, 39, 539; 1920, 43, 529, 543). It has a direct stimulating action on plain muscle; cardiac muscle is mildly stimulated, and skeletal muscle is not affected. The drug produces narcosis, and is a mild stimulant to the salivary glands and pancreas; for its toxic effect, cf. Freund (Chem. Zentr. 1914, 1, 1200 from Zeitsch. offentl. Chem. 20, 61). M. A. W.

HOANG-NAN v. NUX VOMICA.

HOFMANN'S VIOLET v. TRIPHENYLME-THANE COLOURING MATTERS.

HOG GUM v. GUMS.

HOLARRHENINE. $\text{C}_{24}\text{H}_{35}\text{ON}_2$ an alkaloid discovered by Pyman, in 1913, in the bark of *Holarrhena congolensis* (Stapt.), silky needles, m.p. 197°-198° (corr.). Insoluble in water, readily soluble in alcohol or chloroform but sparingly so in cold ethyl acetate, acetone, or ether. $[\alpha]_D -7.1^\circ$ in chloroform. The *hydrobromide* $\text{C}_{24}\text{H}_{35}\text{ON}_2\cdot 2\text{HBr}\cdot 3\text{H}_2\text{O}$ crystallises from water in flat needles, m.p. 265°-268° (corr.), after drying. Readily soluble in hot, sparingly so in cold, water; $[\alpha]_D +12.1^\circ$ for the anhydrous salt.

Acetylholarrhenine prepared by the action of acetic anhydride and anhydrous sodium acetate on holarrhenine crystallises from acetone in large colourless oblong plates, m.p. 180° (corr.). Insoluble in water, sparingly soluble in cold alcohol, acetone, or ether, readily soluble in chloroform (Pyman, Chem. Soc. Trans. 1919, 163).

HOLLANDITE. A manganese ore of essentially the same composition as psilomelane, but occurring in a crystallised condition, usually as fibrous masses and sometimes as tetragonal crystals. It is a manganate with the general formula $m\text{R}_2''\text{MnO}_5 + n\text{R}_4'''(\text{MnO}_5)_3$, where R'' is Mn, Ba, K, H, (Fe, Ca, Mg, Na, Co, Ni, Cu), and R''' is Mn, Fe, (Al). The extreme values shown in four analyses are: MnO_2 65.63-75.05, MnO 5.12-14.20, Fe_2O_3 4.43-10.56, BaO 2.96-17.59, K_2O 0.3-3.1, H_2O 0.1-10 p.c. The colour is greyish-black, and the lustre sub-metallic; sp.gr. 4.70-4.95; H. 4-6. The mineral occurs abundantly in the manganese ore deposits at several places in Central India, and is largely exported from the mines at Sitapur and Balághát. Closely allied minerals, perhaps identical with hollandite, are the crystalline manganates romanechite (containing less iron and more water) from Romanèche, France, and coronadite (with high lead and low barium) from Arizona. (L. L. Fémor, The Manganese Ore Deposits of India, Mem. Geol. Survey India, 1909, 37; Rec. Geol. Survey India, 1917, 48, 103.) L. J. S.

HOLMIUM. Ho. At. wt. 163.4. An element discovered by Cleve in the terbia of Mosander or erbia of Berlin, giving a pale yellow oxide and yellow salts with a slight tinge of orange (Holmberg, Arkiv. Kem. Min. Geol. 1911, 4, No. 2 and No. 10).

According to Forsling (Bihang K. Svenska Vet. Akad. Handl. 1902-1903, 28, ii. No. 1) holmium is not an individual substance but a mixture of several components to which correspond the different absorption bands. It probably consists of dysprosium with its two components as well as of at least four other substances. Langlet (Arkiv. Kem. Min. Geol. 1907, 2, No. 32), however, was unable to find any evidence of a decomposition of holmia into several components, and the later observations of Holmberg appear to have established the individuality of the element. For observations on the relative advantages of phthalic acid and sodium nitrite in separating holmium from yttrium, see Yntema and Hopkins (J. Amer. Chem. Soc. 1918, 40, 1163).

HONEY. Honey is the substance secreted by the working-bee (*Apis mellifica*) from the nectar of flowers, and deposited by the insect in the wax-cells forming the honeycomb. Its essential constituents are varying quantities of the sugars, dextrose, levulose, and sometimes cane-sugar, together with a small quantity of water. It also contains very small quantities of wax, colouring matters, aromatic substances, phosphoric acid, nitrogenous compounds, and occasionally mannitol.

Lactase, proteases and lipases are not present in honey and the occurrence of inulase is doubtful. Invertase is present more in natural honey than in that produced by bees fed on sugar. This enzyme is destroyed when honey is heated to 60°. The presence of invertase in honey explains why the cane sugar in honey gradually disappears when the honey is kept for some considerable time. Honey also contains catalase and diastase, and an estimation of the activity of the diastase is an indication of the genuineness of the honey. According to

Hudson and Sherwood (J. Amer. Chem. Soc. 1920, 42, 116), American honey-dew honey occasionally contains considerable quantities of melecitose.

The relative proportions in which the above-named sugars occur is very variable. Thus Hohner (Analyst, 9, 164) obtained the following results from the analysis of 25 different varieties:

	Maximum	Minimum	Mean
Water . . .	23.26	12.43	19.3
Glucose . . .	75.34	61.42	67.2
Other constituents	16.51	8.48	13.5

In 8 cases the amount of glucose was unaltered by inversion, in 7 increased, and in the remainder slightly diminished.

Sieben (Bied. Zentr. 1885, 134) analysed 60 specimens of honey, and states that the quantity of cane-sugar may amount to as much as 4 or even 8 p.c., and that the ratio of dextrose to levulose varies considerably, the total amount of these two sugars being 68–78 p.c. The average composition of the 60 specimens was as follows:

Dextrose . . .	34.71 p.c.
Levulose . . .	39.24 „
Sucrose . . .	1.68 „
Water . . .	19.98 „
Non-saccharine matter . . .	5.02 „

For the composition of Russian honey see Sarin, Zeitsch. Untersuch. Nahr. Genuss. 1913, 25, 131; Analyst, 1913, 149.

Turning now from average results to the composition of the several varieties, we find the following table of the analysis of 9 specimens of honey from different localities (J. C. Brown, Analyst, 1878, 257).

	England	Wales	Nor-mandy	Germany	Greece	Lisbon	Jamaica	California	Mexico
Water expelled at 100° .	19.10	16.40	15.50	19.11	19.80	18.80	19.46	17.90	18.47
Water expelled at a high temperature and loss .	7.60	6.56	4.95	11.00	7.80	6.66	7.58	8.13	10.03
Levulose . . .	36.60	37.20	36.88	33.14	40.00	37.26	33.19	37.85	35.96
Dextrose . . .	36.55	39.70	42.50	36.58	32.20	34.94	35.21	36.01	35.47
Sucrose . . .	?	—	—	—	—	1.20	2.20	—	?
Wax, pollen, and insoluble matter . .	trace	trace	trace	trace	0.05	1.00	2.10	trace	trace
Mineral matter . .	0.15	0.14	0.17	0.17	0.15	0.14	0.26	0.11	0.07

For a large number of other analyses see Fiehe and Stegmüller (Arbeit. Kaiserl. Gesund. 1913, 44, 78; Analyst, 1913, 265).

The characteristic composition of ordinary honey can be judged from the analysis of 10 samples of genuine honey by Hoitsemma (Zeitsch. anal. Chem. 1899, 439) which gave the following results:—

Specific gravity . . .	1.102–1.140
Water . . .	8.3–17.8 p.c.
Rotation . . .	–9.1° to –3.0°
Ash . . .	0.12–0.34 p.c.
Pollen and wax . . .	0.02–0.46 „
Reducing sugars . . .	71.2–74.4 „
Sucrose . . .	0.2–6.4 „

The amount of water present in honey varies with the dryness of the season and the conditions of storage, evaporation being much lessened when all the cells of the comb are closed (Graftian, Analyst, 1895, 251).

Erlenmeyer and v. Plata (Rep. Pharm. 23, 610) found that in 6 samples of good honey the amount of water varied from 17.5 to 19.5 p.c., whilst a liquid honey from Senegal contained as much as 25.6 p.c. The amount of phosphoric acid present (calculated on the dried substance) varied from 0.0123 to 0.883 p.c.

Sumatra honey, formed by *Apis indica*, contains water, dextrose, levulose, a little wax and pollen, and 0.23 p.c. ash, but no cane-sugar or dextrin (Franchimont, Rec. trav. chim. 1, 223). An Ethiopian honey, made in hollows without wax by a kind of mosquito, gave the following result on analysis (Compt. rend. 88, 292):—

Water . . .	25.5
Levulose and dextrose ($\frac{1}{2}$) . . .	32.0
Mannitol . . .	3.0
Dextrin . . .	27.9
Ash . . .	2.5
Other constituents . . .	9.1

It has also been shown that honey frequently but not invariably contains a small quantity of formic acid. It amounts only to from 0.0060 to 0.0100 p.c., therefore most of the acidity of honey must be due to some other acid, possibly malic acid (Farnsteiner, *Zeitsch. Nahr. Genussm.* 1908, 15, 598; Fincke, *ibid.* 1912, 23, 255).

The formic acid may be estimated by conversion into sodium formate, heating with conc. sulphuric acid, and measuring the volume of carbon monoxide evolved. As lactic acid also gives this gas it must be oxidised with potassium permanganate and estimated as oxalate and a correction applied (Merl, *Zeitsch. Nahr. Genussm.* 1908, 16, 385; Heiduschka and Kaufmann, *ibid.* 1911, 21, 375; Heiduschka, *Chem. Zeit.* 1911, 35, 1104).

If bees be fed on dextrose only, the honey formed contains that sugar alone. Heather-fed honey, on the other hand, contains invert sugar only, whilst Cuban honey contains dextrose in larger quantity than lævulose (Röders, *Chem. Zentr.* 1864, 1002).

Eucalyptus honey is produced in Australia by a black bee which builds large hives on the *Eucalypti* containing as much as 5000 kilogs. of honey. The honey is a thick syrup, having a strong aromatic odour (Maquenne, *Ann. Chim.* [vi.] 17, 495).

Marck has given the following figures for the composition of East Indian honeys (Analyst, 1890, 196):—

Glucose, about 30 p.c.; lævulose, 23–37 p.c.; ash, 0.12–0.54 p.c.; sp.gr. 1.3099–1.3586; rotation $+13^{\circ}$ to $-2^{\circ} 54'$.

In the honey of *Polybia apicipennis* large crystals of cane-sugar are frequently found (J. pr. Chem. [i.] 71, 314). The honey of the Mexican honey-ant is almost a pure solution of lævulose, and when dried *in vacuo*, has the composition $C_6H_{12}O_6 \cdot H_2O$. It contains traces of a volatile acid which reduces silver salts (J. pr. Chem. [i.] 58, 430).

To obtain honey the syrup is first simply allowed to flow from the comb at the ordinary temperature, the portion thus collected being known as 'virgin-honey.' As soon as the flow ceases, the residual comb is heated and pressed, by which means a darker and less pure variety is obtained. According to Zwilling (Bied. Zentr. 1885, 67) it is best to gather the honey when it has thickened and the cells are sealed, as then sufficient sugar and formic acid are present.

The honey-syrup remains clear for a long time if kept in the dark, but on exposure to light dextrose gradually separates, and such varieties as contain that sugar in the largest quantity become sufficiently solid to be cut with a knife into pieces which are not hygroscopic. As, however, the composition of honey is so variable, the consistency and colour likewise differ considerably in the different samples. Thus Narbonne honey has a light yellow colour, and forms an almost solid mass, whereas Cuban honey is a clear and almost colourless syrup.

Honey has a sp.gr. of from 1.439 to 1.448. When diluted with water it gives a somewhat cloudy, faintly acid solution, the cloudiness being due to small quantities of proteid matter. Its specific rotatory power varies from -5.5 to $+2$, but dextrorotatory honey is exceptional.

Frühling has shown (*Zeitsch. öffentl. Chem.* 4, 410) that freshly prepared solutions of honey in cold water show an abnormal rotation, which, after some hours, becomes normal. This behaviour, which is due to 'bi-rotation,' may lead to erroneous observations unless care is taken to dissolve the honey in boiling water and to add about 0.1 p.c. of ammonia.

A pure solution of honey does not readily undergo alteration in the air, but when impure, both acid and alcoholic fermentation speedily take place. An alcoholic liquor known as 'mead' (Ger. *Meth*; Fr. *Hydromel*) has long been prepared from honey by fermentation. The process is, however, frequently unsuccessful, owing to the fact that honey does not usually contain sufficient nitrogenous food for the sustenance of the ferment. If a suitable food be added, the fermentation proceeds smoothly and with certainty (Gastine, *Compt. rend.* 109, 479). According to Boussingault (*Ann. Chim.* [iv.] 26, 362) the quantity of carbon dioxide formed during fermentation is greater, and the quantity of alcohol less, than would be expected from the amount of sugar fermented. Thus, instead of the calculated quantities of 193.6 parts of alcohol and 170 parts of carbon dioxide, he obtained 177.6 parts of alcohol, and 190 parts of carbon dioxide.

For medicinal purposes honey is purified by warming on the water-bath, and straining it through flannel which has been previously moistened with hot water. The purified compound is known as *Mel depuratum*. Dietrich (*Chem. Zentr.* 1877, 318) brought a filtered solution of 1 part of honey in 3 parts of water on to a dialyser, and found that 50 p.c. of the honey passed through. The solution of the crystalloids gave on evaporation a honey having an unusually pleasant aromatic taste. The colloidal liquid, in which gummy flocculæ remained suspended, gave on evaporation a syrup possessing a purely sweet, insipid, non-aromatic taste.

In order to purify honey Riecker (J. 1873, 1066) adds a little precipitated aluminium hydroxide, which carries down any foreign substances present. If ordinary honey be shaken with absolute alcohol, dextrose remains behind. Ether precipitates lævulose from the alcoholic solution, and the ethereal solution when shaken with lime loses tannic acid, whilst wax remains in solution.

Honey is frequently adulterated with starch-sugar, invert-sugar, molasses, water, &c., and owing to the wide variations in the composition of genuine honey such adulteration is frequently difficult to detect (Racine, *Zeitsch. öffentl. Chem.* 1902, 281).

For a method of detecting commercial invert sugar in honey by means of β -naphthol which gives a Bordeaux red to bluish-violet colour with an ethereal extract of adulterated honey, see Litterschied, J. Soc. Chem. Ind. 1913, 376.

Dextrorotatory honey was formerly regarded with suspicion (Haele, *Zeitsch. anal. Chem.* 1894, 99), but it has been shown that pine-honey, and honey made by bees using honey-dew, contain a dextrin which can be isolated by precipitation with alcohol, and is strongly dextrorotatory (König and Karsch, *Zeitsch. anal. Chem.*

1895, 1; Raumer, *ibid.* 1896, 397; Hilger, *Zeitsch. Nahr. Genussm.* 1904, 189). For a detailed account of the 'honey-dextrins' of pine-honey, see Haenle and Scholz (*Zeitsch. Nahr. Genussm.* 1903, 1027).

Several methods have been recommended for distinguishing between genuine and adulterated honey. Brautigam states that genuine honey contains an albumin by the reactions of which it can be distinguished (*Pharm. Zeit.* 47, 109). Methods for the microscopic examination of honey have been described by Dietrich (*Analyst*, 1896, 255). Langer has found in natural honey an inverting ferment which can be precipitated by alcohol and tested on cane-sugar (*Zeitsch. angew. Chem.* 1902, 1041). For the biological examination of honey as a test of its genuineness, see Gadamer and Laske, *Arch. Pharm.* 1916, 254, 306.

Adulteration with starch-syrup, which usually contains erythro-dextrin and amylo-dextrin can usually be detected by adding methyl alcohol to the conc. aqueous solution, when the dextrins are precipitated. The addition of molasses is best detected by testing for raffinose with basic lead acetate (Beckmann, *Zeitsch. anal. Chem.* 1896, 263).

Ley's reagent, an ammoniacal solution of silver oxide, when warmed with a strong solution of pure honey gives a greenish coloration, but if the honey is adulterated the liquid becomes dark brown or black (Utz, *Zeitsch. angew. Chem.* 1907, 993).

If 1 gram of honey be rubbed down with ether in a mortar, the ether filtered off and evaporated, and the residue treated with a drop of a solution of 1 gram resorcinol in 100 c.c. of hydrochloric acid of sp.gr. 1.19, only a momentary pink colour will be obtained with pure honey, whilst adulterated or artificial honey will give an orange-red colour, changing through cherry-red to a strong brown-red (Fiehe, *Zeitsch. Nahr. Genussm.* 1908, 75; Keiser, *Analyst*, 1909, 299; cf. Halphen, *Ann. Falsif.* 1912, 5, 105; Stacklin, *ibid.* 1912, 5, 116; Fiehe and Stegmüller, *Arbb. Kais. Gesundh.-Amt.* 1912, 40, 305; J. Soc. Chem. Ind. 1912, 31, 943; *Analyst*, 1912, 449).

Adulteration with cane-sugar may be detected by determining the reducing power of the honey with Barreswil's solution, both before and after inversion. This is not very reliable, as in cases where the bees feed on sucrose it is found in the honey, though the larger proportion undergoes inversion in the insect's stomach (Raumer, *Zeitsch. anal. Chem.* 1902, 333; see also Lipmann, *Analyst*, 1889, 20; Bakker, *Rec. Trav. Chem.* 1921, 40, 600).

Sugar in honey is estimated by diluting with twice its volume of water, and ascertaining the sp.gr. This varies between 1.101 and 1.115. The first number corresponds to 24 p.c., and the latter to 27 p.c. of sugar in the solutions, or to 72 p.c. and 82 p.c. in the original honey (Flückiger, *Pharmaceut. Chemie*, [ii.] 267).

Wiley has described a process for the estimation of levulose in honey, &c., based on the fact that its optical rotation is much diminished with rise of temperature. The observation tube of the polarimeter is jacketed, and can be cooled to zero or heated to 88°, at which temperature a mixture of molecular proportions of

dextrose and levulose becomes optically inactive (*J. Amer. Chem. Soc.* 1896, 81).

Witte recommends that the following determinations and tests should be made in order to ascertain the purity or otherwise of honey, a solution containing 1 part by weight of the honey to two parts of water being used: Total nitrogen (Kjeldahl); tannin precipitate; polarisation before and after inversion. Leys' reaction (*v. supra*) and Fiehe's test with resorcinol and hydrochloric acid for the presence of added invert sugar. The quantity of water present should not exceed 20 p.c., whilst the acidity of native (German) honey usually lies between 0.06 and 1.2 p.c. The quantity of ash is generally from 0.1 to 0.35 p.c., but may sometimes be as little as 0.065 p.c. The sucrose should not exceed 6 p.c., a larger amount than this indicating that the honey is 'unripe,' that the bees have been fed on sucrose, or that the honey is adulterated. Sucrose may be inverted by means of honey at a suitable temperature. The nitrogenous substances vary in amount from 0.25 to 0.55 p.c.; artificial honey seldom contains more than 0.22 p.c. of nitrogenous substances (*Zeitsch. Nahr. Genussm.* 1909, 18, 625; 1911, 21, 305; cf. Bruhns, *Chem. Zeit.* 1921, 45, 661 *et seq.*). The *J. Soc. Chem. Ind.* 1911, 30, 702, gives a useful bibliography of honey and its chemistry.

HONTHIN *v.* SYNTHETIC DRUGS.

HOPEÏNE is a crystalline alkaloid said to be contained in wild American hops. It melts below 100° and partially sublimes below 160°. It is doubtful, however, whether it really exists (Ladenburg, *Ber.* 1886, 19, 783; *J. Pharm. Chim.* [v.] 12, 460; Williamson, *Chem. Zeit.* 1886, 10, 20, 38, 207, 238, 491).

HOPEÏTE. Hydrated zinc phosphate,

crystallised in the orthorhombic system. The crystals are remarkable in consisting of an intimate zonal intergrowth of two modifications— α -hopeite and β -hopeite—differing in their optical characters and in the rate at which water is expelled by heat. They are colourless, white, or brownish; sp.gr. 3.0–3.1; H. 3½. For many years hopeite was known only as a rare mineral from the zinc mine of Altenberg, or Vieille Montagne, between Liège and Aachen; but in 1907 it was found finely crystallised and in considerable quantity in a cave with bone-breccia and associated with ores of zinc and lead at Broken Hill in North-Western Rhodesia. In 1916 it was incorrectly described under the new name hibbenite from the Hudson Bay zinc mine near Salmo in British Columbia.

Parahopeite, from Broken Hill, Rhodesia, has the same composition as hopeite, but the crystals are anorthic. L. J. S.

HOPOGAN. A trade name for magnesium perhydrol.

HOPS *v.* BREWING.

HORDEIC ACID *v.* DODECATOIC ACID.

HORDEIN *v.* Barley, art. BREWING.

HORDENINE (*p-Hydroxyphenylethylidimethylamine*) $\text{C}_{10}\text{H}_{15}\text{NO}$ was discovered by Léger (*Compt. rend.* 1906, 142, 108) in malt culms, from which it is extracted by Stas' method. The ethereal solution of the alkaloid thus obtained is evaporated to dryness and the

hordenine residue is purified by repeated recrystallisation from alcohol. Its constitution was determined by Léger (Compt. rend. 1906, 143, 234, 916) and by Gaebel (Arch. Pharm. 1906, 244, 435).

Hordenine has also been synthesised from phenyl ethyl alcohol (Barger, Chem. Soc. Trans. 1909, 2194; Léger, Bull. Soc. chim. 1910, [iv.] 7, 172), and by the methylation of β -*p*-methoxyphenylethylamine hydrochloride with alcoholic potash and methyl iodide at 100° (Rosenmund, Ber. 1910, 43, 306).

Properties.—Hordenine forms colourless, almost tasteless anhydrous orthorhombic prisms, m.p. 117·8° and subliming like camphor at 140°–150°. It is readily soluble in alcohol, ether, or chloroform, but sparingly so in benzene, xylene, or toluene. It is optically inactive. It is a strong base, is alkaline towards litmus and phenolphthalein, liberates ammonia from its salts, reduces acid solutions of potassium permanganate in the cold and ammoniacal solutions of silver nitrate and iodic acid on warming. It is not attacked by concentrated sulphuric acid or by potash, but readily forms soluble salts with acids. When boiled with nitric acid it yields picric acid, and when methylated and oxidised with alkaline permanganate it gives anisic acid (Léger, J. Pharm. Chim. 1907, 25, 5; Compt. rend. 1907, 144, 488).

Hordenine sulphate crystallises in needles and has a slightly bitter taste. It forms brown crystals with iodine, but gives no precipitate with the tannins of vegetable infusions. In small doses it has a tonic action on the heart, but in toxic doses (1–2 grams per kilo) it produces the reverse effect.

It has been employed as a remedy in cases of typhoid, dysentery, enteritis, &c. It is not so energetic as digitalis, sparteine, or strophanthus, but is less toxic than any of these (Sabrazès and Guérove, Compt. rend. 1908, 147, 1076; see also Camus, *ibid.* 1906, 142, 110, 237).

Hordenine methiodide, which probably possesses a similar physiological action to that of adrenaline, has been synthesised from *p*-methoxyphenylethylamine by treatment with methyl iodide, an almost quantitative yield being obtained. It crystallises in colourless prisms, m.p. 229°–230° (Rosenmund, *l.c.*). Other organic and inorganic compounds of hordenine have also been obtained (Léger, *l.c.*, and Compt. rend. 1907, 144, 208).

Detection.—A few drops of hordenine are dissolved in a few c.c. of acetic acid and boiled with a few drops of formaldehyde; 3 c.c. of sulphuric acid is now added, when a green coloration is produced (Denigès, Bull. Soc. chim. 1908, [iv.] 3, 786).

1 c.c. of 1 p.c. hordenine sulphate solution is boiled with an equal volume of urotropine solution of the same strength, and 2 c.c. of strong sulphuric acid, a fine emerald-green colour is produced even with 0·0001 gram of hordenine sulphate (Labat, J. Pharm. Chim. 1909, 29, 433).

HOREHOUND v. MARRUBIUM.

HORNBLÉNDE. An important rock-forming mineral belonging to the monoclinic series of the amphibole group, consisting mainly of metasilicates of calcium, magnesium, and iron. The name hornblende is sometimes applied to

the group itself, which includes the useful minerals asbestos (*q.v.*), nephrite (*v.* Jade), and crocidolite (*q.v.*). More usually, however, it is restricted to the darker-coloured (green, brown, black) aluminous varieties, the composition of which is expressed by mixtures in various proportions of the molecules $\text{Ca}(\text{Mg}, \text{Fe})_3(\text{SiO}_3)_4$, $(\text{Mg}, \text{Fe})(\text{Al}, \text{Fe})_2\text{SiO}_6$, and $\text{NaAl}(\text{SiO}_3)_2$. It forms part of many kinds of igneous rocks, *e.g.* hornblende-granite, syenite, basalt, &c., and crystalline schists, *e.g.* hornblende-schist. L. J. S.

HORNFEELS v. HORNSTONE.

HORN LEAD v. LEAD.

HORN QUICKSILVER. Calomel v. MERCURY.

HORNSILVER. Native silver chloride v. CERARGYRITE; SILVER.

HORNSTONE and HORNFEELS. Names applied to a variety of hard and tough, fine-grained and compact, splintery, siliceous rocks with a horny appearance, which have generally been formed by the baking action of igneous rock-masses on surrounding sedimentary rocks (sandstones, grits, shales, slates, &c.). They frequently show a banded structure representing the original bedding planes, but they do not break along these directions. The name hornstone is more usually applied by mineralogists to the highly siliceous kinds, and regarded as a variety of quartz allied to flint, chert, novaculite, and jasper; whilst the German name hornfels is applied by petrographers to materials more of the nature of rocks, *e.g.* biotite-hornfels, andalusite-hornfels, tourmaline-hornfels, calc-silicate-hornfels, &c., the last-named having been produced by the thermal metamorphism of impure siliceous limestones. The Swedish *Hållefinta* (meaning rock-flint) is also very similar in character; this may in some cases represent an altered felsitic lava, but in others it does not differ from hornfels. These materials are used as hones (*v.* Whetstone). L. J. S.

HORSE-CHESTNUT. *Marronnier d'Inde*, Fr.; *Roskastanie*, Ger. The well-known horse-chestnut tree, *Æsculus hippocastanum* (Linn.), is a native of Persia and Northern India, and was introduced into Europe in the sixteenth century. The bark contains, besides tannin, fat, and other common substances, a glucoside *æsculin* and a little of its fission product *æsculetin*. On account of its blue fluorescence in aqueous solution, still recognisable at 1:15,000,000, the substance attracted early attention, and was first termed Schillerstoff in German. It has been chiefly examined by Rochleder and Schwarz (Annalen, 1853, 87, 186; 88, 356). *Æsculin* is obtained by extracting the bark (best collected in March) with boiling water, precipitating the extract with lead acetate, removing the excess of lead from the filtrate with hydrogen sulphide, and then concentrating until crystallisation begins. After a few days the crystals are collected and recrystallised first from alcohol and then from boiling water. *Æsculin*, $\text{C}_{15}\text{H}_{10}\text{O}_6 \cdot \frac{1}{2}\text{H}_2\text{O}$, forms white needles of slightly bitter taste, which lose their water of crystallisation at 120°–130° and melt at 200°–202°; it dissolves in 600 parts of cold, and 12·5 parts of boiling water, in 100 parts of cold, and 24 parts of boiling alcohol. As in many cases, acids abolish the fluorescence. Agitation with a little nitric acid gives a yellow solution, turning deep red with ammonia (Sonnenschein,

Ber. 1876, 9, 1182). The solution in a few drops of concentrated sulphuric acid is coloured deep violet by gradual addition of sodium hypochlorite solution. Bromine furnishes crystalline dibromoæsculin, $C_{15}H_{14}O_8Br_2$, m.p. 194°, sodium amalgam amorphous hydroæsculin; crystalline penta-acetyl and benzoyl derivatives are known. Emulsion and warm dilute mineral acids hydrolyse to dextrose and *æsculetin* (Zwenger, *Annalen*, 1854, 90, 65). *Æsculetin* and glucosan are formed by heating *æsculin* to 230°. *Æsculetin*, $C_8H_6O_4 \cdot H_2O$, may be purified by precipitation in alcoholic solution with lead acetate, washing the lead compound with alcohol and regenerating with hydrogen sulphide. It crystallises in needles, m.p. 270°, little soluble in cold, moderately in hot water, readily in hot alcohol, hardly in ether. It reduces Fehling's and ammoniacal silver solutions. It is 6:7-dihydroxycoumarin as shown by the synthesis

from hydroxyhydroquinone aldehyde, acetic anhydride, and sodium acetate (Gattermann and Köbner, Ber. 1899, 32, 288). *Æsculetin* has in aqueous solution only a very slight fluorescence. For reduction products, see Liebermann and Lindenbaum (Ber. 1902, 35, 2919); for *æsculase*, Sigmund (Monatsh. 1910, 31, 657); for the microchemistry of *æsculin*, Tunmann (Chem. Soc. Abstr. 1917, ii, 59).

The bark of the horse-chestnut further contains the glucoside *fraxin* $C_{16}H_{18}O_{10}$, also present in the bark of the ash. It is hydrolysed to dextrose and *fraxetin* $C_8H_8O_4OMe$, a methoxy *æsculetin* (Körner and Biginelli, Gazz. chim. ital. 1891, 21, ii, 452). *Scopoalin*, in the root of *Scopolia* sp., in *Atropa belladonna*, and in other *Solanaceæ*, is a glucoside of scopoletin or 7-hydroxy-6-methoxy coumarin, and therefore of *æsculetin* monomethyl ether (Moore, Chem. Soc. Trans. 1911, 99, 1043; in this paper an account of the earlier literature is given; a different system of numbering the substituents is employed). Scopoletin has sometimes been confused with *æsculetin*; it occurs free in *Gelsemium sempervirens*.

The cotyledons contain two little-known glucosides and other derivatives (Rochleder, J. pr. Chem. [i.] 87, 1; [i.] 101, 415). The leaves quercitrin, the flowers quercetin (Rochleder, J. 1859, 522).

Horse-chestnuts are rich in carbohydrates, and can be used for the production of alcohol and acetone by fermentation; the yield of alcohol may be 11.5-12 p.c. of the nuts as picked. Cf. J. Soc. Chem. Ind. 1919, 411, T. Bitter and harmful principles (saponins) can be extracted by boiling water, and then the nuts constitute a valuable cattle food; they have even been incorporated in bread (cf. Dechambre, Compt. rend. Acad. Agric. 1917, 3, 927). Entire fresh chestnuts contain about 45 p.c. of water, and air dry about 11 p.c. The following percentage analysis (Baker and Hulton, Analyst,

Nov. 1917) refers to peeled and grated nuts dried at 55°: moisture, 1.85-3.5; ash, 2.45-2.9; ether extract (oil), 5.0-7.2; protein ($N \times 6.25$), 7.25-10.8; reducing sugars as dextrose, 1.6-9.1; cane-sugar, 7.27-17.5; starch (Lintner), 21.9-47.8; starch (taka diastase), 15.2-39.0; pentosans, 4.75-5.44; crude fibre, 2.0-2.6; matter soluble in cold water, 32.5-48.4. The oil, at one time used in medicine, has been examined by Stillesen (Chem. Zeit. 1909, 33, 497), G. Masson (Bull. Sci. Pharmacol. 1918, 25, 65; Chem. Soc. Abstr. 1918, i, 518). G. B.

HORSE FAT. The fat obtained from different parts of the horse is a pale yellow to orange semi-solid mass with an unpleasant odour. On standing it separates into a solid and liquid portion, the latter being known in commerce as *horse oil*, not to be confused with *horse foot oil*. Both the fat and the oil have drying properties, which render them unsuitable for lubricating purposes. The fat does not appear to contain any stearic acid (Hehner and Mitchell), but contains about 10 p.c. of linolic acid. It melts at about 34°-39°, and has an iodine value varying from about 75-90 according to the part of the animal whence it was derived (cf. Heiduschka and Steinruck, J. pr. Chem. 1921, 102, 241).

Horse fat is used as a substitute for lard in some parts of Europe. Its use is claimed in Eng. Pat. 25046, 1905, as a medium for coating calcium carbide in the production of acetylene.

C. A. M.

HORSE-RADISH. The root of *Cochlearia Armoracia* (Linn.), used as a condiment. Its pungent flavour is due to the presence of isobutyl isothiocyanate $C_4H_9 \cdot NCS$. The root contains—

Nitrogenous		N-free	Crude	Organic
Water substances	Fat	extract	fibre	Ash sulphur
76.7	2.7	0.3	15.9	2.8
				1.5
				0.08

The following is an analysis of the ash of horse-radish:—

Percent. of ash in the dry subst.	K ₂ O	Na ₂ O	CaO	MgO	Fe ₂ O ₃	P ₂ O ₅	SO ₃	SiO ₂	Cl
7.1	30.8	4.0	8.2	2.9	1.9	7.8	30.8	12.7	0.9

H. I.

HUANTAJAYITE v. HALITE.

HÜASCOLITE v. ZINC-BLENDE.

HÜBERLITE v. WOLFRAMITE.

HULSITE. A black, opaque, orthorhombic (?) mineral originally described as a hydrous borate of ferrous and ferric iron and magnesium, but subsequently found to contain some tin (SnO_2 , 7.07 p.c. in a sample with a considerable amount of insoluble gangue), the formula being given as $12(Fe,Mg)O \cdot 2Fe_2O_3 \cdot SnO_2 \cdot 3B_2O_3 \cdot 2H_2O$. It occurs as small crystals and tabular masses in a metamorphic limestone, near the contact of this rock with granite, at Brooks Mountain, Seward Peninsula, Alaska, and is associated with magnetite and tin-ore. L. J. S.

HUMIC ACID. The substance produced by the decay of vegetable matter and found in the soil. Various humic acids have been described; an octobasic acid $C_{80}H_{54}O_{27}$ (Detmer, J. 1873, 844); an acid $C_{22}H_{10}O_{10}$ (Thenard, J. 1873, 844); an acid $C_{30}H_{22}O_{10}$, from brown coal (Hoppe, Zeitsch. physiol. Chem. 13, 108); and an acid

$C_{46}H_{46}O_{25}$ from coal (John, Zeit. Kryst. Min. 23, 289). According to Robertson, Irvine, and Dobson (Bio-Chem. J. 1907, 2, 458), the natural humic acid from peat varies greatly in composition, according to the method of preparation. The artificial acid from sugar, according to them, has the composition $C_{39}H_{32}O_{14}$, but Berthelot and André (Compt. rend. 112, 1916) state that this acid is tribasic and has the composition $C_{18}H_{16}O_7$. Humic acid is capable of absorbing ammonia, which is then removed by the acid of sprouting seeds, humic acid being regenerated (Borntraeger, Chem. Zentr. 1900, ii. 1202). Gautreau, Charbonnier, and Serrant (Eng. Pat. 22028; J. Soc. Chem. Ind. 1895, 977) treat peat or vegetable refuse with dilute sulphuric acid, to produce humic acid. The mass after the removal of the liquid matter is treated with excess of lime, potassium sulphate is added, and the resulting substance sold as a manure.

HUMULON (*α -hop-bitter acid* or *lupulic acid*) $C_{21}H_{30}O_5$. A substance contained in lupulin, one of the bitter principles of hops. It may be obtained by repeated precipitation as the lead salt from a methyl alcoholic extract of lupulin and may be purified by crystallisation of its combination with *o*-phenylenediamine. With it forms slender yellow needles, m.p. 115°–117°.

Humulon melts at 66°, $[\alpha]_D^{20}$ –212° in 96 p.c. alcohol, –232.2° in benzene; is odourless and almost tasteless. Reduces ammoniacal silver oxide in the cold and gives a deep reddish-violet colour with alcoholic ferric chloride. Gives crystalline precipitates with salts of copper and lead. Subjected to hydrolysis forms *iso*-butyraldehyde, acetic acid, humulic acid, an unsaturated acid, $C_6H_{10}O_2$, b.p. 105°/10 mm., giving characteristic zinc, cadmium, and silver salts, and a bitter resin (35–40 p.c. of the whole). *Humulic acid* $C_{15}H_{22}O_4$ (cf. Lintner and Schnell, Zeitsch. ges. Brauw. 1904, 27, 668) is only feebly acidic, and is probably not a real carboxylic acid; it contains a ketonic group, and therefore behaves as an enol; is unsaturated, and may be reduced by palladium and hydrogen to *dihydrohumulic acid* $C_{15}H_{24}O_4$, flat needles and leaflets, m.p. 125°–126° (*phenylhydrazone*, faintly yellow, short prisms, m.p. 133°–134°).

Humulon may also be catalytically hydrogenated, whereby it suffers fission into an acid $C_{16}H_{24}O_5$ and β -methylbutane: $C_{21}H_{30}O_5 + 3H_2 = C_{16}H_{24}O_5 + C_5H_{12}$. The acid forms yellow crystals, m.p. 123°–125°, behaves as a monobasic acid; forms a *tetrabenzoate* $C_{16}H_{20}O_5 \cdot Bz_4$ in colourless flat prisms, m.p. 168°. Alcoholic solutions give a dark blue coloration with lead acetate. A warm methyl-alcoholic solution in a current of air yields a *dihydroxyquinone* $C_{16}H_{22}O_5$; slender, red needles, m.p. 63°–64°, which condensed with *o*-phenylenediamine gives a dark red azine $C_{22}H_{26}O_5N_2$, m.p. 109° (Wöllmer, Ber. 1916, 49, 780).

HUNGARIAN TURPENTINE v. OLEO-RESINS.

HUNGARY BLUE. Cobalt blue v. PIGMENTS.

HUNGARY GREEN. Malachite green v. PIGMENTS.

HUTCHINSONITE. Sulph-arsenite of thallium, lead, silver, and copper

$(Tl, Ag, Cu)_2S \cdot As_2S_3 + PbS \cdot As_2S_3$

crystallised in the orthorhombic system, and

one of the few minerals that contain thallium (18–25 p.c.) as an essential constituent. It is of rare occurrence as minute, red, transparent crystals in the white, crystalline dolomite of the Binnenthal in Switzerland.

L. J. S.

HYACINTH or **JACINTH.** A name loosely applied to several kinds of gem-stones of a yellowish-red or red shade, but more usually to zircon (*q.v.*). Other stones of similar colour to which the name is sometimes applied include: ferruginous quartz from Santiago de Compostella in the north of Spain (*Compostella hyacinth*); hessonite (*v.* garnet); brown idocrase or vesuvianite from Vesuvius; yellowish-red spinel from Minas Novas, Brazil; topaz from Brazil; and reddish-brown corundum (*Oriental hyacinth*). The *υακινθος* or *hyacinthus* of the ancients was, however, a blue or purple stone, probably corundum (sapphire), or perhaps amethyst.

L. J. S.

HYÆNASIC ACID $C_{24}H_{40}COOH$, m.p. 77.5°, is found as a glyceride in the anal glandular pouches of the striped hyæna (Carius, Annalen, 129, 168).

HYALINE CORUNDUM v. ALUMINIUM.

HYALITE v. OPAL.

HYDANTOIN, *glycolycarbamide* $CO \begin{matrix} \nearrow NH \cdot CH_2 \\ \searrow NH \cdot CO \end{matrix}$

is found, together with allantoin in the leaf buds of *Platanus orientalis* (Linn.) (Schulze and Barbieri, Ber. 1881, 14, 1834); and also in beet juice (v. Lippmann, Ber. 1896, 29, 2652). It is prepared (1) by reducing allantoin or alloxanic acid with concentrated hydrogen iodide at 100° (Baeyer, Annalen, 1864, 130, 158); (2) by the action of excess of alcoholic ammonia on brom-acetylurea at 100° (Baeyer, Ber. 1875, 8, 612); (3) by the condensation of sodium dihydroxytartrate and carbamide in the presence of hydrochloric acid at 50°–60° (Anschütz, Annalen, 1889, 254, 258); (4) by the condensation of glyoxal and carbamide in the presence of hydrochloric acid (Siemonsen, Annalen, 1904, 333, 101); (5) from ethyl hydantoate by heating at 135° for 7 hours, or by warming with 25 p.c. hydrochloric acid (Harries and Weiss, Ber. 1900, 33, 3418), or by heating with alcoholic ammonia at 100° (Harries, Annalen, 1908, 361, 69); the ethyl hydantoate is prepared by the condensation of the hydrochloride of the ethyl ester of glycine with potassium cyanate (Harries and Weiss, *l.c.*) or by the interaction of glycollic ester and ethyl sodicarbonate (Diels and Heintzel, Ber. 1905, 38, 305). It may be prepared from hippuric acid by converting it into 3-benzoyl-2-thiohydantoin (Johnson and Nicolet, J. Amer. Chem. Soc. 1911, 13, 1973) and then desulphurising this compound with an aqueous solution of chloracetic acid (Johnson and Bengis, *ibid.* 1913, 35, 1605).

Hydantoin crystallises in colourless needles, m.p. 216° (Schulze and Barbieri, Anschütz, *l.c.*); 217°–220° (Harries and Weiss, *l.c.*); its heat of combustion at constant volume is +312.4 Cal., and heat of formation +109 Cal. (Matignon, Ann. Chim. 1893, [vi.] 28, 70). Its dissociation constant K_a is 7.59×10^{-10} (Wood, Phil. Trans. 1906, 1833). It is sparingly soluble in cold, readily so in hot water, and the solution has a sweetish taste. Hydantoin is not attacked by ammonia, hydrochloric, or dilute nitric acid;

when boiled with baryta water it is converted into the barium salt of *hydantoinic acid*

the heat of combustion of which is 308.9 Cal. and heat of formation +181.6 Cal. (Matignon, *l.c.*), m.p. 179°–180°.

The *silver derivative* $\text{C}_2\text{H}_3\text{O}_2\text{N}_2\text{Ag}\cdot\text{H}_2\text{O}$ is precipitated by silver nitrate from an ammoniacal solution of hydantoin.

Spiro-4 : 4-dihydantoin

prepared by boiling 5-amino-4-hydroxy-4 : 5-dihydrouic acid with concentrated hydrochloric acid, crystallises in stout rhombohedra which only slowly blacken and decompose above 400°. It is remarkably stable towards acids, and is not attacked by alkaline permanganate; it is converted by hot concentrated aqueous barium hydroxide into allantoin. It is the parent substance of hypoxanthine (1 : 7 : 9-*tri-methyl-spiro-4 : 4-hydantoin*) (Biltz and Heyn, *Annalen*, 1916, 413, 38).

Substituted derivatives of hydantoin are

by the action of nitric acid on hydantoin, forms shining crystals, melting and decomposing at 170° (Franchimont and Klobbie, *Rec. trav. chim.* 1888, 7, 12).

4-Aminohydantoin hydrochloride, prepared by the action of concentrated hydrochloric acid on triacetylaminohydantoin, has m.p. 218°–222° (decomp.). Silver oxide reacts with it to yield 3-*silver-4-aminohydantoin* and aqueous potassium cyanate reacts with it with formation of allantoin (Biltz and Giesler, *Ber.* 1913, 46, 3423).

tained by the action of acetic anhydride on hydantoin, has m.p. 104°–105°, and yields

when boiled with water, and this forms a sparingly soluble *lead salt* (Harries and Weiss, *Annalen*, 1903, 327, 355; Siemonsen, *Annalen*, 1904, 333, 101).

in the form of lustrous crystalline leaves, m.p. 120°–121°, by the action of chlorine on an aqueous solution of hydantoin, has the characteristic properties of a chlorimino compound (Harries and Weiss, *Annalen*, 1903, 327, 355; Siemonsen, *Annalen*, 1904, 333, 101; Biltz and Behrens, *Ber.* 1910, 43, 1984). Attempts to prepare bromine derivatives of hydantoin have been unsuccessful; by the action of $\frac{1}{2}$ molecule of bromine hydantoin is converted into *isocallitric acid*

260°, when a larger proportion of bromine is employed, parabanic acid (oxalylcarbamide), is

being probably first produced.

Condensation with aldehydes. Hydantoin condenses with formaldehyde (1–3 mols.) in aqueous solution to form *hydroxymethyl-*

or

m.p. 125°–135°, it yields *chloromethylhydantoin* $\text{C}_4\text{H}_5\text{O}_2\text{N}_2\text{Cl}$, m.p. 150°–157°, when treated with phosphorus pentachloride or concentrated hydrochloric acid. When hydantoin is warmed with formaldehyde in the presence of acids more complex products are obtained (Behrend and Niemeyer, *Annalen*, 1909, 365, 38).

Hydantoin condenses with aromatic aldehydes in the presence of glacial acetic acid and sodium acetate to form compounds of the type

m.p. 220°, yields 4-*benzylhydantoin* (*phenyl-alaninehydantoin*) $\text{PhH}_2\text{C}\cdot\text{CH} \begin{array}{c} \text{CO}\cdot\text{NH} \\ \diagdown \quad \diagup \\ \text{NH}\cdot\text{CO} \end{array}$, m.p.

188°–190° on reduction, from which phenylalanine is obtained by boiling with baryta water (Ruhemann and Stapleton, *Phil. Trans.* 1900, 246). Johnson and Bates (*J. Amer. Chem. Soc.* 1915, 37, 383) record two isomeric modifications of benzylidenehydantoin: the ordinary form (*cis*), m.p. 220°, and a *trans*-form, m.p. 246°, which crystallises in aggregates of distorted needles (*cf.* Komatsu, *Mem. Coll. Sci. Eng. Kyoto*, 1912, 5, 13).

Anisylidenehydantoin

m.p. 243°–244° (decomp.) yields a *bromo* derivative, m.p. 247°; and on reduction with hydrogen iodide forms 4-*p-hydroxybenzylhydantoin* (*tyrosinehydantoin*)

m.p. 257°–258°, from which *tyrosine* is obtained by prolonged boiling with hydrogen iodide. The tyrosinehydantoin, m.p. 275°–280°, described by Blendermann (*Bied. Zentr.* 1883, 209) is probably the optically active isomeride of this compound.

Piperonylidenehydantoin

m.p. 245°.

4-Cinnamylidenehydantoin

crystallises from hot glacial acetic acid in clusters of canary-yellow needles which melt at 272°–273° to a red oil (decomp.) (Johnson and Wrenshall, J. Amer. Chem. Soc. 1915, 37, 2133).

Furfurylidenhydantoin

m.p. 232°.

3:5-Dichloro-4-hydroxybenzylidenehydantoin

p-Nitrobenzylidenehydantoin

m.p. 254° (Wheeler and Hoffmann, Amer. Chem. J. 1911, 45, 368). See Johnson and Brautlecht (J. Biol. Chem. 1912, 12, 184) for the preparation of 1-phenyl-4-paranitrobenzylhydantoin and allied compounds from thiohydantoin derivatives.

Alkyl and aryl substituted derivatives,

1-Methylhydantoin $\begin{array}{c} \text{NH} \cdot \text{CH}_3 \\ \diagdown \quad \diagup \\ \text{CO} \quad \text{NMe} \cdot \text{CO} \end{array}$ by methylating

hydantoin by means of methyl iodide, potassium hydroxide, and methyl alcohol at 100° (Franchimont and Klobbie, Rec. trav. chim. 1889, 8, 289); from methylcarbamide and glycine (Guareschi, Chem. Zentr. 1892, i. 140); crystallises in prisms, m.p. 182°. The nitro derivative

$\begin{array}{c} \text{N}(\text{NO}_2) \cdot \text{CH}_2 \\ \diagdown \quad \diagup \\ \text{CO} \quad \text{NMe} \cdot \text{CO} \end{array}$ has m.p. 168° (Franchimont and Klobbie, l.c.). 1-p-tolylhydantoin

from p-tolylcarbamide and glycine (Quenda, Chem. Zentr. 1892, i. 140); it has m.p. 206°.

3-Methylhydantoin $\begin{array}{c} \text{NMe} \cdot \text{CH}_2 \\ \diagdown \quad \diagup \\ \text{CO} \quad \text{NH} \cdot \text{CO} \end{array}$ prepared

(1) by fusing sarcosine and urea (Huppert, Ber. 1873, 6, 1278; Horbaczewski, Monatsh. 1887, 8, 586); (2) by passing cyanogen chloride through fused sarcosine (Traube, Ber. 1882, 15, 2111); (3) by heating caffuric acid with baryta water (Fischer, Annalen, 1882, 215, 236); or (4) by reducing 3-methylallantoin with hydrogen iodide (Fischer and Ach, Ber. 1899, 32, 2748) forms soluble prisms, m.p. 156°; the silver derivative $\text{AgC}_4\text{H}_7\text{N}_2\text{O}_2$ is crystalline.

3-Phenylhydantoin from phenylglycine and urea has m.p. 191°; 3-tolylhydantoin has m.p. 210° (Schwebel, Ber. 1877, 10, 2045; 11, 1128).

Homologues of hydantoin containing the substituent in position 4- are most numerous; and are prepared by the following general methods: (1) by interaction between the

cyanohydrin of an aldehyde and carbamide (Pinner, Ber. 1887, 20, 2351; 21, 2320; 22, 685); (2) by the action of dilute hydrochloric acid on the hydantoin acid obtained by evaporating to dryness a solution of an α-amino acid and potassium cyanate (Dakin, Amer. Chem. J. 1910, 44, 48); or by the interaction of carbamide, the α-amino acid and baryta water (Lippich, Ber. 1908, 41, 2953); (3) by reducing the compound obtained by the condensation of hydantoin and an aromatic aldehyde (Wheeler and Hoffmann, l.c.).

4-Methylhydantoin (lactylurea) $\begin{array}{c} \text{NH} \cdot \text{CHMe} \\ \diagdown \quad \diagup \\ \text{CO} \quad \text{NH} \cdot \text{CO} \end{array}$

(Heintz, Annalen, 1873, 169, 125; Urech, Ber. 1873, 6, 1113), m.p. 140° or 145°. The nitro-

derivative $\begin{array}{c} \text{NH} \cdot \text{C}(\text{NO}_2)\text{Me} \\ \diagdown \quad \diagup \\ \text{CO} \quad \text{NH} \cdot \text{CO} \end{array}$ m.p. 148°

(Franchimont and Klobbie, Rec. trav. chim. 1888, 7, 13). 4-isoButylhydantoin

has m.p. 209°–210° (Pinner and Lifschütz, Ber. 1887, 20, 2351), 212° (Lippich, *ibid.* 1908, 41, 2953). 4-isoButylhydantoin has m.p. 212°, $[\alpha]_D^{20} -68.2^\circ$ in normal sodium hydroxide solution, becoming zero in 30 hours owing to the enol-keto desmotropy of the group

4:4-Methylethylhydantoin $\begin{array}{c} \text{NH} \cdot \text{CMeEt} \\ \diagdown \quad \diagup \\ \text{CO} \quad \text{NH} \cdot \text{CO} \end{array}$ has

m.p. 172°–173°, and $[\alpha]_D^{20} +32^\circ$, and this is constant in normal sodium hydroxide solution (Dakin, l.c.). 4-Phenylhydantoin, m.p. 178°. The acetyl derivative has m.p. 145° (Pinner, l.c.); the bromo derivative

melts above 200°, and is decomposed by hot water, yielding 4-hydroxy-4-phenylhydantoin (Gabriel, Annalen, 1906, 350, 118). 4:4-Phenylethylhydantoin (nirvanol), m.p. 197°, and its sodium salt are hypnotics; the free acid is tasteless, the sodium salt has a bitter taste (Wernecke, Deut. Med. Woch. 1916, 42, 1193; Piotrowski, Chem. Zentr. 1916, 11, 1182; from Münch. Med. Wochschr. 63, 1572; Farb. vorm. M.L. and B. Swiss, 72, 561). 4:4-Propylhydantoin is also a soporific, m.p. 170° (Farb. vorm. M.L. and B. Swiss, 74, 189, and 79, 190). For the preparation of 4:4-disubstituted hydantoins which have soporific properties, see Chemische Fabrik von Heyden, D. R. PP. 309508, 310426.

Phenylalaninylglycinehydantoin (4-benzylhydantoin-1-acetic acid)

polypeptide hydantoin, has m.p. 184°–185°, and crystallises in flat prisms or rhombic plates (Johnson and Bates, J. Amer. Chem. Soc. 1916,

38, 1087). 4-Methoxyphenylhydantoin has m.p. 183°-189°. Hydantoin-4-carboxylemine

has m.p. 214°-215°. Hydantoin-4-propionic acid has m.p. 165°. Hydantoin-4-β-bromopropionic acid has m.p. 228°-230°; hydantoin-4-β-propionic acid has m.p. 222°-223°; hydantoin-4-β-chloropropionic acid forms rectangular plates; hydantoin-4-acrylic acid has m.p. 256°-258° (Dakin, Biochem. J. 1919, 13, 398). 4-Cinnamyl hydantoin

m.p. 171°-172° (Pinner and Spilker, Ber. 1889, 22, 685). 4-Ethylhydantoin, m.p. 117°-118°, yields 4-bromoethylidenhydantoin

m.p. 230°-236°, on bromination; the corresponding methyl compound yields 4-bromomethylene-

(Gabriel, Annalen, 1906, 348, 50).

4:4-Dimethylhydantoin (acetonylcarbamide)

cyanic acid, and cyanic acid on acetone has m.p. 175°; the nitro derivative has m.p. 161°-162° (Urech, Annalen, 1872, 164, 264; Errera, Gazz. chim. ital. 1896, 26, 1, 210); 4:4-diethylhydantoin has m.p. 165°, and 4:4-dipropylhydantoin, m.p. 199° (Errera, *l.c.*). By the action of sodium hypochlorite and free hypochlorous acid on 4:4-disubstituted hydantoins, the corresponding 1:3-dichloro compounds

are obtained. These compounds can be crystallised from chloroform, but are decomposed by water, alcohol, or hydrogen iodide, regenerating the original hydantoin (Biltz and Behrens, Ber. 1910, 43, 1984).

1:3-Dichloro-4:4-diphenylhydantoin

has m.p. 164° with decomposition, it yields 4:4-diphenyl-1:3-dimethylhydantoin when treated with methyl sulphate.

1-Methyl-4-phenylhydantoin has m.p. 161°-162° (Pinner, Ber. 1888, 21, 2320). 4-Methyl-3-ethylhydantoin forms volatile plates (Duvillier, Bull. Soc. chim. 1895, [ii.] 13, 487).

3:4-Dimethylhydantoin has m.p. 120°-121°, and yields 3-methyl-4-bromomethylidenhydantoin

action of bromine (Gabriel, Annalen, 1906, 348, 50).

4-Benzylhydantoin (inactive)

was prepared by Wheeler and Hoffmann (Amer. Chem. J. 1911, 45, 372) by heating benzal hydantoin with phosphorus and hydriodic acid. It crystallises from alcohol in lancet-shaped crystals or in prisms, m.p. 190°. Dakin and Dudley (J. Biol. Chem. 1914, 17, 35) prepared *d*- and *l*-benzylhydantoin by hydrolysis of *l*- and of *d*-β-phenyl-α-uramido propionic acids (C₆H₅CH₂:CH(NH·CONH₂)COOH; *d*-benzylhydantoin has m.p. 181°-183°, and [α]_D+96.4° in 50 p.c. alcohol; it racemises completely on standing in alkaline solution at room temperature; *l*-benzylhydantoin has m.p. 181°-183°; on prolonged heating with concentrated acid it racemises completely; the melting point of the *r*-acid being 194°-195°.

4-*p*-Nitrobenzylhydantoin

crystallises in pale yellow prisms, and has m.p. 238°-240° (decomp.). 4-*p*-Aminobenzylhydantoin has m.p. 145°; when diazotised and heated it yields tyrosine hydantoin (Johnson and Brautlecht, J. Biol. Chem. 1912, 12, 187).

4:4-Dimethyl-1-*o*-tolylhydantoin

crystallises in thin prismatic plates, m.p. 172° (Bailey and McPherson, *ibid.* 1916, 11, 2526; Ber. 1908, 41, 2497).

For the synthesis of the polypeptide hydantoin, phenylalanylglycinehydantoin

m.p. 184°-185°, *v.* Johnson and Bates (J. Amer. Chem. Soc. 1916, 38, 1087). For other derivatives of hydantoin, see West, J. Biol. Chem. 1918, 34, 187.

Thiohydantoins. 2-Thiohydantoin

was obtained by Klason (Chem. Zeit. 14, Rep. 200). It may be obtained quantitatively by hydrolysis with hydrochloric acid of 2-thio-3-acetylhydantoin or of 2-thio-3-benzoylhydantoin (produced respectively by the action of potassium thiocyanate on glycocholic or on hippuric acid in presence of acetic anhydride). It crystallises in yellow prisms, m.p. 227°-228° (decomp.). It is stable and yields stable sodium and potassium salts (Johnson and Nicolet, J. Amer. Chem. Soc. 1911, 33, 1973; *ibid.* 1913,

35, 780). 2-Thio-1-*p*-tolylhydantoin, m.p. 228°, is converted into 1-*p*-tolylhydantoin on heating with aqueous solution of chloracetic acid (*ibid.* 1912, 34, 1045). 5-Thiohydantoin is formed by the condensation of carboxyamidooacet-thioamide in presence of alkali

It crystallises from hot water in spear-shaped twinned crystals and gradually decomposes above 200°; it hydrolyses with hydrochloric acid, yielding hydantoin and sulphuretted hydrogen (Johnson and Chernoff, *ibid.* 1912, 34, 1208).

2-Thiohydantoin-4-propionic acid has m.p. 165° (Johnson and Guest, Amer. Chem. J. 1912, 47, 242).

2-Thio-4-benzalhydantoin, microscopic needles, has m.p. 258° (slight decomp.). (Johnson and Nicolet, J. Amer. Chem. Soc. 1912, 34, 1048; cf. also Ruhemann and Stapleton, Chem. Soc. Trans. 1900, 77, 246).

2-Thio-4-*o*-hydroxybenzylhydantoin

m.p. 107°, is readily desulphurised by heating with 25 p.c. solution of monochloroacetic acid at 140°–150°, yielding 4-*o*-hydroxybenzylhydantoin (4-*o*-tyrosinehydantoin).

Acylthiohydantoin. 2-Thio-3-acetylhydantoin crystallises from absolute alcohol in beautiful square tables or blocks; it melts at 175°–176° to a clear oil without effervescence. 2-Thio-3-benzoylhydantoin crystallises from alcohol in square plates; it melts at 165° to a clear oil without effervescence. 2-Thio-3-acetyl-4-benzylhydantoin, prepared by the action of ammonium thiocyanate on phenylalanine in acetic anhydride solution, has m.p. 170°. 2-Thio-3-acetyl-4-methylhydantoin, prepared by the action of potassium thiocyanate on alanine in presence of acetic anhydride, crystallises in stout prisms, and has m.p. 166° (Johnson and Nicolet, J. Amer. Chem. Soc. 1911, 33, 1975; *ibid.* 1912, 34, 1041; *ibid.* 1913, 35, 1130; Amer. Chem. J. 1913, 49, 200; J. Biol. Chem. 1912, 11, 98).

4 : 4-Dimethyl-1-*o*-tolyl-2-thiohydantoin

is prepared by boiling equimolecular amounts of *o*-tolyl mustard oil and aminoisobutyrate for an hour, distilling off the alcohol, dissolving the residue in water, and precipitating the thiohydantoin by the addition of hydrochloric acid, m.p. 195.5° (Bailey and McPherson, J. Amer. Chem. Soc. 1916, 38, 2525). M. A. W.

HYDNO-CARPIC ACID, HYPOGALIC ACID, v. OILS, FIXED, and FATS.

HYDRACETIN. Mono-acetyl derivative of phenylhydrazine.

HYDRACRYLIC ACID v. LACTIC ACID.

HYDRÆSCULIN v. HORSE-CHESTNUT.

HYDRAMIN. A trade name for a combination of *p*-phenylenediamine and quinol.

HYDRARGILLITE v. GIBBSITE.

HYDRARGOL. Mercury succinimide

HYDRARGOTIN. Trade name for mercury tannate.

HYDRARGYROL. A mercury salt of *p*-phenol sulphonic acid ($\text{HO} \langle \text{C}_6\text{H}_4 \rangle \text{SO}_2\text{O}$)₂Hg.

HYDRARSAN. A solution of arsenic and the iodides of mercury and potassium with antipyrine.

HYDRASTINE C₂₁H₂₁O₆N. An alkaloid occurring together with berberine and canadine in the root of *Hydrastis canadensis* (Linn.), 'Golden Seal,' to the extent of about 1.5 p.c.

Its preparation and physical properties are described by Durand, Amer. J. Pharm. 1851, 23, 112; Perrins, Pharm. J. 1861–1862, [ii.] 3, 546; Mahla, Amer. J. Sci. 36, 57; Power, Pharm. J. 1884–1885, [iii.] 15, 297; Eijkman, Rec. trav. chim. 1886, 5, 290; Freund and Will, Ber. 1886, 19, 2797; 1887, 20, 88; Schmidt and Wilhelm, Arch. Pharm. 1888, 226, 329; and Elsa Schmidt (Amer. J. Pharm. 1919, 91, 270).

Preparation.—Hydrastine may be isolated from the mother-liquor from which the berberine salt has crystallised (*see* BERBERINE). This is largely diluted with water, and almost neutralised with ammonia. On evaporation, ammonium sulphate, resin, &c., separate out; these are removed, and the hydrastine precipitated from the cold liquid by ammonia. The coloured precipitate is dissolved in alcohol (Perrins, Power), or ethyl acetate (Schmidt and Wilhelm), and the colouring matter removed by digestion with animal charcoal; the alkaloid crystallises from the concentrated solution. Purification of the hydrastine is effected by repeated crystallisation from alcohol.

Some authors prefer to extract hydrastine from the root before berberine, thus, according to Freund and Will, hydrastine is most readily obtained by percolating finely powdered hydrastis root with ether, and crystallising the ethereal residue from alcohol. Elsa Schmidt employs a similar method, using benzene as the solvent.

Properties.—Colourless, rhombic prisms, m.p. 132°. Insoluble in water, readily soluble in chloroform or benzene; less readily so in ether or alcohol. [α]_D in chloroform, –67.8° (Freund and Will); in chloroform, –63.8°; in dry alcohol, –49.8°; in 50 p.c. alcohol, +115° (Carr and Reynolds, Chem. Soc. Trans. 1910, 97, 1334). The ordinary salts of hydrastine are soluble in water, giving dextrorotatory solutions, but do not crystallise well (*cf.* Schmidt and Kerstein, Arch. Pharm. 1890, [iii.] 228, 49). Hydrastine and its hydrochloride, a hygroscopic powder, are official in the U.S.P. 1916; they are chiefly employed for the arrest of uterine hæmorrhage in doses of $\frac{1}{4}$ to $\frac{1}{2}$ grain. Hydrastine is poisonous in larger doses.

Detection and estimation.—The most characteristic colour reaction of hydrastine is the production of a fluorescent solution (due to the formation of hydrastinine) by the addition of permanganate to an aqueous solution of its sulphate (*cf.* Lyons, Pharm. J. 1885–1886, [iii.] 16, 880). For other colour reactions of hydrastine, *see* Power, Pharm. J. 1885–1886, [ii.] 16,

1092; Labat, Bull. Soc. chim. 1909, [iv.] 5, 742, 745. The assay of hydrastis rhizome prescribed in the U.S.P. 1916 consists in the gravimetric estimation of the ether-soluble alkaloids, which should amount to not less than 2.5 p.c. For other methods of assay, see Gordin and Prescott, Arch. Pharm. 1899, 237, 439; 1901, 239, 638; van der Haar, Pharm. Weekblad. 1911, 48, 1302.

Constitution.—The oxidation of hydrastine by nitric acid yields opianic acid and hydrastinine.

The determination of its constitution is bound up with that of these fission-products and is due mainly to the researches of Freund and Roser. The work, which has been reviewed by Freund (Annalen, 1892, 271, 311), leads to the following constitutional formulæ:—

An optically-inactive stereoisomeride of hydrastine has been prepared synthetically (Hope and Robinson, Chem. Soc. Proc. 1912, 28, 17).

Hydrastinine $\text{C}_{11}\text{H}_{13}\text{O}_3\text{N}$, is prepared by the oxidation of hydrastine (Freund and Will, Ber. 1887, 20, 88), and has been synthesised by Fritsch (Annalen, 1895, 286, 18); Decker (D. R. P. 234850, 1911); Rosenmund (Ber. Deut. pharm. Ges. 1919, 29, 200).

It may also be prepared from berberine (Freund, D. R. P. 241136, 1911) and cotarnine (Pyman and Remfry, Chem. Soc. Trans. 1912, 101, 1595). Like berberine (*q.v.*), the free base occurs in two isomeric forms, in aqueous solution as the quaternary hydroxide shown above, and in the solid state as the carbinolamine (*cf.* Dobbie and Tinkler, Chem. Soc. Trans. 1904, 85, 1005). It melts at $116^\circ\text{--}117^\circ$, crystallises from light petroleum, and is easily soluble in alcohol or ether, but sparingly so in water.

The hydrochloride, properly hydrastinium chloride, $\text{C}_{11}\text{H}_{12}\text{O}_3\text{NCl}$, is official in the U.S.P. 1916. It melts and decomposes at 210° , and is easily soluble in water, giving a neutral solution showing a blue fluorescence. It gives no turbidity with ammonia, but sodium hydroxide causes a milky turbidity which disappears on shaking, and, on keeping, the solution deposits free hydrastinine.

Canadine $\text{C}_{20}\text{H}_{21}\text{O}_4\text{N}$ occurs with crude hydrastine (*see above*), from which it may be isolated by fractional crystallisation of the nitrates, the canadine salt being less soluble. Silky needles, m.p. 132.5° , $[\alpha]_D -298^\circ$ in chloroform (Schmidt, Arch. Pharm. 1894, 232, 136). On oxidation with iodine it is converted into berberine. By fractional crystallisation of tetrahydroberberine *d*-bromocamphorsulphonate, Gadamer (*ibid.* 1901, 239, 648) isolated a *l*-vo-

rotatory base identical with canadine, which is therefore *l*-tetrahydroberberine. Jowett and Pyman have found *l*-a-canadine methochloride in *Xanthoxylum brachycanthum* (Chem. Soc. Trans. 1913, 103, 293). F. L. P.

HYDRAULIC CEMENTS *v.* CEMENTS.

HYDRAULIC LIME *v.* CEMENTS.

HYDRAZINES. The name 'hydrazine' was applied by Emil Fischer to the then unknown diamide $\text{H}_2\text{N}\cdot\text{NH}_2$, which he regarded as the parent substance of the hydrazines, a large and important class of bases which had been prepared by him and the reactions of which showed them to possess a structural formula derived from diamide by the replacement of one or two hydrogen atoms by hydrocarbon radicles. The name was intended to indicate the connection of these compounds with the azo and diazo compounds and particularly with hydrazobenzene, $\text{C}_6\text{H}_5\cdot\text{NH}\cdot\text{NH}\cdot\text{C}_6\text{H}_5$, the oldest known member of this class, which itself may be regarded as a symmetrically disubstituted hydrazine.

It is apparent that there are five different ways in which the four hydrogen atoms of diamide may be replaced by hydrocarbon radicles, thus: (1) $\text{RNH}\cdot\text{NH}_2$, (2) $\text{RRN}\cdot\text{NH}_2$, (3) $\text{RHN}\cdot\text{NHR}$, (4) $\text{RRN}\cdot\text{NHR}$, (5) $\text{RRN}\cdot\text{NRR}$, but the name hydrazine was formerly only applied to those derivatives of diamide which had the hydrocarbon radicle or radicles asymmetrically attached to the molecule, that is to say, those which are constituted in accordance with formulæ (1) and (2).

This was mainly owing to the fact that the compounds constituted as in formula (3) had already been named, as for example hydrazobenzene, $\text{C}_6\text{H}_5\text{NH}\cdot\text{NH}\cdot\text{C}_6\text{H}_5$, and that no substances of the formulæ 4 and 5 had as yet been prepared. At the present time compounds of all five classes are known, and therefore the name hydrazine is applied to all derivatives of diamide.

The hydrocarbon radicles forming the hydrazines may belong either to the aliphatic or aromatic series, although the most important members of the group belong to the aromatic series. Like the amines, they are divided into primary and secondary hydrazines, according as one or two hydrocarbon radicles are contained in them; that is to say, the primary hydrazines are constituted as in formula (1), the secondary hydrazines as in formula (2). The secondary hydrazines may be symmetrical or asymmetrical as in formula (2) or (3): compounds constituted as in formula (4) are tertiary hydrazines, whilst quaternary hydrazines have a structure represented by formula (5).

General methods of preparation.—The primary and secondary hydrazines can be considered as being derived from the primary and secondary amines respectively by the replacement of one of the hydrogen atoms attached to the nitrogen by the primary amino group—

These compounds are therefore prepared from the primary and secondary amines through the agency of nitrous acid.

Since the primary aromatic amines yield diazonium salts when treated with nitrous acid, these salts are always intermediate products in

the formation of the primary aromatic hydrazines and are converted into them by the action of reducing agents. For general purposes this reduction may be effected in one of two ways—

(1) By the reduction of the solution of the diazonium salt by stannous chloride (V. Meyer and Lecco, Ber. 1883, 16, 2976)—

(2) By treating the diazonium salt with alkali sulphite, in order to prepare the alkali salt of the sulphonio acid, and then by reducing this with zinc dust and acetic acid to form the alkali salt of the hydrazine sulphonio acid thus—

Finally, by boiling this salt with hydrochloric acid to convert it into the hydrochloride of the hydrazine and potassium hydrogen sulphate (E. Fischer, Annalen, 1877, 190, 71; Reychler, 1887, 20, 2463).

These reactions can only be applied to the aromatic amines because those of the aliphatic series do not form diazonium salts.

Primary aliphatic hydrazines have, however, been prepared by E. Fischer (Ber. 1884, 2841; Annalen, 1877, 199, 281) from the symmetrical dialkyl ureas by transforming them into their nitroso derivatives by the aid of nitrous acid and then by converting the hydrazinuress, formed from these on reduction, into the primary hydrazines by the action of fuming hydrochloric acid.

Primary hydrazines of the aromatic series are also formed when certain diazoamino compounds are reduced in alcoholic solution with zinc dust and acetic acid. Thus diazoaminobenzene passes in this manner into phenylhydrazine (E. Fischer, Annalen, 1887, 90, 77).

The secondary hydrazines both of the aromatic and aliphatic series are prepared from the corresponding secondary amines. The amines are converted into their nitroso derivatives by the aid of nitrous acid, which are then transformed into the hydrazines by reduction.

Phenylhydrazine $C_6H_5 \cdot NH \cdot NH_2$, the most important member of the hydrazine group, can be prepared by either of the methods mentioned above.

(1) *From aniline by the aid of stannous chloride.* Ten grams of aniline are dissolved in 100 grams of concentrated hydrochloric acid, and the semi-solid mass of aniline hydrochloride is then cooled, externally, by means of ice. A solution of 10 grams of sodium nitrite dissolved in 50 c.c. of water is then gradually added until a test portion diluted with water shows, by means of starch and potassium iodide paper, the presence of excess of nitrous

acid. The solution of benzene-diazonium chloride formed in this manner is then treated with a solution of 60 grams of stannous chloride dissolved in 50 c.c. of concentrated hydrochloric acid, the reducing agent being cooled by means of ice and added gradually with constant stirring to the solution of the diazonium salt. After standing for one hour, the phenylhydrazine hydrochloride is filtered at the pump, dissolved in water and converted into the free base by the addition of excess of aqueous caustic potash. The liberated base is extracted with ether, dried by potassium carbonate and purified by distillation under diminished pressure.

(2) *From aniline by the aid of sodium sulphite.* A solution of 50 grams of aniline in $2\frac{1}{2}$ molecules of hydrochloric acid and 300 c.c. of water is diazotised by the addition of the calculated quantity of sodium nitrite solution, and is then mixed with a cold concentrated aqueous solution of $2\frac{1}{2}$ molecules of sodium sulphite. The whole is then gently warmed on the water bath and treated with zinc dust and a little acetic acid until colourless, when it is heated to the boiling-point and filtered, whilst hot, from the unchanged zinc. One-third of its volume of concentrated hydrochloric acid is then added to the hot solution and the phenylhydrazine hydrochloride, which separates on cooling, is removed by filtration and treated in the same manner as in the previous preparation.

For the preparation of phenylhydrazine and its derivatives from urea and substituted ureas by the action of alkaline hypobromites, cp. Schestakow, D. R. P. 164755; Patentol. 26, 1869.

Tertiary aromatic hydrazines of the general formula $RNH \cdot NR_2$ may be prepared by the interaction of β -arylhydroxylamine and magnesium halogen aryl (Busch and Hobein, Ber. 1907, 40, 2099). Thus triphenylhydrazine $C_6H_5 \cdot NH \cdot N(C_6H_5)_2$ is formed when phenylmagnesium bromide reacts with β -phenylhydroxylamine. The corresponding quaternary hydrazine tetraphenylhydrazine

has been prepared by Chattaway and Ingle (Trans. 1895, 67, 1090) by the action of iodine on the sodium compound of diphenylamine, and by Weland and Gambarjan (Ber. 1906, 39, 1501) by the oxidation of diphenylamine.

Certain compounds belonging to the group of the dihydrazines have been prepared by V. Braun (Ber. 1908, 41, 2169; *ibid.* 2604; 1910, 1495), and are recommended as reagents for compounds containing carbonyl oxygen. Thus diphenylmethandimethyldihydrazine

is prepared by condensing methylaniline with formaldehyde to give *p*-dimethyldiaminodiphenylmethane $[HN(CH_3)C_6H_4]_2CH_2$, the nitroso compound of which gives the dihydrazine on reduction with zinc and acetic acid.

Properties and reactions of the hydrazines. The primary aromatic hydrazines are mono-acid bases which form well-defined, stable salts with both mineral and organic acids. Unlike the corresponding aliphatic primary hydrazines

they do not form salts containing two equivalents of a mono-basic acid. The secondary aromatic hydrazines are also mono-acid bases, but their salts are partially decomposed by water. The primary aromatic hydrazines, for example phenylhydrazine, react with metallic sodium forming a sodium compound from which alkyl derivatives can be prepared by the action of alkyl iodides—

(*cp.* Michaelis, *Ber.* 1886, 19, 2448; 1887, 20, 43; also *Annalen*, 1889, 252, 267). The pure sodium compound can be prepared by acting on sodamide with a dilute benzene solution of phenylhydrazine (Titherley, *Chem. Soc. Trans.* 1897, 71, 461)—

The corresponding potassium salt may be obtained as large colourless rhombic crystals when phenylhydrazine is treated with a saturated alcoholic solution of potassium hydroxide in the absence of air (Chattaway, *Chem. Soc. Trans.* 1907, 91, 1326).

The primary hydrazines are readily affected by oxidising agents and are consequently strong reducing agents. Phenylhydrazine reduces Fehling's solution in the cold, even in very dilute solution, a reaction which distinguishes this compound from the secondary base, diphenylhydrazine, which reduces Fehling's solution only on warming. (For the behaviour of phenylhydrazine on oxidation, *cp.* Fischer, *Annalen*, 1878, 190, 67; 1879, 199, 281; Fischer and Ehrhard, *Annalen*, 1879, 199, 333; Haller, *Ber.* 1885, 18, 90; Zincke, *ibid.* 1885, 18, 786; Strache, *Monatsh.* 1891, 12, 523; 1892, 13, 316; Murster, *Ber.* 1887, 20, 2633.)

The original statement by Fischer that the oxidation of phenylhydrazine by mercuric oxide leads to a partial production of the diazonium salt has been modified by Chattaway (*Chem. Soc. Trans.* 1908, 93, 270), who finds that diazonium salts are not produced when the action is carried out in alkaline solution but only in the presence of a large excess of strong acid. Azoimides are formed when alkali is absent and the hydrazines are present in excess. The quantitative conversion of phenylhydrazine into benzenediazonium chloride may be effected by dissolving the hydrazine in glacial acetic acid, cooling the solution to about -15° by the addition of crushed ice and either by passing in a rapid stream of chlorine or (if the diazonium bromide is desired) adding the calculated quantity of bromine dissolved in acetic acid and similarly cooled by ice. The reaction evidently proceeds in accordance with the scheme

(Chattaway, *Chem. Soc. Trans.* 1908, 93, 853).

The mechanism of the reaction involved in the oxidation of phenylhydrazine either by oxygen or an oxidising agent, is explained in the following way (Chattaway, *Trans.* 1908, 93, 270):—

In the first instance, one of the hydrogen atoms of the hydrazino group is attacked and a hydroxyhydrazine is produced

This substance, however, not being stable in the presence of alkali, undergoes disruption in accordance with the scheme

the splitting off of the hydrocarbon and water occurring in either one or two stages.

If, however, a very energetic oxidising agent is used, a certain number of molecules may, before breaking down, undergo a further oxidation thus:—

yielding a phenol and free nitrogen. In the absence of alkali, which acts as a catalytic agent and much accelerates the decomposition of these hydroxyhydrazines, the introduction of the second hydroxyl group takes place to a much greater extent, and in the presence of strong acid and at a low temperature a diazonium salt is formed, thus—

The oxidation of phenylhydrazine by basic metallic oxides leads to the formation of the free metal. The following process is recommended for producing a film of metallic copper on glass vessels (Chattaway, *Chem. Soc. Trans.* 1908, 93, 275; see also *Proc. Roy. Soc.* 1908, A, 80, 88). One part of freshly distilled phenylhydrazine and 2 parts of water are heated until a clear solution is obtained, when it is mixed with about half its bulk of a warm saturated solution of cupric hydroxide in strong ammonia. Nitrogen is freely evolved during the addition, and the cupric hydroxide is reduced to cuprous hydroxide, which remains dissolved in the ammoniacal liquid and does not undergo any immediate further reduction. A hot 10 p.c. solution of potassium hydroxide is then added until a slight permanent precipitate of cuprous hydroxide is produced, and the clear liquid is then cautiously heated in contact with a perfectly clean glass surface. Metallic copper is deposited on it in the form of a thin reflecting coherent lamina. To obtain a film of sufficient thickness, it is best not to pour off the warm reducing fluid but to allow it to remain in contact with the glass until cold. When the liquid is poured off, the film of copper should be well washed with water and afterwards with alcohol and ether. It should then be protected by one or two coats of quickly drying varnish.

When phenylhydrazine is oxidised with copper sulphate or ferric chloride, the parent hydrocarbon is formed and the whole of the nitrogen is eliminated in the free state (Haller, *Ber.* 1885, 18, 90; Zincke, *ibid.* 786)—

This reaction can be used as a means of estimating phenylhydrazine by measuring the amount of nitrogen evolved (Gallinek and V. v. Richter, *Ber.* 1885, 18, 3177; Strache, *Monatsh.* 1891, 12, 524; Strache and Kitt, *ibid.* 1892, 13

316). (For other methods of estimating hydrazines, *cp.* Denigès, *Ann. Chim.* 1895, [vii.] 6, 381; Causse, *Compt. rend.* 1897, 125, 712, and Forster, *Chem. Soc. Trans.* 1898, 74, 792.)

Phenylhydrazine also reacts with hydrogen peroxide, yielding benzene together with some diazobenzeneimide; it moreover acts as a strong reducing agent towards nitro compounds, reducing them to the corresponding amino derivatives (Barr. *Ber.* 1887, 20, 1498). (For the reduction of nitro compounds, *cp.* also Walter, *J. pr. Chem.* 1896, [ii.] 53, 433. Reduction of 1:5-dinitroanthraquinone, Schmidt and Gattermann, *Ber.* 1896, 29, 2941. Reduction of nitro derivatives of phenanthraquinone, Schmidt and Kampf, *Ber.* 1902, 35, 3124. Reduction of hydroxyazo compounds, Oddo and Puxeddo, *Ber.* 1905, 38, 2752. Reduction of 5-nitrosalicylic acid, Puxeddo, *Gazz. chim. ital.* 1906, 36, ii. 87.) The hydrazines resist the action of reducing agents but pass on protracted treatment with zinc dust and hydrochloric acid into aniline and ammonia (E. Fischer, *Annalen*, 1887, 239, 248)—

Primary hydrazines yield with nascent nitrous acid in ice-cold solution unstable nitroso derivatives which pass into diazo-imides and water, when warmed with alkali—

The diazoimide is formed directly if the above reaction is carried out at a higher temperature (E. Fischer, *Annalen*, 1877, 190, 89, 158, 181). Phenylhydrazine yields isodiazobenzene salts with amyl nitrite in the presence of sodium or potassium ethoxide (Stolle, *Ber.* 1908, 41, 2811). The primary aliphatic hydrazines are hygroscopic liquids readily soluble in water and which possess a smell resembling that of ammonia. The aromatic primary hydrazines are usually solids at the ordinary temperature. They possess a faint aromatic smell and are only sparingly soluble in water.

Phenylhydrazine $\text{C}_6\text{H}_5\cdot\text{NH}\cdot\text{NH}_2$ when freshly distilled is a practically colourless, highly refracting oil which distils under diminished pressure without decomposition, or at $240^\circ\text{--}241^\circ$ (780 mm.) with slight evolution of ammonia. When cooled it sets to a mass of tabular monoclinic crystals which melt at 17.5° . According to E. Fischer (*Ber.* 1908, 41, 73), the melting point of phenylhydrazine is 19.6° , after the substance has been purified first by fractional distillation at $15\text{--}20$ mm., then by solidification and removal of the liquid portion, an operation repeated four times, then by recrystallisation from anhydrous ether, and finally by distillation under a pressure of 0.5 mm. For ordinary purposes it is sufficient to crystallise the base once or twice from its own volume of pure ether and then distil under a pressure of $10\text{--}20$ mm. The base should be coloured pale yellow and should dissolve in 10 times its volume of a mixture of 50 p.c. acetic acid (1 part) and water (9 parts). Phenylhydrazine is rather less volatile with steam than aniline and rapidly becomes brown when exposed to the air. It has a sp. gr. of 1.097 at 23° . The base is sparingly soluble in water but forms a hydrate

of the formula $2(\text{C}_6\text{H}_5\cdot\text{NH}\cdot\text{NH}_2)\cdot\text{H}_2\text{O}$ which melts at 24.1° . It is almost insoluble in concentrated aqueous caustic alkali, but is very readily soluble in certain alkaline salts, such as the alkali salts of the sulphinic and sulphonic acids, soaps, &c. (Otto, *Ber.* 1894, 27, 2131). For some time it has been prepared on the large scale from diazotised aniline by the sulphite method, and is used commercially for the production of antipyrine, &c., and in the form of its sulphonic acid for the production of the so-called tartrazine colouring matters. Phenylhydrazine is a valuable reagent in organic chemistry, owing to the ease with which it forms crystalline compounds with substances containing carbonyl oxygen. These compounds, which belong to the class of the hydrazones and osazones, are dealt with elsewhere (*see* HYDRAZONES).

When taken internally phenylhydrazine acts as a violent poison, and when brought in contact with the skin causes painful inflammation. Chemists who work much with this substance usually suffer from ill health, of which the most prominent feature is a kind of eczema. It seems to form a definite green compound with the blood to which the name *hæmoverdin* has been given (*cp.* Lewin, *Compt. rend.* 1901, 133, 599; *Zeit. Biol.* 1901, 42, 107).

Of the salts of phenylhydrazine, the *hydrochloride* $\text{C}_6\text{H}_5\cdot\text{NH}\cdot\text{NH}_2\cdot\text{HCl}$ is the most important. It crystallises as colourless glistening leaflets which dissolve readily in hot water but separate from the solution on cooling. It can be recrystallised from alcohol and by careful heating can be sublimed unchanged. Other aromatic hydrazines of importance are—

Diphenylhydrazine $(\text{C}_6\text{H}_5)_2\text{N}\cdot\text{NH}_2$. This compound is produced by the reduction of nitrosodiphenylamine $(\text{C}_6\text{H}_5)_2\text{N}\cdot\text{NO}$, which is obtained from diphenylamine $(\text{C}_6\text{H}_5)_2\text{NH}$ by the action of nitrous acid (E. Fischer, *Annalen*, 1877, 190, 174; Stahel, *ibid.* 1890, 258, 242; Overton, *Ber.* 1893, 26, 19). It forms colourless plates which melt at 34.5° , and is partially decomposed on distillation under diminished pressure. The hydrazine yields well-defined crystalline compounds with sugars and can be used for the quantitative estimation of arabinose (Neuberg and Wohlgemuth, *Ber.* 1894, 27, 3106).

Methylphenylhydrazine $\text{C}_6\text{H}_5(\text{CH}_3)\text{N}\cdot\text{NH}_2$ may be prepared either by the reduction of the nitroso compound $\text{C}_6\text{H}_5(\text{CH}_3)\text{N}\cdot\text{NO}$ (E. Fischer, *Annalen*, 1877, 190, 150), or by the alkylation of sodium phenylhydrazine by means of methyl iodide (A. Michaelis, *Ber.* 1886, 19, 2450; Phillips, *ibid.* 1887, 20, 2485). It is a colourless liquid, boiling with slight decomposition and evolution of ammonia at 227° (745 mm.); under a pressure of 75 mm. it boils without decomposition at 131° . Methylphenylhydrazine is a valuable reagent for the isolation of certain ketones (Neuberg, *Ber.* 1902, 35, 959).

Phenylbenzylhydrazine

(Ofner, *Monatsh.* 1904, 25, 593) is prepared by the direct action of benzyl chloride on phenylhydrazine and is a colourless liquid boiling at $216^\circ\text{--}218^\circ$ at 38 mm. It is a useful reagent for the isolation of the sugars, as the hydrazones

formed from it are less soluble and more easily produced than those from simpler hydrazines (*cp.* Ruff and Ollendorf, Ber. 1899, 32, 3255; Lobry de Bruyn, Rec. trav. chim. 15, 97, 227).

***p*-Bromophenylhydrazine** $\text{H}_2\text{N}\cdot\text{NH}\cdot\text{C}_6\text{H}_4\text{Br}$ may be prepared by brominating phenylhydrazine hydrochloride in the presence of a large excess of strong hydrochloric acid (Neufeld, Annalen, 1888, 248, 94; L. Michaelis, Ber. 1893, 26, 2191). It crystallises from hot water as long needles which melt at 107° and is a useful reagent for the characterisation of sugars. It has been used for the preparation of hydrazones from certain naturally occurring ketones, as for example camphor (Tiemann and Kruger, Ber. 1895, 28, 1756; Tiemann, *ibid.* 2191).

Phenylhydrazine-*p*-sulphonic acid

is of historical interest as being the first derivative of hydrazine to be prepared, and was obtained from diazotised *p*-amidobenzenesulphonic acid by reduction with sodium hydrogen sulphite (Strecker and Römer, Ber. 1871, 4, 784; Römer, Zeitsch. Chem. 1871, 482). It may be prepared by the direct sulphonation of phenylhydrazine and when pure crystallises as glistening needles containing $\frac{1}{2}$ a molecule of water of crystallisation. It is prepared on the large scale from *p*-sulphanilic acid by diazotisation and reduction with sodium sulphite, and is used for the production of the tartrazine colouring matters (*q.v.*).

***p*-Nitrophenylhydrazine** $\text{C}_6\text{H}_4(\text{NO}_2)\text{NH}\cdot\text{NH}_2$. This substance is recommended by Bamberger (Ber. 1899, 32, 1806) for the investigation of aldehydes and ketones as being more stable than *p*-bromophenylhydrazine. It is prepared from the sodium salt of *p*-nitrophenylhydrazinesulphonic acid by the action of concentrated hydrochloric acid (Purgotti, Ber. 1892, 25 119; Bamberger and Sternitzki, *ibid.* 26, 1306), and also by boiling the potassium salt of *p*-nitrophenylhydrazinedisulphonic acid with dilute hydrochloric acid (Hantzsch and Borghaus, Ber. 1897, 30, 91). It may also be prepared from *p*-nitraniline by diazotisation and reduction. The base forms orange-red leaflets and needles from hot alcohol, which melt with decomposition at 157° . (For the use of this base in the preparation of hydrazones of the aldehydes and ketones, *cp.* Bamberger, Ber. 1899, 32, 1806; Hyde, *ibid.* 1810.)

The naphthylhydrazines. Both the α - and β -naphthylhydrazines can be used for the preparation of hydrazones from compounds containing carbonyl oxygen, but the β - compound is especially recommended by Hilger and Rothenfusser (Ber. 1902, 35, 2627) for the isolation of numerous sugars. The two bases are prepared in a similar manner from the corresponding diazonaphthalenes on reduction with stannous chloride, or by heating the naphthol with hydrazine hydrate at 160° (Hoffmann, Ber. 1898, 31, 2909). α -Naphthylhydrazine forms leaflets from water which melt at 116° – 117° and boil almost without decomposition at 203° (20 mm.) (Knorr, Ber. 1884, 17, 551). β -Naphthylhydrazine forms glistening leaflets from water which melt at 124° – 125° (*cp.* also Franzen, Ber. 1905, 38, 266).

HYDRAZINE AND SOME OF ITS DERIVATIVES USED AS REAGENTS FOR THE ISOLATION OF ALDEHYDES AND KETONES.

Hydrazine $\text{H}_2\text{N}\cdot\text{NH}_2$. This substance was first prepared by Curtius by the action of hot dilute acids on triazoacetic acid (Ber. 1887, 20, 1632). It has since been obtained by other methods of which the more important are (1) from aminoguanidine $\text{H}_2\text{N}\cdot\text{C}(\text{NH})\text{NH}\cdot\text{NH}_2$ on treatment with caustic alkali (Thiele, Annalen, 270, 1). (2) From sodium hypochlorite and ammonia (Raschig, D. R. P. 192783, 198307; Chem. Zentr. 1908, i. 427, 1957). This process consists in heating the hypochlorite solution with excess of ammonia, when the monochloramine first formed reacts with the ammonia to form hydrazine: on boiling off the excess of ammonia and neutralising with sulphuric acid the sparingly soluble hydrazine sulphate crystallises out.

hydrazine hydrochloride.

By adding cane sugar, dextrin, starch, glycerol, gelatin, albumin, &c., to the solution so as to increase its viscosity reaction (2) is retarded and the yield of the hydrazine salt according to equation (3) is greatly increased (Eng. Pat. 39, 1908). (3) From dichlorocarbamide (Chattaway, Chem. Soc. Trans. 1909, 95, 237). The last-named preparation is carried out in the following way:—

Dichlorocarbamide $\text{NHCl}\cdot\text{CO}\cdot\text{NHCl}$ (Chattaway, Chem. Soc. Trans. 1909, 95, 465). Six grams of carbamide are dissolved in 50 c.c. of distilled water and 10 grams of finely divided zinc oxide are added. The mixture is cooled to about -5° in a freezing mixture and a rapid stream of chlorine passed through the liquid. If the operation is carried out in a small flask, and this is well shaken in the freezing mixture during the passage of the gas, the temperature does not rise above zero. The zinc oxide quickly dissolves and a clear liquid results, from which in a short time crystals of dichlorocarbamide begin to separate. When the liquid has become a thick pulp from the separated solid and crystals no longer appear to separate, the dichlorocarbamide is rapidly collected at the pump, washed twice with 5 c.c. of ice-cold distilled water and then several times with chloroform. The yield is 77.5 p.c. of the theory.

***p*-Urazine.** This substance is formed by the elimination of hydrogen chloride from two molecules of monochlorocarbamide, which may be regarded as the initial product formed by the action of ammonia on dichlorocarbamide—

the condensation is therefore effected by the action of ammonia (Chattaway, Chem. Soc. Trans. 1909, 95, 237). Crude dichlorocarbamide free from all adhering mother-liquor is dissolved in from 10 to 20 times its weight of water and rapidly added to excess of strong ammonia, the mixture being thoroughly stirred. A vigorous evolution of nitrogen takes place and a white

crystalline powder separates; a little more crystallises out on keeping, and a still further small quantity on evaporating the mother-liquor after neutralising with hydrochloric acid.

Hydrazine sulphate. When *p*-urazine is mixed with about 5 times its weight of concentrated sulphuric acid and warmed to about 80°, it dissolves apparently without change; on heating the solution to about 95°–100°, hydrolysis slowly takes place with evolution of carbon dioxide. On raising the temperature still higher, the rate of evolution of carbon dioxide increases, until, at about 120°–130°, it is very rapidly liberated; at this temperature, hydrolysis is soon complete and a clear colourless liquid is obtained which deposits crystals of hydrazine sulphate on cooling. It is best, however, to add to the cooled liquor its own bulk of water, when pure hydrazine sulphate at once separates as a white crystalline powder.

Free hydrazine has been prepared by Lobry de Bruyn (Ber. 1895, 27, 3085) by the action of sodium methoxide in methyl alcohol on hydrazine hydrochloride, and also by heating the hydrate $N_2H_4 \cdot H_2O$ with barium oxide at 100°. It is a very stable liquid which boils without decomposition at 113.5° (761 mm.), and at 56° (71 mm.). It solidifies when cooled below 0°, and then melts at 1.4°. It has a sp.gr. of 1.003 at 23° (*cp.* Raschig, Ber. 1910, 43, 1927).

Hydrazine hydrate $N_2H_4 \cdot H_2O$ is the form in which hydrazine is liberated from its salts by the action of aqueous alkalis. It is a strongly refracting, almost odourless liquid, which boils without decomposition at 118.5° (739.5 mm.) and solidifies when placed in a mixture of solid carbon dioxide and ether, but melts again below –40°. It is advisable when preparing this substance to employ a silver retort and to avoid the use of rubber connections, as the hydrate, when hot, attacks glass strongly and quickly destroys cork and rubber.

Semicarbazide $H_2N \cdot CO \cdot NH \cdot NH_2$. This substance was first used for the preparation of derivatives of ketones by Baeyer acting on the suggestion of Thiele (Ber. 1894, 27, 1918), the compound having been prepared earlier in the year by Thiele and Stange (Ber. 1894, 27, 31; Annalen, 1894, 283, 19), who obtained it by the action of potassium cyanate on hydrazine sulphate, and by Curtius and Heidenreich (Ber. 1894, 27, 56), who prepared it by the interaction of hydrazine hydrate and urea. Semicarbazide may be conveniently prepared in the following way: 225 grams of nitrourea in 1700 c.c. of concentrated hydrochloric acid are mixed at 0° with excess of zinc dust and are then left for a short time after all action has subsided. The filtered solution, after being saturated with sodium chloride, is treated with 200 grams of sodium acetate and 100 grams of acetone. The acetonesemicarbazone zinc chloride, which separates after some time, is washed with salt solution and decomposed by strong ammonia (350 c.c. to 200 grams of the compound) (Thiele and Heuser, Annalen, 1895, 288, 312).

Semicarbazide crystallises from absolute alcohol as prisms which melt at 96°. It readily reacts with substances containing carbonyl oxygen, in accordance with the scheme

forming semicarbazones which possesses the advantage of being readily decomposed into their components on treatment with dilute acids. The method recommended by Baeyer (Ber. 1894, 27, 1918) for the preparation of a semicarbazide is as follows:

Semicarbazide hydrochloride is dissolved in a little water and the requisite amount of alcoholic potassium acetate together with the ketone are added, as well as sufficient alcohol and water to effect complete solution. The length of time required for the reaction depends on the nature of the ketone and varies from a few minutes to 4–5 days; it is finished when the addition of water precipitates a crystalline solid. Semicarbazide is usually met with in the form of its hydrochloride. The free base slowly alters on keeping.

Thiosemicarbazide $NH_2 \cdot CS \cdot NH \cdot NH_2$. This substance, like semicarbazide, reacts with compounds containing carbonyl oxygen in accordance with the equation—

forming thiosemicarbazones, which possess the property of forming insoluble salts with the heavy metals from which the ketone or aldehyde can be readily regenerated (Neuberg and Neimann, Ber. 1902, 2049).

The base can be prepared from hydrazine sulphate in the following manner (Freund and Schander, Ber. 1896, 29, 2501; Freund and Ingart, *ibid.* 1895, 28, 948): 50 grams of hydrazine sulphate and 27 grams of anhydrous potassium carbonate are dissolved in 200 c.c. of water and mixed with 40 grams potassium thiocyanate. The mixture is boiled for some minutes and is then treated with 200–300 c.c. of hot alcohol and filtered. The filtrate is freed from alcohol by vigorously boiling and, when cooled, deposits long needles of the base which melt at 181°.

Semioxamazide $H_2N \cdot CO \cdot CO \cdot NH \cdot NH_2$ (Kerp and Unger, Ber. 1897, 30, 586). This substance may be prepared by gently heating oxamethane with an alcoholic solution of hydrazine for a short time on the water bath. It crystallises in slender lustrous leaflets which melt and decompose at 220°–221°. Semioxamazones are produced in quantitative yield from aldehydes, but the ketones react in a less general manner and seem to require special conditions for their formation.

Aminoguanidine $H_2N \cdot C(NH) \cdot NH \cdot NH_2$ is prepared from nitroguanidine on reduction (Thiele, Annalen, 270, 23; D. R. P. 59241; *Frdl.* iii. 16), and from cyanamide, hydrazine hydrochloride and alcohol (Pellizari and Cuneo, Gazz. chim. ital. 1894, 24, 453). The hydrochloride forms long prisms from dilute alcohol which melt at 163°.

The base is recommended by Baeyer (Ber. 1894, 27, 1919) for the preparation of derivatives of ketones, the following method being used.

Aminoguanidine hydrochloride is dissolved in a little water containing a trace of hydrochloric acid and is then mixed with the ketone together with sufficient alcohol to effect solution. The reaction is finished after warming for a short time on the water bath, when water and caustic potash solution are added and the base is

extracted by ether. The oil which remains after evaporating the ether is suspended in hot water and heated with an aqueous solution of picric acid. The picrate separates as a crystalline precipitate which is recrystallised either from dilute or absolute alcohol, according to its solubility.

J. F. T.

HYDRAZOBENZENE. Prepared by reducing nitrobenzene in hot alkaline solution with zinc dust or iron in presence of alcohol or solvent naphtha. May also be obtained by electrolysis; m.p. 127° (Darmstädter, D. R. P. 181116, 189312).

HYDRAZONES. Substances containing the complex $>N\cdot NH_2$ react with those compounds which have in their molecule an oxygen atom doubly bound to carbon, forming condensation products in accordance with the general equation

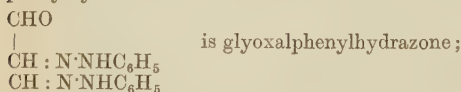

Such condensation products are termed hydrazones. Only the carbonyl compounds which belong to the groups of the aldehydes and ketones react in this manner; the carboxylic acids containing the group $COOH$ do not react as if they contained carbonyl oxygen, but give hydrazides in accordance with the scheme.

One or more carbonyl-groups present in the compound may enter into combination with the hydrazine residue, forming—for example, in the case of the dicarbonyl derivatives—dihydrazones, thus

Those dihydrazones, which are derived from dicarbonyl compounds having the two carbonyl-groups on contiguous carbon atoms, are termed osazones. Thus in the case of the two compounds formed from glyoxal $CHO\cdot CHO$ and phenylhydrazine

(Fischer, Ber. 1888, 21, 985).

Phenylhydrazine $C_6H_5\cdot NH\cdot NH_2$ was the first member of the class of the hydrazines to be applied to the characterisation and isolation of the carbonyl compounds (comp. E. Fischer, Ber. 1884, 17, 572), but since that time the reaction has been shown to be a general one for all derivatives of hydrazine having a primary amino group intact.

Hydrazine $H_2N\cdot NH_2$ itself reacts with aldehydes and ketones, as Curtius has shown, forming either hydrazones of the type

(or $RRC:N\cdot NH_2$), in which one molecule of the carbonyl compound reacts, or azines of the formula $R\cdot CH:N\cdot N:CHR$ (or $RRC:N\cdot N\cdot CRR$), in which two molecules of the carbonyl derivative take part. The azines from the aldehydes are known as aldazines, those from the ketones as ketazines. In the aliphatic series, the alde-

hydes pass directly into the aldazines when treated with hydrazine, whilst the hydrazones, $RRC:N\cdot NH_2$, which can be isolated from the product of the interaction of ketones and hydrazine, readily pass into the ketazine and hydrazine in accordance with the equation

It is apparent that azine formation in the manner described above cannot occur with the substituted derivatives of hydrazine of the general formulæ $RNH\cdot NH_2$ and $R_2N\cdot NH_2$, and it is therefore compounds of this type which are of such great importance as reagents for the preparation of the hydrazones, osazones, and semicarbazones

Constitution of the hydrazones. The constitution of the hydrazones formed from carbonyl compounds by the action of secondary asymmetric hydrazines $R_2N\cdot NH_2$, admits of only one formula, namely, $R_2N\cdot N:CR_2$; but the hydrazones formed from the primary hydrazines may conceivably be constituted in accordance with one or other of the three forms

Of these, formula (2) may be discarded, because the same compound is formed by the interaction of benzaldehyde and phenylethylhydrazine

as by the ethylation, by means of sodium ethoxide and ethyl iodide, of the hydrazone formed by the condensation of benzaldehyde and phenylhydrazine

The azo formula (3) would appear, at first sight, to be untenable, because the hydrazone prepared from phenylhydrazine and acetaldehyde is different from ethaneazobenzene

which is prepared by the oxidation of ethanehydrazobenzene. It has been shown, however, that there is an intimate connection between these two substances, and that the change

is readily effected by mineral acids (Fischer, Annalen, 1879, 199, 328; Ber. 1896, 29, 703), or by sodium ethoxide (Bamberger, Ber. 1903, 36, 56); whereas the reverse change

is effected by the action of light (Chattaway, Chem. Soc. Trans. 1906, 89, 462). The question as to the azo or hydrazone structure of these compounds has given rise to a great deal of controversy, and is even at the present time not definitely settled. The discussion may be said to have arisen owing to the discovery made by Japp and Klingemann (Ber. 1887, 20, 3284, 3398), that the hydrazone of pyruvic acid

was identical with benzene- α -azopropionic acid $C_6H_5N:N'CH(CH_3)CO_2H$. R. Meyer (Ber. 1888, 21, 118) also showed that the dicarboxylic acid obtained by the hydrolysis of the ethyl salt which is formed by the interaction of benzene-diazonium chloride and ethyl malonate, thus :

was identical with the compound prepared by the condensation of mesoxalic acid and phenylhydrazine, thus :

That is to say, the question arose as to whether these compounds were true hydrazones having the structure $R \cdot NH:N : C <$ or whether they were azo compounds having the structure $R \cdot N:N'CH <$.

Since that time many other instances of the same kind as that recorded by these chemists have been investigated, and repeated attempts have been made to establish either one or other of these constitutional formulæ for the hydrazones (R. Meyer, Ber. 1891, 24, 1241; Japp and Klingemann, Annalen, 1888, 247, 190; V. Meyer, Ber. 1888, 21, 11; Haller, Compt. rend. 1888, 106, 1173; Beyer and Claisen, Ber. 1892, 25, 746; v. Pechmann, Ber. 1892, 25, 3190; Bamberger and Wheelwright, *ibid.* 1892, 25, 3201; Bamberger, *ibid.* 1894, 27, 2591).

Much of the evidence falls under the head of the constitution of the azo compounds, and the article under this heading should be consulted for further information; but it is evident that much still remains to be learnt regarding the conditions controlling the tendency of a hydrogen atom attached to the terminal atom of any system such as

to pass to the other terminal atom with a consequent shifting of the double bond, thus :

The evidence at present available seems to show that the hydrogen atom in compounds of this type may assume either one or other of these positions, in which case definite compounds are formed, having, as in the case under discussion, either the azo or hydrazone form : on the other hand, there may be tautomerism between the two forms, in which case the hydrogen atom acts as if it vibrated between the two terminal atoms of the system (*cf.* Bülow and Hopfner, Ber. 1901, 34, 71; Bülow and Hailer, *ibid.* 1902, 35, 915). There is, however, little doubt that in the majority of cases the compounds formed from benzenediazonium chloride and substances of the type of ethyl malonate as well as those produced by the action of phenyl-

hydrazine on carbonyl compounds have the hydrazone structure.

The formation of phenylhydrazones. As a rule, phenylhydrazine readily reacts with ketones and aldehydes, yielding phenylhydrazones, which are crystalline and of definite melting-point. The following method generally gives the phenylhydrazone in a pure condition. Phenylhydrazine is dissolved in 50 p.c. aqueous acetic acid and diluted with three times its volume of water. The carbonyl compound diluted when necessary by a suitable solvent is then added and the whole is warmed. The phenylhydrazone then separates either in the crystalline condition or as an oil which usually crystallises when scratched with a glass rod.

Derivatives of phenylhydrazine, such as phenylhydrazone-*p*-sulphonic acid

p-nitrophenylhydrazine $C_6H_4(NO_2)NH \cdot NH_2$ or *p*-bromophenylhydrazine

may be used for the production of hydrazones; moreover other hydrazines, such as β -naphthylhydrazine $C_{10}H_7 \cdot NH \cdot NH_2$, methylphenylhydrazine $C_6H_5(CH_3)N \cdot NH_2$, *asym*-diphenylhydrazine $(C_6H_5)_2N \cdot NH_2$, and benzylphenylhydrazine $C_6H_5 \cdot CH_2(C_6H_5)N \cdot NH_2$ are often used for this purpose (*cp.* HYDRAZINES).

Reaction of the hydrazones. When warmed with mineral acids, the hydrazones are more or less readily hydrolysed into the carbonyl compound and the hydrazine. This reaction proceeds, however, much more readily when the hydrazone is warmed with an aqueous solution of pyruvic acid, when the following reaction often occurs (Fischer and Ach, Annalen, 1889, 253, 57) :—

The hydrazones of the aliphatic aldehydes and ketones form addition products with hydrocyanic acid, yielding nitriles in accordance with the equation

(*cp.* V. Miller and Plöchl, Ber. 1892, 25, 2023).

Hydrazones when reduced break at the point of union of the two nitrogen atoms and pass into amines. This method has been made use of by Tafel (Ber. 1886, 19, 1924; 1889, 22, 1854) for the formation of primary amines from aldehydes and ketones. Thus the hydrazone of acetaldehyde yields in this manner a mixture of aniline and ethylamine

When oxidised by amyl nitrite, hydrazones are converted into hydrotetrazines (V. Pechmann, Ber. 1893, 26, 1045).

These compounds dissolve in concentrated sulphuric acid, forming intensely coloured solutions. It is probable that Bülow's reaction for hydrazides and hydrazones, which depends on the formation of a coloured solution, when

identified. Concentrated sulphuric acid dissolves the various osazones, giving characteristic colorations, and the solution generally exhibits some particular colour-change on standing (Japp and Klingemann, Ber. 1888, 21, 549). Fuming hydrochloric acid hydrolyses the osazones in the cold into phenylhydrazine and the α -dicarbonyl compound from which they are derived (E. Fischer, *ibid.* 1888, 21, 2631).

HYDROGEN. At.wt. 1·0077. Symbol H. The existence of this gas was recognised in the 16th century; its combustible property was discovered in the following century by Turquet de Mayerne, and in 1700 Lemery observed the detonating property of a mixture of air and hydrogen.

Cavendish, in 1766, showed that when the gas was produced from dilute acid and one of the metals, iron, zinc, or tin, it was obtained in amount varying with the metal used.

Hydrogen was for a time confounded with other combustible gases, such as marsh-gas, carbon monoxide, and vapour of ether; all were supposed to contain the same inflammable principle, *phlogiston*, modified by variable amounts of other substances.

Macquer and De la Metherie first observed, in 1766, that water was produced by burning hydrogen, but it was then thought that other products than water were produced at the same time, and Lavoisier made many experiments with the object of detecting the presence of an acid which he imagined should be among the products of combustion, as was the case in the combustion of such bodies as sulphur, carbon, phosphorus, &c. Cavendish, however, in 1781, proved conclusively that water was the only product of combustion when hydrogen burns in air or oxygen, and that if a mixture of hydrogen and oxygen in the proportion of two volumes of the former to one of the latter were burnt, the whole of the gases were converted into water.

Sources. Hydrogen occurs free in nature in the gaseous mixtures evolved from certain volcanos (Bunsen, Ann. Chim. Phys. 1853, [iii.] 38, 215; Deville, Compt. rend. 1862, 55, 75). The gases evolved from Mte. Pelée in Martinique during the eruptions of 1902 contained 22·3 p.c. of hydrogen by volume (Moissan, Compt. rend. 1902, 135, 1085). It also occurs in the jets of steam, known as *fumaroles*, which

occur in Tuscany and other places. The gases issuing from the salt beds of Stassfurt (Reichardt, Arch. Pharm. 1860, [ii.] 103, 347; Precht, Ber. 1880, 13, 2326), and Wieliczka (Rose, Pogg. Ann. 48, 353) contain hydrogen, and it also occurs in the gases given off by the oil-wells of Pennsylvania, West Virginia, Ohio, and Indiana (Engler, Ber. 1888, 21, 1816; U.S.A. Geol. Sur. 1909, 2, 297). Hydrogen has been found occluded in certain meteorites (Graham, Proc. Roy. Soc. 1867, 15, 502; Mallet, *ibid.* 1872, 20, 365), and in a large number of minerals (Ramsay and Travers, Proc. Roy. Soc. 1897, 60, 442; Tilden, *ibid.* 1897, 60, 453), and in clays. To a very slight extent, hydrogen occurs free in the atmosphere (Gautier, Ann. Chim. Phys. 1901, [vii.] 22, 5; Liveing and Dewar, *ibid.* 1901, 22, 482; Rayleigh, Phil. Mag. 1902, [vi.] 3, 416; Leduc, Compt. rend. 1902, 135, 860, 1332). According to Claude (Compt. rend. 1909, 148, 1454), there is less than 1 part of hydrogen in one million parts of air. Its presence in the air is probably due to the decomposition of cellulose under the influence of anaerobic micro-organisms. Hydrogen is also produced in the decay of various organic bodies, being found in the intestinal gases of many animals (Tappeiner, Ber. 1881, 14, 2375).

Spectroscopic observations have shown that hydrogen completely surrounds the sun, forming an envelope which has received the name of the *chromosphere*. Hydrogen also occurs in certain stars and nebulae.

In a state of combination, hydrogen forms one-ninth the weight of water and one-fourth the weight of marsh-gas. It also occurs in smaller quantities in combination with phosphorus, sulphur, iodine, bromine, carbon, and nitrogen. It is an essential constituent of all acids; most animal and vegetable substances contain it, and it is a constituent of many minerals. It exists in the air in small quantities in combination with nitrogen as ammonia; and in certain mineral and volcanic springs it is found in combination with sulphur and chlorine as hydrogen sulphide and hydrochloric acid respectively.

Preparation. (1) *Electrolysis of certain aqueous solutions.*—Pure hydrogen is readily prepared by the electrolysis of a mixture of 1 part of sulphuric acid and 10 parts of water between platinum electrodes. The potential difference between the terminals must exceed 1·7 volts. The hydrogen is evolved at the cathode, and suitable provision must be made to prevent oxygen from the anode diffusing into the hydrogen. A convenient method consists in immersing the anode in a mass of liquid zinc-amalgam, which absorbs the oxygen completely, forming zinc oxide and eventually zinc sulphate. The current from three or four Bunsen elements is sufficient to work such an electrolytic cell for laboratory use. A suitable piece of apparatus is described in Amer. Chem. J. 1897, 19, 810. A 30 p.c. solution of sodium hydroxide may also be employed; plate nickel electrodes are most convenient, and a useful piece of apparatus for this purpose is described by Vèzes and Labatut (Zeitsch. anorg. Chem. 1902, 32, 464). Hydrogen prepared from sodium hydroxide solution always contains a little organic matter, owing to the presence of

carbonate in solution (Morley); it can be obtained quite pure by electrolysing a solution of pure recrystallised baryta (Baker, Chem. Soc. Trans. 1902, 81, 400).

These electrolytic methods are employed on a commercial scale, dilute sulphuric acid being electrolysed between lead electrodes, or sodium or potassium hydroxide between iron electrodes. The chief difficulty encountered is that a mixture of oxygen and hydrogen is given off at both electrodes. The hydrogen contains about 1 p.c. of oxygen, and the oxygen about 2 p.c. of hydrogen. Under certain circumstances this admixture of oxygen may prove dangerous. The introduction of diaphragms increases the resistance of the cell, and is therefore to be avoided if possible. Various patterns of cell have been devised, and are described in J. Soc. Chem. Ind. 1900, 19, 1120; 1901, 20, 258; 1902, 778; 1905, 94; 1905, 1240; 1908, 946; 1909, 799; Eng. Pats. 2820, 1902, and 27249, 1903; Fr. Pats. 355652, 1905, and 397319, 1908; D. R. P. 198626, 1906. The Elektron works at Griesheim use as electrolyte potassium chloride, thereby obtaining potassium hydroxide and chlorine in addition to the hydrogen. The Oerlikon Maschinenfabrik employ the Schmidt process, using potassium carbonate solution, and the Heraeus Company at Hanau a 20 p.c. solution of caustic soda at about 60° (Schuckert process). Large quantities of hydrogen are also made by the Castner-Kellner Company by the electrolysis of common salt solutions. They supply the gas in a compressed state. Other electrolytic processes which have proved commercially successful are those of Garuti Schoop, the International Oxygen Co. of Newark, N.J., Schriver, Churchill, and Burdett. For descriptions of the various cells employed, nature of electrodes, diaphragms, &c., yields, and energy expenditure, see Greenwood's Industrial Gases, 1920; C. F. Hale, J. Soc. Chem. Ind. 1921, 40, 122 B.

(2) *Chemical decomposition of water.*—Hydrogen may be prepared by decomposing water; a large number of readily oxidisable substances can be employed for this purpose.

The alkali metals and the metals of the alkaline earths decompose water at ordinary temperatures, liberating hydrogen and producing the corresponding metallic hydroxide. The action is very violent, particularly with potassium, rubidium, and caesium. The reactions can be readily controlled, however, by employing the amalgams of these metals. The action of steam on pure sodium has been used for the preparation of pure hydrogen (Scott, Phil. Trans. 1893, 184, 548; Mellor and Russell, Chem. Soc. Trans. 1902, 81, 1279), and the use of sodium, mixed with oil, aluminium, and infusorial earth, for the preparation of hydrogen on a commercial scale has been patented (U.S. Pats. 883531, 1908; 909536, 1909).

Magnesium decomposes water at temperatures above 70° (Ditte, Compt. rend. 1871, 73, 108), and burns vigorously when heated in steam. Magnesium amalgam decomposes cold water (Fleck and Basset, J. Amer. Chem. Soc. 1895, 17, 789).

Aluminium does not decompose water unless some means is afforded of removing the oxide from the surface of the metal. This is easily

effected by amalgamating it with $\frac{1}{15}$ its weight of mercury, when the amalgam produced readily decomposes water and can be employed as a source of pure hydrogen (Baille and Féry, Ann. Chim. Phys. 1889, [vi.] 17, 246; Wislicenus and Kauffmann, Ber. 1895, 28, 1323). Hydrogen is readily obtained pure by slowly adding water to a mixture of fine aluminium filings containing 1 to 2 p.c. of mercuric chloride and 0.5 p.c. of potassium cyanide, keeping the temperature at 70° (Mauricheau-Beaupré, Compt. rend. 1908, 147, 310; Fr. Pat. 392725, 1908). One kilo. of this mixture yields 1300 litres of hydrogen.

At a red heat, water vapour is easily decomposed by iron, hydrogen and tri ferric tetroxide being produced (Lavoisier, Œuvres, 2, 360). This method is employed on a large scale and has been the subject of numerous patents (Eng. Pats. 7518, 1887; 20752, 1890; 4134, 1891; 28721, 1896; 10356, 1903; 21479, 1908; 17591, 1909; 12117, 1912; Fr. Pats. 373271, 1907; 386991, 1908; 395132, 1908; 444105, 1912; 461480, 461623, 461624, 1913; U.S. Pat. 971206, 1908; D. R. PP. 226453, 1909; 254222, 263390, 263391, 268062, 268339, 1912; cf. Bergius, J. Soc. Chem. Ind. 1913, 32, 462. The oxide produced is reduced to metal by heating with coal or by treatment with water gas as in the Messerschmidt process, or by either carbon or carbon monoxide as in the Bergius process, and used again.

Steam is readily decomposed by passing it over red-hot coke, when a mixture consisting essentially of carbon monoxide and hydrogen in approximately equal volumes, is produced, known as *water-gas* (v. GAS, WATER). Numerous methods have been proposed for the purpose of preparing hydrogen commercially from this mixture. In one process (Frank, Fr. Pat. 371814, 1906), the dried mixture is passed over calcium carbide at a temperature above 300°, when carbon monoxide and dioxide react with the carbide, forming calcium oxide, carbonate and carbon, while the nitrogen present is converted into calcium cyanamide. The oxides of carbon may be partially removed by a preliminary cooling process, whereby the monoxide is liquefied and the dioxide solidified. Jouve and Gautier (Fr. Pat. 372045, 1906) propose to pass the gas through a porous partition in order to separate the hydrogen by reason of its rapid power of diffusion. It is said that by one such operation the percentage of carbon monoxide may be reduced from 45 to 8 p.c. In other processes, the carbon monoxide is removed by chemical means; for this purpose it is passed over a catalyser, e.g. ferric oxide, heated to 400°–500° with excess of steam, when the monoxide is replaced by an equal volume of hydrogen, carbon dioxide being produced, which may be removed by solution in water or by absorbing it in milk of lime (Henry and Hembert, Compt. rend. 1885, 101, 797; D. R. P. 224862, 1907; Claude, *idem*. 1921, 173, 653).

The oxidation of carbon monoxide by steam with the liberation of hydrogen can be effected at 400°–500° in the presence of reduced iron or nickel (Fr. Pats. 355324, 1905; 375164, 1906; cf. Mond and Langer, Eng. Pat. 12608, 1888, and Fr. Pat. 361429, 1905).

The Griesheim Elektron Company (Eng. Pat. 13049, 1912, J. Soc. Chem. Ind. 1913, 278)

pass water-gas mixed with steam, into a heated retort containing lime, when the oxides of carbon are removed as calcium carbonate. In the Linde-Frank-Caro process water-gas is first treated with lime or a solution of caustic soda to remove carbon dioxide, and is then subjected to pressure and cooled with liquid air whereby carbon monoxide, nitrogen, and other impurities are liquefied whilst the hydrogen still remains gaseous. The liquid carbon monoxide can be burnt in a gas engine and so serve to drive the plant. By further treatment hydrogen of 99.2-99.4 p.c. purity is obtained which may be employed for filling balloons or for catalytic reactions. (For a method of determining small quantities of carbon monoxide in hydrogen, see S. K. Rideal and Taylor, *Analyst*, 1919, 89.)

Hydrogen free from compounds of carbon and oxygen, can be prepared by heating coke, impregnated with 10 p.c. potassium carbonate and mixed with five times its weight of burnt lime, in a current of steam at 550°-750° (Eng. Pat. 8734, 1910).

The decomposition of steam may also be effected by passing it over red-hot barium sulphide, which becomes oxidised to sulphate, with the simultaneous formation of hydrogen (Fr. Pat. 361866, 1905). The sulphate is reduced with coal or producer gas to sulphide, and used again.

(3) *Action of metals on acids.*—The commonest method of preparing hydrogen for laboratory purposes consists in acting upon granulated zinc with either dilute hydrochloric acid (1 of acid to 2 of water), or sulphuric acid (1 of acid to 8 of water), when hydrogen is evolved and zinc chloride or sulphate is left in solution. Very pure hydrogen is obtained from pure zinc and pure diluted acid, but the action is extremely slow. A regular stream of the gas may be obtained, however, by adding a little platinic chloride solution. Platinum is deposited over the surface of the zinc, and the liberated hydrogen escapes freely from the surface of the platinum, leaving the zinc surface free from bubbles of gas (Gourdon, *Compt. rend.* 1873, 76, 1250). A similar effect is produced by adding a small quantity of a salt of copper, silver, gold, tin, antimony, bismuth, nickel, or cobalt.

The apparatus shown in the annexed figure may be used for obtaining pure hydrogen for

FIG. 1.

laboratory purposes (Edwards, *J. Ind. Eng. Chem.* 1919, 11, 961). The apparatus is exhausted through *a*, whilst the tube *d*, which dips into mercury, serves as an indicator of the

residual pressure and as a safety valve. The acid flask, *f*, is nearly filled with dilute sulphuric acid (1:8) and contains a few fragments of zinc, so that the hydrogen evolved will sweep out all air. The vent *e* is then closed until the pressure of the gas is sufficient to force the acid into the tube, to free the connections from air. The tube beyond the tap, *b*, enters the generator through a rubber stopper, which is always under liquid. The rate of generation of the gas is controlled by the tap *c* (*J. Soc. Chem. Ind.* 1920, 20 A).

Other metals, *e.g.* aluminium, magnesium, and iron, may be used instead of zinc for generating hydrogen from acids. Pure hydrogen is readily prepared by acting upon aluminium with mercuric chloride solution slightly acidified with hydrochloric acid (Bodenstein, *Zeitsch. physikal. Chem.* 1897, 22, 3). The use of zinc, and more particularly of iron and sulphuric acid upon a commercial scale, is very common (*v. Eng. Pats.* 15509, 1897; 16277, 1896; 17515, 1898; 25084, 1897).

(4) *Action of metals and non-metals on alkalis.*—The metals zinc, aluminium, and tin readily dissolve in warm concentrated alkali hydroxide solutions, liberating hydrogen and forming alkali zincate, aluminate, and stannate respectively. Very pure hydrogen is thus produced from aluminium free from carbon. The non-metallic element, silicon, similarly dissolves, and considerable quantities of hydrogen may be prepared by heating powdered silicon or ferro-silicon with sodium hydroxide solution and milk of lime (D. R. P. 216768, 1908; Eng. Pat. 21032, 1909) (*v. infra*, *Hydrogen for Balloons*).

Hydrogen may be prepared by heating slaked lime with either zinc dust (Schwarz, *Ber.* 1886, 19, 1141) or coal. The resulting calcium carbonate in the latter process may be reconverted into slaked lime by heating in steam (Bloxham).

(5) *Decomposition of metallic hydrides.*—The hydrides of the alkali metals and those of the alkaline earths readily decompose water at ordinary temperatures, liberating hydrogen and forming the corresponding metallic hydroxide. The use of calcium hydride for preparing hydrogen is very convenient, since the hydride is readily portable, and each gram of the substance yields more than 1 litre of hydrogen when decomposed by water. The hydrogen liberated is twice that which is absorbed by the metallic calcium in the preparation of the hydride (Fr. Pat. 327878, 1902); (*v. infra*, *Hydrogen for Balloons*).

Palladium, especially when amorphous, capable of adsorbing large quantities of hydrogen; from the substance thus produced, pure hydrogen is readily obtained by heating it under reduced pressure (*v. infra*).

Purification.—The electrolysis of either dilute sulphuric acid or a solution of pure baryta, yields practically pure hydrogen, as also does the action of steam on pure sodium. Most methods of preparation, however, yield hydrogen containing more or less of a number of impurities, nearly all of which may be removed by treating the gas with reagents capable of absorbing them. The precise nature of most of the impurities depends upon the method of preparation employed, but one in particular,

viz. atmospheric air, is common to nearly all methods. Its presence in the gas is due partly to its presence in the liquids employed in the preparation of the gas, a source of error which may be diminished by previously boiling the solution, partly to the difficulty of completely expelling air from the apparatus, and partly owing to leakage into the apparatus through cork or rubber joints, which should therefore be as few as possible. The oxygen thus introduced may be removed by passing the gas over red-hot copper or spongy platinum or through chromous chloride solution, but the nitrogen cannot be similarly removed.

A convenient but expensive method of obtaining pure hydrogen consists in passing the dried, approximately pure gas over palladium, the metal having been previously strongly heated, introduced into a tube fitted with a stopcock and the tube evacuated. The metal is allowed to cool during the absorption of the gas. The gas left in the apparatus is finally pumped out. From the palladium-hydrogen, pure hydrogen is readily obtained by attaching the palladium tube to the apparatus into which the gas is to be introduced, and gently warming the metal.

Hydrogen prepared from acid and ordinary iron, which contains a certain amount of carbide, invariably contains gaseous hydrocarbons which give the gas an unpleasant odour, and this method of preparation is never used for laboratory purposes. The hydrocarbons may be removed by passing the gas through alcohol, or a tube filled with pieces of wood-charcoal or paraffin (Stenhouse, *Annalen*, 1858, 106, 125; Varenne and Hèbré, *Bull. Soc. chim.* 1877, [ii.] 28, 523).

According to Morley, the purest redistilled zinc always contains a little occluded oxides of carbon, which find their way into hydrogen prepared from the metal and acid. The commercial metal may also contain, besides a little lead, traces of sulphur, arsenic, antimony, carbon, silicon, and even phosphorus, which cause the hydrogen generated from the metal by means of acid to contain the corresponding gaseous hydrides. Sulphuric acid may contain sulphur dioxide, which will be partly evolved with the hydrogen and partly reduced to hydrogen sulphide (Kolbe, *Annalen*, 1861, 119, 174), and also nitrogen compounds, which lead to the formation of nitrogen and nitrous oxide in the hydrogen. Frequently sulphuric acid contains arsenic and selenium, which leads to the formation of the corresponding hydrides. Hydrochloric acid prepared from sulphuric acid may contain the same impurities.

Sulphur dioxide, the hydrides of sulphur, selenium, silicon, and hydrogen chloride carried over by the hydrogen may be absorbed in a solution of potassium hydroxide. The hydrides of phosphorus, arsenic, and antimony may be absorbed by solutions of various metallic salts, e.g. mercuric chloride, lead nitrate, or silver sulphate (Dumas, *Ann. Chim. Phys.* 1843, [iii.] 8, 189).

All the above impurities are decomposed when the hydrogen is passed over red-hot copper turnings. The small quantity of nitrogen that may be introduced by the decomposition of oxides of nitrogen is usually not inconvenient.

For laboratory purposes, hydrogen is best purified from phosphine, arsine, and stibine, by passing it through saturated permanganate solution and then through 5-10 p.c. silver nitrate. After washing hydrogen with concentrated permanganate solution, however, the gas contains traces of oxygen. For removing traces of arsine from large quantities of hydrogen, bromine is the best absorbent; on a technical scale potassium hypochlorite or bleaching powder may be substituted (Reckleben and Lockemann, *Zeitsch. angew. Chem.* 1908, 21, 433).

Arsine is said to be completely removed from hydrogen by bubbling the gas through petroleum spirit cooled by liquid air to -110° , and the process has been recommended for technical use (*Compt. rend.* 1903, 136, 1317).

An elaborate method for purifying hydrogen by freezing out the impurities is described by Kamerlingh Onnes (*Proc. K. Akad. Wetensch. Amsterdam*, 1909, 11, 883); using 25 litres of liquid air, 10,000 litres of hydrogen can be purified in 8 hours.

Hydrogen may be dried for ordinary purposes by passing it over anhydrous calcium chloride or through concentrated sulphuric acid. The latter process, however, slightly contaminates the gas with sulphur dioxide (Dittmar and Henderson, *Proc. Roy. Soc. Glasgow*, 1891, 22, 33; Berthelot, *Compt. rend.* 1897, 125, 743; Milbauer, *Zeitsch. physikal. Chem.* 1907, 57, 649). The use of phosphoric anhydride, free from lower oxides, is to be preferred.

Properties.—Hydrogen is a colourless, odourless, tasteless gas. It is the lightest gas known, 1 litre of hydrogen at N.T.P. and at sea-level in lat. 45° , weighs 0.089873 ± 0.0000027 gram (Morley, *Zeitsch. physikal. Chem.* 1896, 20, 242; cf. Regnault, *Relation des Expér.* 2, 121; Leduc, *Compt. rend.* 1891, 113, 186; Thomsen, *Zeitsch. anorg. Chem.* 1896, 12, 1). The density of hydrogen compared with air is therefore 0.0694. The product pv , instead of being constant as Boyle's law demands, continually increases as the pressure is increased. At 200 atmos. (absolute) it is 1.134 (Amagat, *Ann. de chim. et de Phys.* [6] 29, 1883, 68). The coefficient of thermal expansion at constant pressure is 0.003661 (Regnault), and at constant volume the coefficient is 0.0036624 (Chappuis). The thermal conductivity of hydrogen is seven times that of air (Stefan). Between 0° and 200° the molecular specific heat at constant pressure is 6.81 and at constant volume is 4.81 calories. The specific heat increases with rise of temperature. According to Mallard and Le Chatelier (*Compt. rend.* 1887, 104, 1780), the mean molecular specific heat of hydrogen at constant pressure between 0° and t° is $6.5 + 0.0006(t + 273)$; the value at constant volume is $4.700 + 0.00045t$ (Pier, *Zeitsch. Elektrochem.* 1909, 15, 536). According to Crofts, $C_p = 4.86 + 0.00064t$, where C is the mean specific heat between t and 15° (*Chem. Soc. Trans.* 1915, 290). The ratio of the specific heats is 1.405 (Röntgen). Hydrogen is diamagnetic.

Hydrogen is very slightly soluble in water, its absorption-coefficient between 0° and 25° being given by the formula

$$0.021528 - 0.00019216t + 0.000001728t^2$$

(Timofejeff, *Zeitsch. physikal. Chem.* 1890, 6, 141; *cf.* Winkler, *Ber.* 1891, 24, 89; Bohr and Bock, *Wied. Ann.* 1891, 44, 316; Geffken, *Zeitsch. physikal. Chem.* 1904, 49, 257). For its solubility in alcohol, *v.* Timofejeff, *l.c.*, and in various aqueous salt solutions, *v.* Geffken, *l.c.*

The liquefaction of hydrogen for many years presented the most difficult problem to experimenters on the liquefaction of gases. In 1877, Cailletet submitted hydrogen to the same process as he had successfully used in the liquefaction of oxygen and nitrogen, and observed the formation of a fine mist when hydrogen was subjected to a pressure of 280 atmos. and then suddenly released. In 1884 Wroblewski (*Compt. rend.* 1884, 100, 979) liquefied hydrogen by cooling the gas, under a pressure of 190 atmos., by means of boiling nitrogen, and then quickly releasing the pressure. By a similar method, Olszewski (*Compt. rend.* 1884, 99, 133; 1885, 101, 238) succeeded in obtaining colourless drops of liquid hydrogen. Dewar (*Chem. Soc. Proc.* 1895, 229; *Chem. Soc. Trans.* 1898, 528; *Proc. Roy. Soc.* 1901, 68, 260) was the first to succeed in preparing liquid hydrogen in sufficient quantity to show a definite meniscus by applying the regenerative process to the compressed gas after first cooling it to -205° . Travers (*Phil. Mag.* 1901, [vi.] 1, 411), Olszewski (*Ann. Chim. Phys.* 1903, [vii.] 29, 289), and Nernst and Pollitzer (*Zeitsch. Elektrochem.* 1911, 17, 735) have described processes whereby liquid hydrogen may be prepared in quantity.

Liquid hydrogen forms a clear, colourless liquid, boiling at -252.5° (Dewar, *Proc. Roy. Soc.* 1898, 63, 256; Travers, *Phil. Mag.* 1902, [vi.] 3, 535). The vapour pressures of the liquid at various temperatures between 24.59° and 32.93° (abs.) have been measured by Cath and Kamerlingh Onnes, and may be represented by the formula $T \log p = -56.605 + 3.8015T - 0.10458T^2 + 0.003321T^3 - 0.00005102T^4$, in which p = pressure in international atmospheres. Liquid hydrogen has the greatest specific heat of any liquid, namely 6.4 (Dewar) (*cf.* Keesom and Onnes *K. akad. Amsterdam Proc.* 20, 1000, 1918). When cooled by rapid evaporation under diminished pressure, the liquid solidifies to a transparent solid, melting at -257° (Dewar) or -258.9° (Travers, *Proc. Roy. Soc.* 1902, 70, 484), and having a sp.gr. at -259.9° of 0.0763 (*ibid.* 1904, 73, 251). According to Kamerlingh Onnes and Crommelin the density of liquid hydrogen increases from 0.07086 at the boiling-point (-252.77°) to 0.07631 at -258.27° . Contraction occurs on freezing, and at -262.0° the density of solid hydrogen is 0.08077. The density of liquid hydrogen at the triple point (-159.2°) is 0.07709, and on the assumption that the density of solid hydrogen at this temperature does not differ appreciably from that at -162° , the contraction on freezing is about 4.8 p.c. of the liquid volume. Augustin (*Ann. Physik.* 1915, [iv.] 46, 419) found the density of liquid hydrogen 0.07105 at -252.83° and 745.42 mm. The refractive indices obtained by the method of total reflexion were at this temperature and pressure $\lambda 656.3$, 1.10924; $\lambda 579.0$, 1.10974; $\lambda 546.1$, 1.11003; $\lambda 435.9$, 1.11179; $\lambda 404.7$, 1.11262 (Augustin, *l.c.*). According to Verschaellert the viscosity of liquid hydrogen at 20.43° (abs.) is 0.00013. For the

vapour of hydrogen it is 0.000010. The critical pressure of hydrogen is 15 atmos. and its critical temperature is -243° to -241° (Dewar) (33.18° (abs.) and 12.8° atmos. (Onnes, Crommelin, and Cath).

Apparatus for liquefying hydrogen. The apparatus works on Linde's principle, with preliminary cooling by means of liquid air. It is so arranged that many experiments can be carried out in the apparatus itself, without

FIG. 2.

transferring the liquefied hydrogen; to this end the liquefying chamber is closed air-tight, and a special small vacuum vessel provided for the collection of the liquid. The compressed hydrogen enters by the middle tube, shown thickened in the sections of the spirals, then enters the bath of liquid air, through which it passes in a great number of windings (*b*) of very fine spiral copper tube, thence into the sheet brass vessel (*c*) in 26 windings, where it expands, cools, and liquefies. After passing at *V* a valve (not shown in the figure) and expanding nearly to atmospheric pressure, it leaves, through a similar number of windings, to utilise its low temperature as far as possible, by the tube shown. The evaporated air also leaves by a third spiral tube (*d*), to utilise its cold. The axial tube with cross pieces (one to a manometer, the other fitted with a cork which will yield in case of rise of pressure through any stoppages) is of German silver, and is $2\frac{1}{2}$ cm. wide. It permits of the entry of, for example, the little apparatus shown, for specific heat determinations. The brass vessel can be separated into two halves, to allow the little vacuum vessel shown to be placed in position. With a passage of 2–3 cb. m. of hydrogen gas per hour the hourly yield of liquid is 300–400 c.c., or about 10 p.c., and the consumption of liquid air about 0.3 litre. The apparatus, when used, is first warmed, and the hydrogen from a compressor or cylinder passed through till all is quite dry. Then liquid air is passed in from the vacuum vessel on the left till the brass vessel is covered, and the apparatus left to itself till the whole has reached the temperature of liquid air. Hydrogen at 150 atmospheres is now passed in, and after about ten minutes liquefaction begins. If needed,

the hydrogen can be transferred by a siphon vacuum-tube with a gauze filter on the end to stop any accidental frozen air. Very pure hydrogen must be used; with a cylinder it is possible to work till the pressure is reduced from 150 to 70 atmospheres—with a compressor, practically all the hydrogen can of course be utilised, whilst with a cylinder nine-tenths of it is lost (Nernst, *Zeitsch. Elektrochem.* 1911, 17, 735; *J. Soc. Chem. Ind.* 1911, 30, 1159).

The spectrum of hydrogen consists essentially of four bright lines—one in the red, corresponding with Fraunhofer's dark line C, and one in the greenish-blue, coincident with the dark line F. Their wave-lengths are (Ångström) C=6562, F=4861, blue=4340, indigo=4101 in ten-millionths of a millimetre.

Hydrogen is an inflammable gas, burning in air or oxygen with an extremely hot, almost colourless flame, and producing water. Even with pure hydrogen, however, the centre of the flame is coloured green, while the external portions are of a violet-blue colour. On reducing the pressure, the blue colour is transformed to green, and from that successively to yellow, orange, and red. Under increased pressure, hydrogen burns with a luminous flame.

The combination of hydrogen and oxygen proceeds slowly at ordinary temperatures in the presence of sunlight (Baker, *Chem. Soc. Trans.* 1902, 81, 400). The rate of combination is slow at 180° (Gautier and Hélier, *Bull. Soc. chim.* 1896, [iii.] 15, 468), but with rise of temperature it becomes quicker and quicker, and explosion occurs at about 550° (Gautier and Hélier, *l.c.*; Berthelot, *Compt. rend.* 1897, 125, 271; *Ann. Chim. Phys.* 1898, [vii.] 13, 30; Meyer and Raum, *Ber.* 1895, 28, 204; Bone and Wheeler, *Phil. Trans.* 1906, A, 206, 1; Rowe, *Zeitsch. physikal. Chem.* 1907, 59, 41). Mixtures of the two gases, if perfectly pure and dry, may be heated to the melting-point of silver without combination occurring (Baker, *l.c.*). The ignition-points of various mixtures of oxygen and hydrogen, from $3\text{H}_2 + \text{O}_2$ to $\text{H}_2 + 4\text{O}_2$, vary between 557° and 507° when fired by adiabatic compression, electrolytic gas having an ignition-point of 536° (Dixon, *Chem. Soc. Trans.* 1910, 97, 661; *cf.* Falk, *J. Amer. Chem. Soc.* 1906, 28, 1517; 1907, 29, 1536). The union of hydrogen and oxygen proceeds quickly at ordinary temperatures in the presence of finely divided palladium, platinum, iridium, osmium, or gold.

Mixtures of air and hydrogen are explosive within the limits 74.2-4.1 p.c. of hydrogen (Coward, *Chem. Soc. Trans.* 1914, 1859; Coward, Carpenter, and Payman, *idem.* 1919, 27).

Hydrogen unites at 250° with sulphur and selenium, and at 400° with tellurium. It can be made to unite directly with nitrogen under the influence of the silent discharge (Chabrier, *Compt. rend.* 1872, 75, 489; Donkin, *Proc. Roy. Soc.* 1881, 31, 281) or of electric sparks (Berthelot, *Ann. Chim. Phys.* 1880, [v.] 21, 285); for its combination with nitrogen under the influence of high pressure, temperature, and catalysts, *see* AMMONIA, SYNTHESIS OF. Compounds of hydrogen with arsenic, phosphorus, antimony, boron, and silicon, can be prepared indirectly.

Hydrogen unites with pure carbon directly when heated to 1150°, methane being produced

(Bone and Jerdan, *Chem. Soc. Trans.* 3897, 71, 41; Bone and Coward, 1908, 93, 1975; 1910, 97, 1219). By passing an electric arc between carbon poles in an atmosphere of hydrogen, acetylene is produced, accompanied by a little methane and ethane (Berthelot, *Compt. rend.* 1862, 54, 640; Bone and Jerdan, *Chem. Soc. Trans.* 1901, 79, 1062).

Gaseous hydrogen combines with fluorine even in the dark and at ordinary temperatures, with explosive violence, hydrogen fluoride being produced (Moissan, *Ann. Chim. Phys.* 1891, [vi.] 24, 224). With liquid fluorine at -210°, explosion also occurs, and a similar result follows on mixing solid fluorine and liquid hydrogen (Moissan and Dewar, *Bull. Soc. chim.* 1897, [iii.] 17, 932; *Compt. rend.* 1903, 136, 641).

Chlorine does not combine appreciably with hydrogen at ordinary temperatures in the dark, but only when heated above 400° or exposed to light. In diffused light, combination occurs slowly, and there is usually an initial *period of induction* (Bunsen and Roscoe, *Phil. Trans.* 1857, ii. 378) during which the rate of combination slowly increases to its maximum value and afterwards remains constant. This period of induction is due to the presence of traces of volatile impurities (Burgess and Chapman, *Chem. Soc. Trans.* 1906, 89, 1399). Under the direct action of actinic rays, mixtures of hydrogen and chlorine explode.

Hydrogen combines directly with bromine above 400°, and slowly even at 100° in the presence of light (Kastle and Beatty, *Amer. Chem. J.* 1898, 20, 159). With iodine, the rate of combination becomes measurable above 200°.

The alkali metals, when heated to 360° in hydrogen, directly absorb the gas, forming white solid hydrides of the type MH (Guntz, *Compt. rend.* 1896, 122, 244; Moissan, *Bull. Soc. chim.* 1902, 27, 1141; *Ann. Chim. Phys.* 1905, [viii.] 6, 289, 323; Holt, *Chem. Soc. Abstr.* 1909, ii. 807). The alkaline-earth metals similarly combine with hydrogen, yielding solid hydrides of the type RH_2 (Moissan, *Bull. Soc. chim.* 1899, [iii.] 21, 876; Guntz, *Compt. rend.* 1901, 133, 1209). According to Winkler (*Ber.* 1891, 24, 884), hydrogen combines directly with various finely divided metals, *e.g.* cerium, yttrium, lanthanum, obtained by reducing their oxides with magnesium powder.

Hydrogen is a reducing agent, and readily displaces a large number of metals from their compounds with oxygen, sulphur, chlorine, &c. Thus the oxides of copper, lead, iron, antimony, &c., are easily reduced to the metallic state, with the formation of water, when heated in a current of hydrogen to a more or less elevated temperature. Silver oxide is slowly reduced at ordinary temperatures, and rapidly and completely at 100° (Colson, *Compt. rend.* 1900, 130, 330), a reaction which may be used to determine hydrogen in gaseous mixtures. Palladium oxide is reduced in the cold by hydrogen (Wöhler, *Annalen*, 1874, 174, 60), as also is the corresponding chloride, either in the anhydrous state or in solution (Phillips, *Amer. Chem. J.* 1894, 16, 255; Campbell and Hart, *ibid.* 1896, 18, 294).

When hydrogen is passed through a solution of silver nitrate, sulphate, or acetate, metallic silver is precipitated; the amount of metal thus separated is small compared with that left

in solution. The reaction is carried further by raising the temperature, and the precipitated metal is very pure. Palladium, platinum, and gold are similarly precipitated. Under great pressures, such reductions are much more complete. Thus silver and mercury are quantitatively precipitated from solutions of their salts at ordinary temperatures under 200 atmos. pressure. At higher temperatures, nickel, cobalt, lead, and bismuth are similarly precipitated, the deposition of nickel being complete at 200° and 180 atmos. (Ipatieff and Werschowsky, Ber. 1909, 42, 2078).

Occluded hydrogen (*v. infra*) is capable of bringing about a great number of chemical changes that the free gas is unable to effect. Thus hydrogen occluded in palladium will unite with chlorine, iodine, and oxygen, even in the dark, at ordinary temperatures (Böttger, Ber. 1873, 6, 1396). It also reduces chlorates to chlorides; nitrates to nitrites and even to ammonia; mercuric chloride to mercurous chloride; ferric salts to ferrous salts; ferriyanides to ferrocyanides; and indigo-blue to indigo-white (Gladstone and Tribe, Chem. News, 1878, 37, 68). A number of these reactions can be utilised in quantitative analysis (Chapman, Analyst, 1904, 29, 346). Hydrogen occluded in platinum or copper produces similar changes.

Hydrogen also becomes much more chemically active in contact with various finely divided metals, such as platinum black and nickel, cobalt, iron and copper reduced from their oxides. Thus, hydrogen and oxygen combine rapidly, at ordinary temperatures, in the presence of platinum black. The union of the gases is started by the heat evolved as they are occluded, and, once started, combination proceeds quickly, the metal being heated so much that it becomes incandescent. Similarly, at 400° hydrogen and iodine vapour rapidly unite in the presence of platinum black.

A very general method of reduction and hydrogenation has been based upon the fact that hydrogen becomes chemically active in the presence of finely divided nickel that has been just previously reduced from its oxide. The best product is formed by calcining nickel nitrate at a low red heat and reducing the oxide at about 300°. The temperature of reduction greatly affects the activity of the nickel. It is further affected by the presence of certain substances, like sulphur, phosphorus, and arsenic, which inhibit the catalytic action of the metal. By passing the vapours of a large number of substances, mixed with hydrogen, over reduced nickel at quite moderate temperatures, reductions are easily effected; thus nitrous oxide produces nitrogen and water, nitric oxide and nitrogen peroxide are reduced to ammonia, and the oxides of carbon are converted into methane. Many substances in the state of liquids may be hydrogenated or reduced under particular pressures and temperatures, and the course of the reaction is occasionally modified by the material of the vessel in which it is effected. Organic nitro compounds, fatty or aromatic, are reduced to amines. Unsaturated fatty hydrocarbons are transformed into paraffins, while benzene and numerous derivatives are easily converted into hexahydrobenzene and its substitution-products. Aldehydes and ketones are

reduced to alcohols with remarkable ease. Indigo blue is reduced to indigo white, and leuco derivatives of other vat dyes may be similarly obtained. The nickel is not altered, and permits of hydrogenation being carried on indefinitely. In certain cases other metals, *e.g.* cobalt, iron, copper, platinum may be used, but nickel is found to be the most generally applicable. The hydrogen must be carefully freed from impurities which under its action and the catalyst after a time loses its activity, which, however, can be renewed by appropriate treatment. (Sabatier and Senderens, Compt. rend. 1897, 124, 1358; 1899, 128, 1173; 1900, 130, 1559, 1628, 1761; 131, 140; 1901, 132, 210, 566, 1254; 133, 321; 1902, 134, 514, 689, 1127; 135, 87, 225; 1903, 136, 738, 921, 983; 137, 301, 1025; 1904, 138, 457, 1257; 1905, 140, 482; Bull. Soc. chim. 1905, [iii.] 33, 263; Ann. Chim. Phys. 1905, [viii.] 4, 319, 433; Sabatier and Mailhe, Compt. rend. 1903, 137, 240; 1904, 138, 407, 245; 1905, 140, 350; 1906, 142, 553; 1907, 144, 824, 955, 784, 1086; 145, 18, 1126; 1908, 146, 457, 1193; Ann. Chim. Phys. 1909, [viii.] 16, 70); Ipatiev and others, various papers in J. Russ. Phys. Chem. Soc. 1906 *et seq.* Cf. Sabatier, La Catalyse en Chimie Organique; *see* art. Catalysis; also Henderon's Catalysis in Industrial Chemistry, Longman's Series of Monographs on Industrial Chemistry.) Many processes of hydrogenation under the influence of catalysts are reversible; by modifying the conditions, particularly of temperature, dehydrogenation may take place; thus, cyclic compounds may be regenerated from their hydrogenated derivatives, hydrocarbons may be degraded, and aldehydes and ketones may be formed from their respective primary and secondary alcohols.

Certain chemical systems which lead to the liberation of hydrogen are capable of acting as reducing agents when another substance is added to them that is capable of being reduced. Thus a solution of potassium chlorate remains unaffected when hydrogen is passed through it, but reduction to chloride readily occurs if zinc and sulphuric acid are added to the solution. Other systems are furnished by the alkali metals or their amalgams in contact with water, which are capable, among other things, of reducing aldehydes and ketones to alcohols; and zinc, iron, or tin, with either hydrochloric, sulphuric, or acetic acid, systems which are capable of reducing nitro compounds to amines, &c. Hydrogen evolved from such systems therefore appears to possess an activity superior to that of the ordinary gas; it is termed *nascent* hydrogen.

The superior activity possessed by hydrogen at the moment of its liberation is supposed by some chemists to be due to the fact that the gas is liberated in the atomic state, and is therefore more capable of entering into chemical reactions than after it has assumed the molecular state, since the combination of atoms to form molecules is accompanied by the degrading of a certain amount of energy. That this cannot be a full explanation is seen, however, by the fact that a reduction effected by one system evolving nascent hydrogen is not necessarily effected by another system, *e.g.* the system zinc and dilute sulphuric acid will reduce chlorates to chlorides,

but the system sodium-amalgam and water will not. For evidence for the dissociation of hydrogen into atoms at high temperatures, see Langmuir and Mackay (J. Amer. Chem. Soc. 1914, 36, 1708; Langmuir, *ibid.* 1912, 34, 1310; Freeman, *ibid.* 1913, 35, 927).

Adsorption of hydrogen by metals. In 1863, Deville and Troost (Compt. rend. 1863, 57, 894) observed that red-hot platinum and iron were permeable to hydrogen. Upon further investigating this subject, Graham (Proc. Roy. Soc. 1867, 15, 223; 1868, 16, 422; 1869, 17, 212, 500) found that palladium possessed this property in a much higher degree, and, further, he showed that there was no need to assume a porosity in the structure of these metals to account for this phenomenon, but that it was due to the fact that such metals absorb hydrogen, yielding substances which still retain metallic lustre and characteristic metallic properties, but which readily evolve the absorbed gas under altered conditions. To this property, Graham gave the name *occlusion*. It may be studied by placing the metal within a porcelain tube, glazed inside and out, evacuating it by means of a mercury pump and heating to redness. Hydrogen is then admitted and allowed to flow over the metal while it cools. The tube is then evacuated again and the contents heated to redness once more, by which means the occluded hydrogen is expelled from the metal, and may be pumped off and measured.

The amount of hydrogen adsorbed depends to some extent on the physical condition of the metal. In one experiment, a palladium wire was found by Graham to absorb 935 times its own volume of hydrogen. Mond, Ramsay, and Shields (Phil. Trans. 1895, A, 186, 657; 1897, A, 190, 129; 1898, A, 191, 105) have shown that palladium black adsorbs at the ordinary temperature 873 to 889 volumes of hydrogen, and that palladium wire and sponge adsorb a similar amount. Amorphous palladium is more active than the crystalline variety, especially at low temperatures (*cf.* Holt, Edgar, and Firth, Zeitsch. physikal. Chem. 1913, 82, 513; Andrew and Holt, Proc. Roy. Soc. 1913, [A] 89, 170; Holt, *idem*, 1914, [A] 90, 226; Firth, Chem. Soc. Trans. 1920, 171). Palladium-hydrogen readily evolves hydrogen in a vacuum, that prepared from the 'black' at the ordinary temperature, while the substance obtained from the foil requires warming to 100°. In all cases, however, a red heat is required to drive off the last traces of gas. Even at a red heat, however, palladium still adsorbs large quantities of hydrogen if the pressure is sufficiently increased (Dewar, Chem. Soc. Proc. 1897, 192; Berry, Chem. Soc. Trans. 1911, 99, 463; Sieverts, Zeitsch. physikal. Chem. 1914, 88, 103, 451). Hydrogen which has been ionised by the action of Röntgen rays or by β and γ rays from radium will not diffuse through a palladium plate at the ordinary temperature (Sieverts). According to Sieverts, Jurisch, and Metz (Zeitsch. anorg. Chem. 1915, 92, 329) the solubility is proportional to the square root of the pressure and diminishes with increasing temperature. Although hydrogen is insoluble in pure silver, the addition of silver to palladium greatly increases the solubility, until a maximum is reached at all tem-

peratures at 40 p.c. Ag, beyond which it again falls rapidly. At 138° an alloy containing 40 p.c. Ag dissolves more than four times as much hydrogen as pure palladium, the solubility becoming *nil* at 70 p.c. Ag. Platinum added to palladium diminishes the solubility. Small quantities of hydrogen sulphide adsorbed by palladium entirely prevent the occlusion of hydrogen by that metal. (*cf.* Maxted, Chem. Trans. 1919, 115, 1050).

Palladium readily adsorbs 935 vols. of hydrogen if it is employed as negative electrode in a water voltameter. Should the electrolysis be continued beyond this point, the metal becomes supersaturated with gas; the excess is, however, evolved as soon as the current ceases (Thoma, Zeitsch. physikal. Chem. 1889, 3, 69).

Colloidal palladium and platinum solutions adsorb hydrogen very readily and in large amounts (Kernot and Niguesa, Rend. accad. Sci. Fis. Mat. Napoli, 1909, [iii.] 15, 168). Various other metals, *e.g.* iron, nickel, cobalt, gold, iridium, and copper, also adsorb small quantities of hydrogen.

The process of occlusion is accompanied by an evolution of heat, 4370 calories being evolved per gram of hydrogen occluded; the thermal effect is the same for each successive fraction of gas adsorbed (Favre, Compt. rend. 1869, 68, 1306; Mond, Ramsay, and Shields, *l.c.*).

The nature of the substances formed when hydrogen is occluded by metals has not yet been determined with certainty. The metals are unaltered in appearance, and such physical properties as thermal and electrical conductivity, sp.gr., and tenacity are only slightly diminished. Graham was of opinion that no chemical union occurs, but that the hydrogen assumes the solid form and acts as a quasi-metal. This adsorbed form of hydrogen he proposed to call *hydrogenium*.

From the expansion of alloys of palladium with platinum, gold, and silver, when charged with hydrogen, Graham calculated the sp.gr. of hydrogen to be 0.733; subsequent determinations by Dewar gave the figure 0.620, a figure which does not compare at all with the actual sp.gr. of solid hydrogen.

Troost and Hautefeuille (Compt. rend. 1874, 78, 686) believed that their experiments indicated the existence of a definite compound, Pd_2H , whilst Dewar (Chem. News, 1897, 76, 274) suggested the existence of Pd_3H_2 . The fact that when fully charged with hydrogen, the composition of palladium-hydrogen approximates closely to this latter formula is, however, almost the only evidence that can be adduced in support of the existence of this compound (Mond, Ramsay, and Shields, *l.c.*). The experiments of Hoitsema (Zeitsch. physikal. Chem. 1895, 17, 1) have shown that between 20° and 200° no definite compounds of palladium and hydrogen exist; at constant temperature the relationship between the vapour tension of the system palladium-hydrogen and the percentage of hydrogen in the solid phase is such, however, as would be expected if two partially-miscible solid solutions of hydrogen in the metal are formed, the miscibility of which increases with rise of temperature.

According to Holt, Edgar, and Firth, the

action of the palladium depends on its treatment. They conclude that the hydrogen exists partly as an adsorbed layer of high pressure removable by evacuation, and partly absorbed and distributed irregularly in the mass of the metal. In the sorption 4370 cal. per gram hydrogen are evolved and the palladium increases about 10 p.c. in volume. About 92-98 p.c. of the hydrogen is evolved at ordinary temperatures *in vacuo*, and the expulsion is complete at 440°. Under high pressure the hydrogen is retained to the extent of 300 vols. at 500°.

The specific electrical conductivity and density of palladium hydrogen alloys have been measured by Wolf (Zeitsch. physikal. Chem. 1914, 87, 575). The diffusion of hydrogen through a palladium septum at temperatures ranging from 70° to 300° and at pressures between 700 and 100 mm. has been measured by Holt (Proc. Roy. Soc. 1915, [A] 91, 148). At these pressures the rate of diffusion is proportional to the pressure of the gas. At pressures below 100 mm. the diffusion is much slower, and no simple relation to the pressure can be traced. As regards platinum, platinum black, made by mixing boiling solutions of sodium chloroplatinate with sodium formate, is much more active towards hydrogen than spongy platinum, absorbing 160 vols. as against 1 vol. at 0°.

The meteoric iron of Lenarto, containing 91 p.c. of iron, yields 2·85 times its volume of occluded gas, mainly hydrogen (Graham, Proc. Roy. Soc. 1867, 15, 502). Since under ordinary pressure iron absorbs only half its volume of hydrogen, this would seem to show that the meteorite has come from an atmosphere containing hydrogen under a pressure much greater than that of our own atmosphere, thus affording a confirmation of the conclusions drawn from spectroscopic observations regarding the existence of dense and heated hydrogen atmospheres in the sun and fixed stars.

Atomic weight of hydrogen. This has been determined by measuring the ratio of the combining weights of oxygen and hydrogen. Since this ratio is of fundamental importance, a very considerable amount of attention has been directed towards its accurate measurement. The methods used may be grouped under two headings: (a) synthesis of water; and (b) determinations of the relative densities of hydrogen and oxygen.

(a) The classical method, first employed by Dulong and Berzelius (1820), and used later by Dumas (Ann. Chim. Phys. 1843, [iii.] 8, 189) in his elaborate series of determinations, consists in reducing heated cupric oxide in a stream of pure, dry hydrogen, and estimating the water produced and the loss in weight experienced by the cupric oxide. The result obtained by Dumas, viz. H : O :: 1 : 15·9607, corroborated as it was by the experiments of Erdmann and Marchand (J. pr. Chem. 1842, 26, 461) was for many years accepted as the true value; but subsequent work has shown that this result deviates considerably from the truth, and has disclosed numerous sources of error in the older determinations. The method of Dumas, with various modifications, has been used by Cooke and Richards (Amer. Chem. J. 1888, 10, 81, 191); Keiser (*ibid.* 1888, 10,

249); Noyes (*ibid.* 1889, 11, 155; 1890, 12, 441); Dittmar and Henderson (Proc. Roy. Soc. Glasgow, 1891, 22, 33), and Leduc (Compt. rend. 1892, 115, 41); their results are given in the table below.

The synthesis of water has been effected by other methods than the above. In 1889, Rayleigh (Proc. Roy. Soc. 45, 425) weighed pure hydrogen and oxygen in glass globes, mixed them and then gradually exploded the mixture in a eudiometer. The residual gas was then analysed, and hence the ratio of hydrogen to oxygen determined. The first complete quantitative synthesis of water in which both gases were weighed separately, and afterwards in combination, is due to Morley (Smithsonian Contributions to Knowledge, 1895, 29). The hydrogen was weighed in palladium (a method due to Keiser) and the oxygen in compensated globes, after the manner of Regnault. After weighing, the gases were burned by means of electric sparks in a suitable apparatus, from which the unburned residue could be withdrawn for examination. Finally, the apparatus containing the water produced was closed by fusion and weighed.

The syntheses of water by Keiser (Amer. Chem. J. 1898, 20, 733) were effected by the direct oxidation of hydrogen occluded in palladium; the hydrogen, oxygen, and water were all determined. The experiments recorded in the elaborate investigation by Noyes (J. Amer. Chem. Soc. 1907, 29, 1718) were performed partly by this method and partly by the method employed in his earlier work (*v. supra*). A novel, but indirect method for measuring the ratio of oxygen to hydrogen has been employed by Thomsen (Zeitsch. anorg. Chem. 1895, 11, 14).

The results of these experiments are collected in the following table:—

Experimenter	Date	Ratio O/H	At. wt. of Hyd. (O = 16)
Dumas	1842	15·9607	1·00246
Erdmann & Marchand	1842	15·9750	1·00156
Cooke & Richards	1887	15·8690	1·00825
Keiser	1888	15·9514	1·00305
Noyes	1889	15·8966	1·00650
Dittmar & Henderson	1891	15·8677	1·00834
Leduc	1892	15·8810	1·00750
Rayleigh	1889	15·8900	1·00692
Morley	1895	15·8790	1·00762
Keiser	1898	15·8799	1·00756
Noyes	1907	15·8745	1·00783
Thomsen	1895	15·8690	1·00825

The weighted mean of these results is H = 1·00769 according to Clarke (A Recalculation of the Atomic Weights, 3rd edit. 1910, 29, 4th edit. 1920).

(b) The ratio of the densities of oxygen and hydrogen is, subject to a correction to be mentioned later, equal to the ratio of their atomic weights. The first accurate measurements of these densities were made by Dumas and Boussingault in 1841 (Compt. rend. 12, 1005); the results obtained four years later by Regnault (*ibid.* 20, 975) were adopted as standard values for many years, and gave for the ratio a value

of 15·9611. The remarkable agreement of this figure with that deduced from Dumas' synthesis of water is only, however, accidental, for in 1885, Agamennone, and independently, Rayleigh in 1888 (Proc. Roy. Soc. 43, 356) pointed out a serious error in all previous determinations of gaseous densities, owing to the fact that the glass globes in which the gases are weighed are elastic, and shrink to a measurable extent when evacuated. The effect of neglecting to correct for this shrinkage is that the apparent weight of gas is slightly lower than its true value. The corrected value for the density ratio from Regnault's experiments is 15·9105 (Crafts, Compt. rend, 1888, 106, 1662).

The densities of hydrogen and oxygen have been frequently determined with the utmost care; *v.* Rayleigh (Proc. Roy. Soc. 1892, 50, 448); Cooke (Amer. Chem. J. 1889, 11, 509); Leduc (Compt. rend. 1891, 113, 186); Thomsen (Zeitsch. anorg. Chem. 1896, 12, 4) and especially Morley (Smithsonian Contributions, 1895). The table below summarises the results obtained:—

Experimenter	Date	Density ratio O/H
Dumas & Boussingault .	1841	15·9015
Regnault	1845	15·9105
Rayleigh	1888	15·8840
Rayleigh	1892	15·8820
Cooke	1889	15·8900
Leduc	1891	15·9060
Morley	1895	15·8955
Thomsen	1896	15·8878

The weighted mean is 15·8948 (Clarke, *l.c.*).

This result is subject to a slight correction for the fact that hydrogen and oxygen do not combine together by volume exactly in the ratio of two to one; according to Morley (*l.c.*), the exact ratio is 2·00274 (*cf.* Scott, Phil. Trans. 1893, 184, 543; Leduc, Compt. rend. 1892, 175, 311; Rayleigh, Proc. Roy. Soc. 1904, 73, 153). Correcting the above mean value for the density ratio in accordance with this result, the figure 15·8726 is obtained, which leads to the value 1·00803 for the atomic weight of hydrogen on the oxygen scale.

Determinations of the volumetric composition of water by Burt and Edgar (Phil. Trans. 1916, [A] 216, 393) gave the volume ratios of H to O as 2·00288 : 1. From this value, taking the normal litre weights of oxygen and hydrogen as 1·42900 and 0·089873 gram respectively the atomic weight of hydrogen becomes 1·00772.

According to Clarke (*l.c.*), the probable mean derived from the results of methods (a) and (b) combined, is $H=1·00772$. A review of the most trustworthy results of the various determinations which have been made since the time of Berzelius leads Hinrichs (Rev. gen. Chim. pure Appl. 1910, 13, 351) to consider 1·0078 as the most probable value. The value at present adopted is $H=1·0077$.

Applications of hydrogen. Hydrogen is used in conjunction with oxygen for the production of the Drummond or oxy-hydrogen lime light. For this purpose, the gases are compressed in iron bottles furnished with taps and jets, so that they can be allowed to escape, and burned as

required. They are allowed to impinge on a cylinder of lime which is thereby heated to whiteness, and gives a light almost equal to the electric arc.

For the autogenous welding of metals, the working of platinum, and the manufacture of laboratory utensils and mercury vapour lamps from fused quartz, hydrogen in the form of the oxyhydrogen blowpipe flame is used in large quantities, although it has here to meet the competition of acetylene, which is cheaper and readily obtainable as required from calcium carbide, requires less gas, and yields a higher temperature.

Autogenous soldering.—This process is much used for uniting the edges of the sheets of lead which are employed in making vessels for the purpose of holding acids. Joints made in this way are much more durable than those made with solder. The apparatus for this purpose is made so that hydrogen can be generated at pleasure, and when not in use the pressure of gas inside the apparatus lifts the acid out of contact with the zinc. The hydrogen generator consists of a cylindrical copper vessel lined with lead; there is an upper and lower chamber connected by a pipe, and they are fitted with arrangements which admit of easy renewal of acid or zinc and the removal of the zinc sulphate formed. The apparatus gives a very constant flame, which may be used with advantage in soldering lead in the way which is practised in the construction of sulphuric acid chambers. The hydrogen is delivered from a platinum-tipped nozzle through which a jet of air also issues from a foot bellows; this is effected by attaching the nozzle by means of india-rubber tubing to a tube which branches out V-shaped into two limbs each provided with a stopcock; each of these limbs is provided with an india-rubber tube, one of which is attached to the bellows and the other to the delivery tube of the hydrogen generator. The operator can, therefore, carry the nozzle in his hand and direct the flame where he pleases, and by means of the stopcock he can readily regulate the supply of air or hydrogen.

The best proportion in which to use the gases for welding is one part of oxygen and four parts of hydrogen; if the amount of oxygen is increased the flame may oxidise the metal.

Tungsten lamps.—The manufacture of tungsten filament lamps requires a regular supply of hydrogen to prepare the inert atmosphere in which the filaments are heated to a high temperature during the final treatment. It is almost the universal custom to employ a mixture of equal volumes of hydrogen and nitrogen when the filaments are electrically heated to whiteness. Since incandescent tungsten filaments are very sensitive to oxidation, it is of great importance that the hydrogen employed should be of a high degree of purity. The process devised by Lane (*v. infra*) is frequently adopted for obtaining the gas, since besides preparing hydrogen, it also admits of nitrogen being collected.

Hydrogen for balloons.—After the publication by Cavendish of his researches on 'inflammable air,' Charles, in 1783, suggested the use of hydrogen for the inflation of balloons. Montgolfier had, during the same year, invented the balloon which he inflated with rarefied air.

In hydrogen, however, Charles recognised a much more suitable means of inflation, although the cost was very considerable, 500 lbs. of sulphuric acid and twice that amount of iron being consumed in the inflation of a balloon about 13 feet in diameter. A military airship of 250,000 cubic feet capacity would require about 18 tons of iron and 31 tons of sulphuric acid.

The first balloon sent up from English soil, on Nov. 25, 1793, was inflated with hydrogen. In the following year, the French Government instituted a series of experiments at Meudon under Guyton de Morveau, Contelle, and Comté, with the view of perfecting the balloon for reconnoitring, signalling, and other warlike purposes. For the preparation of the hydrogen, Guyton de Morveau suggested a method invented by Lavoisier, that of passing steam over red-hot iron, and a furnace was accordingly built, which after many trials, was capable of producing sufficient gas to fill a balloon, 27 feet in diameter, in 4 hours. This balloon, with one filling, remained in use for a month.

Balloons inflated with hydrogen were used in the American Civil War in 1861. The gas was generated from old scrap iron and sulphuric acid in wooden tanks lined with lead: the apparatus was carried from place to place on two carts.

In 1878, Giffard made a gigantic captive balloon for the Paris Exhibition. It was spherical in form, 118 feet in diameter, and had a capacity of 882,902 cub. feet. To fill this great aerial ship with hydrogen gas, 190 tons of sulphuric acid and 80 tons of iron were consumed (Jour. United Service Inst. 27, 735-756).

Hydrogen was also used in the Soudan War for inflating balloons. For this purpose, the gas was compressed in strong iron cylinders, 12 feet long by 1 foot in diameter; these were for a reserve supply, and weighed half a ton each. A gas factory and pumping station were put up. To meet first requirements about 100 lighter cylinders, 9 feet long, and containing 120 feet of gas in a compressed condition, were taken out; these were so constructed as to be easily carried by men. One waggon containing a ton of stores was sufficient for a balloon ascent; a volume of gas occupying 4,150 feet was sufficient to lift a man 1,000 yards (Illus. Nav. and Mil. Gaz. 11, 172).

At the present time it is highly important for the maintenance of large dirigible balloons to be assured of a regular supply of pure hydrogen gas. Minute quantities of impurities, such as phosphine and arsine attack the fabric of the balloon. The chief drawback to the use of hydrogen is its high rate of diffusion, a drawback which is being minimised by improvements in the manufacture of balloon fabrics.

Most of the hydrogen now used for inflating the gas bags of dirigible airships is produced either electrolytically or by the action of steam on red-hot iron. The former method depends for success upon a cheap supply of electrical energy. It yields pure hydrogen and the plant requires very little attention.

In the other method as described by Lane (Eng. Pat. 17591, 1909), iron is heated to redness in a current of steam, and the oxide produced is reduced by heating in a current of water-gas, the resulting metal being used again. By

carrying on the reduction process in a number of the retorts and the preparation of hydrogen simultaneously in the others, it is possible to make the production of hydrogen more or less continuous.

The need for rapid convenient methods for preparing hydrogen for military purposes has led to the introduction of the 'silicol,' 'hydrolith,' and 'hydrogenite' processes for its preparation. These are due to Jaubert, and are employed by the French army. In the 'silicol' process ferrosilicon containing 88-90 p.c. or more of silicon is acted upon by a 35-40 p.c. solution of caustic soda at 60°-80°. The heat of the freshly-prepared solution is sufficient to start and maintain the reaction. This method was employed by the British navy during the recent war. According to Weaver (J. Ind. Eng. Chem. 1920, 12, 232) the process yields the most economical results when about equal weights of sodium hydroxide (as 30 p.c. solution) and ferrosilicon (88 p.c. Si) are used. For a charge of 363 kg. of ferrosilicon, one half of the sodium hydroxide solution and 28 kg. of ferrosilicon are placed in the generator (a cylindrical tank 6 ft. 6 in. high and 6 ft. diameter), and when the temperature reaches 90°, ferrosilicon is added at the rate of 5.6 kg. per minute; sodium hydroxide is at the same time added continuously at such a rate that the temperature remains constant. When all the solution has been added, the temperature is kept at 90° by the introduction of cold water until the solution contains about 20 p.c. sodium hydroxide (J. Soc. Chem. Ind. 1920, 39, 403 A). In the 'hydrolith' process, a white crystalline powder consisting of calcium hydride (90 p.c. pure, the remainder being oxide and nitride), is decomposed by water. One kilo. of the solid yields about 1 cubic metre of hydrogen. The portable apparatus used by the French army can fill an army dirigible in 4 hours. For speed, convenience, and reliability, hydrolith is unexcelled, but its high cost renders its use almost prohibitive for private aeronautics. 'Hydrogenite' is a compressible powder, consisting of ferrosilicon (90-95 p.c. Si) 25 pts., sodium hydroxide 60 pts., and soda lime 20 pts. (Sander, Chem. Zeit. 1911, 35, 1273); when ignited by a suitable 'match,' it reacts spontaneously, much as do thermit mixtures, with the evolution of hydrogen and the production of sodium and calcium silicates. The material is hygroscopic, and is sold in a compressed cake in metal cartridges. One kilo. of substance yields from 270 to 370 litres of hydrogen. (For the method of using the substance for filling balloons, v. Jaubert, Rev. gén. chim. 13, 341, 357; and cf. D. R. P. 218257, 1908.)

Hydrogen in chemical industry. Hydrogen for commercial purposes may be obtained electrolytically, or by purely chemical methods, as in the iron contact process, whereby purified 'blue' water-gas, a mixture containing hydrogen and carbon monoxide, obtained by passing steam over heated coke (v. WATER-GAS) is passed, alternatively with steam, over iron oxide, the oxide being continually reduced and oxidised, with the production of hydrogen and carbon dioxide, which latter gas is removed by washing and absorption; or as in the Badische catalytic process, where the purified 'blue' water-gas

is mixed with steam and passed over some catalytic material (as a preparation of a nickel, iron, or chromium salt) dried and heated to 400°-500°, when the mixture of hydrogen and carbon monoxide reacts with the steam with the formation of more hydrogen and carbon dioxide:

The mixture of hydrogen and carbon dioxide is passed under pressure through water whereby the carbon dioxide is absorbed. Or the purified 'blue' water-gas may be subjected to a regulated cold and pressure, as in the Linde-Frank-Caro process, whereby all its components, with the exception of the hydrogen, may be removed by liquefaction (*cf.* E. K. Rideal, *J. Soc. Chem. Ind.* 1921, 40, 10T.). Hydrogen is now required on a large scale for the hardening of fats and oils (*q.v.*) and for the production of synthetic ammonia (*v.* AMMONIA; CHEMICAL AFFINITY; UTILISATION OF ATMOSPHERIC NITROGEN).

Triatomic hydrogen (hyzone). A reactive modification of hydrogen has been produced by several methods, all of which are dependent on gaseous ionisation: (i) by the α -rays from radium emanation; (ii) by an electrical discharge under reduced pressure; and (iii) by the high potential corona at atmospheric pressure. This active hydrogen reduces sulphur, arsenic, phosphorus, mercury, nitrogen, and both acid and alkaline solutions of potassium permanganate. It is condensed or destroyed by temperatures about that of liquid air. It is very unstable and reverts to the ordinary form in about a minute. The formation of a polyatomic molecule is indicated by the contraction of the hydrogen when ionised. Positive ray analysis at very low pressures shows a large proportion of triatomic molecules responsible for the chemical activity. All the properties of the gas point to its being an ozone form (Wendt and Landauer, *J. Amer. Chem. Soc.* 1920, 42, 930; *Chem. Soc. Abstr.* 1920, 118, ii. 425).

HYDROGENIUM *v.* HYDROGEN.

HYDROGEN PEROXIDE. Symbol H_2O_2 . This compound was discovered in 1818 by Thénard. It occurs at times in small quantities in the atmosphere, in dew, in rain, and in snow (Schöne, *Ber.* 1874, 7, 1695; *ibid.* 1893, 26, 3011; *ibid.* 1894, 27, 1233; *Zeitsch. anal. Chem.* 1894, 33, 137); but Illosva (*Ber.* 1894, 27, 920) maintains that the tests used for detecting it in these media would also be given by the oxides of nitrogen, which are always present. It is said to be contained in many green plants (Bach, *Compt. rend.* 1894, 119, 1218; Chodat and Bach, *Ber.* 1902, 35, 1275, 3943; 1903, 36, 1756; 1904, 37, 36). It is also contained in solution in the water produced by the combustion of hydrogen in oxygen (Schuller and Bach, *Compt. rend.* 1897, 124, 951; Keiser and McMaster, *Amer. Chem. J.* 1908, 39, 96), and in the flames of alcohol, coal gas, ether, and carbon disulphide (Engler, *Ber.* 1900, 33, 1109).

Water in contact with oxygen yields hydrogen peroxide on exposure to sunlight. When air at atmospheric pressure is led through the cathode compartment of an electrolytic cell containing 1 p.c. sulphuric acid hydrogen peroxide is formed at the cathode. With oxygen the amount is increased and is also increased by increasing

the pressure of the oxygen. Working with a potential of 2 volts, a current density of 2 amps. per sq. dm. and a pressure of 100 atmos., a 2.7 p.c. peroxide solution can be obtained. 300-400 grams of hydrogen peroxide can be obtained for each kilowatt-hour.

Hydrogen peroxide is formed in small quantities in the electrolysis of aqueous solutions (Richarz, *Zeitsch. anorg. Chem.* 1903, 37, 75; *Ber.* 1909, 42, 4674; Riesenfeld and Reinhold, *ibid.* 2977); when a Tesla brush discharge, or the silent electric discharge is passed through water vapour (Findlay, *Zeitsch. Elektrochem.* 1906, 12, 129; Nernst, *ibid.* 1905, 11, 710; Löb, *Ber.* 1908, 41, 1517; Ringe and Fischer, *ibid.* 945); during the slow oxidation of many metals, particularly their amalgams, in the presence of water (Traube, *Ber.* 1893, 36, 1471; Smith, *Chem. Soc. Trans.* 1906, 481; Barnes and Shearer, *J. Phys. Chem.* 1908, 12, 155, 468; Rankin, *Proc. Roy. Soc.* 1910, B, 82, 78); with zinc amalgam and in the presence of an alkaline earth a better yield is said to be obtained (D. R. P. 48542; *J. Soc. Chem. Ind.* 1890, 213).

It may be synthesised by the action of the silent electric discharge upon oxy-hydrogen gas cooled by liquid air under a pressure of 3 cm. of mercury (Fischer and Wolf, *Ber.* 1911, 44, 2956). A mixture of hydrogen and oxygen containing oxygen up to 6 p.c. on being subjected to a silent discharge in a Berthelot tube produced large quantities of hydrogen peroxide, the yield in some cases being practically 100 p.c. The best yield was obtained under the following conditions: (1) a current strength of 4.6 amps. on the primary of the induction coil; (2) a gas velocity of 400 c.c. per hour; (3) moist gases; (4) a concentration of 3.5 p.c. oxygen (Wolf, *Zeitsch. Elektrochem.* 1914, 20, 204).

Hydrogen peroxide is also formed under several other circumstances, as, *e.g.*, when freshly-ignited bone black is moistened with as much water as it will take up, and exposed to light and air. Even in a few minutes a perceptible amount of hydrogen peroxide is formed (Dingl. poly. J. 256-519). A carbonic oxide flame (when the gas has been previously passed through water) is said to produce it in quantity, or if burnt in contact with the surface of water the same effect is produced (*J. Soc. Chem. Ind.* 1884, 496).

When turpentine oil or any other hydrocarbon containing a terpene is oxidised by air or ozone in the presence of water, hydrogen peroxide is formed and passes into solution in the water. In this way it is possible to prepare a solution of two volumes strength, that is to say, of such a strength that when fully decomposed it is capable of yielding twice its own volume of oxygen gas (Kingzett, *Eng. Pat.* 12274; *J. Soc. Chem. Ind.* 1898, 691).

It is also said to be produced by the oxidation of a number of organic compounds, such as urine, ether, &c., in direct sunlight (Richardson, *Chem. Soc. Trans.* 1893, 1110; *ibid.* 1896, 1349).

Preparation.—1. By passing a copious stream of well-washed carbon dioxide through cooled distilled water to which is added very gradually pure barium peroxide, finely powdered and suspended in water. The cautious addition of the barium peroxide is necessary, as an excess of it would

cause the decomposition of any hydrogen peroxide formed, with evolution of oxygen and formation of water. After allowing the gas to pass some considerable time, the barium carbonate is filtered off, and the solution evaporated *in vacuo* over sulphuric acid until it acquires a syrupy consistency;

(D. R. P. 179771, 179826; J. Soc. Chem. Ind. 1906, 117).

2. The preparation is also effected by the decomposition of barium peroxide with hydrofluoric, silicofluoric, phosphoric, sulphuric, borofluoric, or hydrochloric acid, of which the last is to be preferred, owing to its cheapness, whilst the purest peroxide is obtained with phosphoric or borofluoric acids. The barium peroxide, which must be of the purest quality and very finely ground, is made into a thin paste with water, and introduced very gradually into the acid solution, the temperature of which must never exceed 10° – 15° , and must be constantly agitated. When the solution is nearly neutralised, the liquid is decanted from the precipitate, and freed from iron and aluminium oxides by treatment with sodium phosphate solution, then with sufficient barium peroxide or waste barium oxide to make the liquid neutral, lastly with ammonia, after which it is rapidly pumped through a filter press. It is then freed from dissolved baryta by the addition of sodium sulphate. The most stable peroxide is that prepared with phosphoric acid, and contains a small amount of that acid in the free state (Chem. Zeit. 9, 949 and 976; Bourgougnon, J. Amer. Chem. Soc. 12, 64; Fawsitt, J. Soc. Chem. Ind. 1902, 229; see also Eng. Pats. 10476, 3628, 21333; J. Soc. Chem. Ind. 1891, 482; *ibid.* 1892, 707; *ibid.* 1900, 70). Nitric acid has also been employed (Fr. Pat. 359523; J. Soc. Chem. Ind. 1906, 374).

3. Hydrogen peroxide has also been conveniently, but not so cheaply, prepared by treating sodium peroxide with hydrofluoric or hydrochloric acids (U.S. Pat. 692139; J. Soc. Chem. Ind. 1902, 364; Forcrand, Compt. rend. 1899, 129, 1246; Merck, Chem. Zentr. 1904, ii. 67); and by treating persulphates, percarbonates, and perborates, obtained by electrolysis of the ordinary acids with dilute acids (Jaubert, Chem. Zentr. 1905, ii. 99; D. R. PP. 217538, 217539, 195351, 199958, 179826; J. Soc. Chem. Ind. 1905, 379; *ibid.* 1906, 321, 379; *ibid.* 1908, 448, 856; *ibid.* 1910, 489).

To obtain hydrogen peroxide from persulphates, acid solutions of persulphates, obtained by electrolysis, or by treating solid persulphates with sulphuric acid, are converted on warming into monopersulphuric acid:

and this into hydrogen peroxide:

The solutions must contain a high concentration of sulphuric acid (*circa* 40 p.c.) in order that $\text{H}_2\text{S}_2\text{O}_8$ may be converted into H_2SO_5 . The concentration must not be too great since the action is reversible; in solutions containing over 58 p.c. H_2SO_4 the H_2O_2 reforms H_2SO_5 . A certain strength of sulphuric acid is needed to obtain a concentrated distillate at a fairly rapid

rate. The general conditions affecting the stability of hydrogen peroxide must be observed. The solution must not contain salts of copper, iron, or manganese, and must be free from dust or organic matter. Traces of platinum derived from the electrodes catalyse the decomposition of H_2O_2 in presence of H_2SO_5

Teuchner (Eng. Pat. 24507, 1905) removes these traces of platinum by adding aluminium, the salts of which have no catalytic influence. For the most successful conditions of distillation, see Pietzsch and Adolph, Eng. Pats. 23158 and 23660.

Persulphates (of potassium and ammonium) are distilled with sulphuric acid, giving H_2O_2 of high concentration:

Water is introduced and the H_2O_2 is distilled as fast as formed at a high concentration. By this means 96 p.c. of the theoretical yield of H_2O_2 from $\text{K}_2\text{S}_2\text{O}_8$ may be obtained as a 20 p.c. solution. On the large scale 1 kilo. of ammonium persulphate is said to be produced by 2.4 kilowatt-hour. Assuming 96 p.c. efficiency of conversion into H_2O_2 and distillation as above, 1 kilowatt-hour produces about 60 grams H_2O_2 (Prideaux, J. Soc. Chem. Ind. 1918, 257 R).

Hydrogen peroxide is produced by Cobellis (U.S. Pat. 1195560) by heating a solution of ammonium persulphate and bisulphate. The process is made continuous by electrolysis a solution of ammonium sulphate at comparatively low temperatures to form the per-salt, heating under pressure to form sulphate and hydrogen peroxide which is subsequently distilled off under diminished pressure in a current of inert gas (Reports of the Progress of Applied Chemistry, 1917, ii. 192).

Pure concentrated solutions of hydrogen peroxide have been prepared by the action of alcohol and dilute sulphuric acid on sodium peroxide in earthenware, glass, or lead vessels at -10° . The alcohol is then removed by distillation *in vacuo* (Dony-Hénault, Fr. Pat. 403294; J. Soc. Chem. Ind. 1909, 1314). A mixture of a perborate with an equivalent amount of a dry solid organic or inorganic acid, or of a solid acid salt has been prepared, which, on treatment with water, yields hydrogen peroxide (Fr. Pat. 401911; J. Soc. Chem. Ind. 1909, 1198).

Hydrogen peroxide has also been prepared by blowing superheated steam against a heated body (Eng. Pat. 20868, 1907; Fr. Pat. 382189, 1907; D. R. P. 205262, 1908; J. Soc. Chem. Ind. 1906, 808; *ibid.* 1908, 123, 226; *ibid.* 1909, 140; Fischer and Ringe, Ber. 1908, 41 945), and by blowing moist air against a spark or arc discharge (D. R. PP. 197023; 228425; J. Soc. Chem. Ind. 1910, 1462).

(For other methods, see D. R. P. 185597; Bornemann, Zeitsch. anorg. Chem. 34, 1; Fr. Pat. 371043; Scheuer and Vernet, Bull. Soc. Ind. Mulhouse, 1907, 77, 336; *ibid.* 1908, 78, 184, 187; J. Soc. Chem. Ind. 1910, 1306; Fr. Pat. 415361; Eng. Pats. 10476, 1913; 22714, 1914.)

Commercial hydrogen peroxide is liable to contain hydrochloric, sulphuric, phosphoric, and hydrofluoric acids, alumina, lime, magnesia,

potash, and soda, derived from water or other materials used in its manufacture, whilst baryta and traces of iron, copper, lead, and manganese are sometimes found if it has been carelessly made.

When these last are present, the product is tolerably stable only if it be sufficiently acid, though even then it is less stable than in the absence of these impurities.

It is usually sold as of so many volumes strength, that is, the unit volume gives 10, 12, 20 unit measures of oxygen.

The commercial liquid of so-called 10 volume or about 3 p.c. strength may be purified by the addition of about $\frac{1}{4}$ p.c. of concentrated phosphoric acid (preferably pure) to precipitate iron, copper, lead, and manganese, and prevent the subsequent formation of their peroxides which would otherwise take place. Saturated baryta water (hot or cold) is then added very gradually, until neutrality is reached. No excess must be used or hydrated BaO_2 will be precipitated, which will induce decomposition of a portion of the hydrogen peroxide.

The clear liquid is now drawn off, and is poured into an excess of cold saturated baryta water, when hydrated BaO_2 is thrown down, and is then washed until no metal except barium can be detected in the washings.

The BaO_2 is then suspended in water and added drop by drop to a solution consisting of 90 parts of distilled water to 10 parts of pure concentrated sulphuric acid until only traces of acid remain free; these are best removed by weak baryta water, for an accidental excess of BaO_2 will induce decomposition of some of the already formed hydrogen peroxide, whilst an excess of BaO will have no such effect. The barium sulphate is allowed to settle, and the clear liquid drawn off, if found free from both barium and sulphuric acid. The resulting product is about 3 p.c. strength, fairly stable and of great purity (Mann, Chem. Zeit. 12, 857; J. Soc. Chem. Ind. 1889, 640).

Hydrogen peroxide does not volatilise appreciably from its aqueous solutions at 50° – 60° . The most important factor in the decomposition is the purity of the water used as solvent, tap-water giving a rate which is 50 times that of the best conductivity water.

The commercial solutions can be concentrated to 95–99 p.c. by evaporating in air at 75° to 20 p.c. strength, then *in vacuo* to 50–55 p.c., after which it is treated with ether, in which the peroxide is readily soluble. The ethereal extract is then carefully distilled and fractionated *in vacuo* (Wolffenstein, Ber. 1894, 27, 3307; Staedel, Zeitsch. angew. Chem. 1902, 15, 642; Tyrer, *l.c.*; Merck, *l.c.*); also by distilling the solutions at a temperature below 85° in a powerful current of an inert gas (D. R. P. 219154).

The concentrated solution remains liquid at -20° , but when immersed in a mixture of ether and carbon dioxide, it crystallises to a solid mass, consisting of the anhydrous peroxide. Clear colourless crystals of the latter can also be obtained by introducing a fragment of the solid into a freshly prepared 90–80 p.c. solution at -8° (Staedel, *l.c.*). Hydrogen peroxide should be kept in paraffin or paraffin-lined vessels.

The decomposition of hydrogen peroxide under the influence of heat is regulated principally by the amount of water existing at each instant in the liquid, and follows a mathematical law resulting from this; thus the water acts as a catalyst. The physical state of the walls of the containing vessels has a marked influence on the results (Lemoine, Compt. rend. 1912, 155, 9; Bull. Soc. chim. 1913, 13, 5).

A number of substances have been proposed as suitable for increasing the stability of hydrogen peroxide, such as sulphuric or phosphoric acids (Tyrer, Pharm. J. 63, 100); sodium pyrophosphate (Eng. Pat. 23676; J. Soc. Chem. Ind. 1910, 151); organic substances such as alcohol, ether, glycerol, &c. (Sanders, Bull. Soc. Ind. Mulhouse, 1897, 95; Freyes, *ibid.* 97, Eng. Pat. 15993); 1 gram pure crystalline naphthalene to 1 litre of solution (Zinno, Bull. Soc. Ind. Mulhouse, 1895, 78); gallic acid or pyrogallol (Arndt, D. R. P. 196370); uric or barbituric acids (D. R. PP. 216263, 203019, J. Soc. Chem. Ind. 1908, 1204; *ibid.* 1909, 1314); phenacetin or an amide or imide or acetyl derivative of an aromatic base (J. Soc. Chem. Ind. 1906, 1219); oxalic acid (Fischer, Pharm. Zentr. 1907, 48, 57, 79); *p*-acetylaminophenol (Schlangk, Apoth. Zeit. 1911, 26, 106).

Acetanilide has been found to be fairly efficient as a preservative. Benzoic and salicylic acids have also been recommended.

According to Allain (J. Pharm. Chim. 1906, 24, 162) sodium or calcium chloride in the proportion of 1 p.c. are more efficient preservatives for medicinal hydrogen peroxide than sulphuric or phosphoric acids. They are also less objectionable than the latter from a therapeutic point of view. See also Kingzett (J. Soc. Chem. Ind. 1890, 3).

Clover (Amer. J. Pharm. 1913, 85, 538) has studied the influence of various acids and salts on the gradual decomposition of hydrogen peroxide solutions. Addition of salts of the alkali and alkaline-earth metals does not appear to have any marked effect. Of the acids used, phosphoric acid gave the best result at all concentrations, but the best preserved solution had lost nearly 30 p.c. in strength after seven months. Traces of copper and iron have a very deteriorating effect, but this is prevented to a great extent by acetanilide.

According to Merck (D. R. P. 275499) the stability of solutions of hydrogen peroxide, or its solid compounds with carbamide, ammonium sulphate, &c., can be greatly increased, without rendering the mixture acid by the addition of acyl derivatives of aminohydroxycarboxylic acids. The solution should react acid to dimethyl yellow and should be kept in brown glass bottles (*cf.* Jensen, Pharm. J. 1920, 87).

The amount of hydrogen peroxide in an aqueous solution may be conveniently determined by titration with a solution of potassium permanganate containing 7.9 grams KMnO_4 per litre. 2 c.c. of hydrogen peroxide solution are introduced into a graduated tube of 35 c.c. capacity, 5 or 6 drops of hydrochloric acid are added, and then the solution of permanganate is gradually introduced with constant agitation until the contents of the tube are of a red or brownish colour; the quantity of solution is then read off, 5 c.c. representing 1 p.c. of

hydrogen peroxide. The results are accurate to within 0.1 p.c. and can be obtained in a few minutes¹ (Chem. Zeit. 9, 940 and 976).

In the presence of persulphates, however, accurate results can only be obtained by using a minimum volume of solution, a large excess of sulphuric acid and performing the titration very rapidly; for this purpose an excess of permanganate is added, and the latter is then titrated back with sodium thiosulphate (Friend, Chem. Soc. Trans. 1904, 597, 1533; *ibid.* 1905, 1367; Skrabal and Vacek, Chem. Zeit. 1910, 34; Rep. 121).

If oxalic acid is present, this must first be removed (Sisley, J. Soc. Chem. Ind. 1901, 1028; *ibid.* 1904, 685; Roche, *ibid.* 1902, 190).

Another and more accurate method is to strongly acidify the solution of hydrogen peroxide with sulphuric or hydrochloric acid, then add a solution of potassium iodide free from iodate, and determine the iodine liberated by means of a standard solution of sodium thiosulphate (Kingzett, Chem. Soc. Trans. December, 1880, and The Analyst, 1888, 13, 62; Rupp, Arch. Pharm. 238, 156; Planés, J. Pharm. Chim. 1904, 20, 538; cf. Auger, Compt. rend. 1911, 152, 712).

Hydrogen peroxide can also be estimated by titrating against ferrous ammonium sulphate in presence of ammonium sulphate and phosphoric acid (Mathewson and Calvin, Amer. Chem. J. 1906, 36, 113); and by estimating the quantity of arsenious acid it will oxidise to arsenic acid (Grützer, Arch. Pharm. 237, 705; Jamieson, Amer. J. Sci. 1917, 44, 150).

According to Dehn the most rapid, convenient, and accurate method of estimating hydrogen peroxide is to measure the volume of oxygen evolved when a known quantity of the solution is treated with sodium hypobromite in a special apparatus described by him (J. Amer. Chem. Soc. 1907, 29, 1315). The following reaction takes place $\text{H}_2\text{O}_2 + \text{NaBrO} = \text{NaBr} + \text{H}_2\text{O} + \text{O}_2$. By this method the presence of preservatives may be neglected. (For the estimation of the peroxide retained by fabrics, see Scheuer and Vernet, *L.c.*)

To determine the quantity of acid present in commercial hydrogen peroxide, the best method is by direct titration in the cold, with N/10 sodium hydroxide solution, using phenolphthalein as indicator (Brown, J. Ind. Eng. Chem. 1910, 377; Endemann, Zeitsch. angew. Chem. 1909, 22, 673; Lüning, *ibid.* 1549).

Properties.—Pure anhydrous hydrogen peroxide forms colourless prismatic crystals of sp.gr. 1.644, latent heat of fusion 74 cal., specific heat of solid 0.470; m.p. -2° , b.p. $84^\circ\text{--}85^\circ/68$ mm., $69.2^\circ/26$ mm. It forms a syrupy transparent acid liquid, which is colourless in thin layers, but bluish-green when viewed in bulk (Spring, Chem. Zentr. 1895, i. 1105). It has sp.gr. 1.4584 at 0° (Brühl, Ber. 1895, 28, 2854); 1.4633 at 6° (Maass and Hatcher, J. Amer. Chem. Soc. 1920, 42, 2548); mean coefficient of ex-

pansion -10° to $+20^\circ$, 0.00107; specific heat of liquid 0.579. It is quite stable if kept at 0° . It forms hydrates $\text{H}_2\text{O}_2 \cdot \text{H}_2\text{O}$; $\text{H}_2\text{O}_2 \cdot 2\text{H}_2\text{O}$ (Wolfenstein, *L.c.* 3311); m.p. -51° (Maass and Herzberg, J. Amer. Chem. Soc. 1920, 42, 2569).

When heated to the boiling-point of water it decomposes with explosive violence into oxygen and water, but when the peroxide or its solutions are quite pure it is not so readily decomposed by heat; the vapours of hydrogen peroxide are said to be quite stable (Wolfenstein Ber. 1894, 27, 3307; Nernst, Zeitsch. physikal. Chem. 1904, 46, 720).

The liquid evaporates slowly *in vacuo* without the residue undergoing any change (Thenard). It bleaches organic colouring matters, but not so quickly as chlorine; when brought in contact with the skin it forms a white blister, which, after a time, produces an irritable, itching sensation (Wolfenstein, *L.c.*). It is almost insoluble in anhydrous ether, but dissolves many salts and attacks glass. Most metals cause decomposition of the pure substance, but not always explosively.

One volume of the concentrated solution yields at 14° and 760 mm. pressure, 475 volumes of oxygen, the theoretical amount being 501.8 volumes (Thenard). The compound is most stable in dilute aqueous solution; when the solution is subjected to great cold, part of the water freezes out.

The hydrogen atoms of hydrogen peroxide may be replaced by metals or acid radicles yielding derivatives which resemble the corresponding compounds of water in constitution and properties. See D'Ans and Friederich, Zeitsch. anorg. Chem. 1912, 73, 325.

Hydrogen peroxide is a remarkable oxidising agent. It converts arsenious into arsenic acid, and sulphurous acid into sulphuric acid; lead and other sulphides into the corresponding sulphate; manganese monoxide into dioxide, and monoxides of iron and cobalt into the sesquioxides. The monoxides of barium, strontium, and calcium are converted by it into their respective peroxides. The concentrated solution of hydrogen peroxide acts with violence on selenium, arsenic, molybdenum, and chromium, converting them at once into their oxides.

It decomposes alkaline copper, silver, and bismuth nitrate solution with evolution of oxygen and formation of the metallic oxide, or in the last case the hydroxide (Berthelot, Compt. rend. 1901, 132, 897; Moser, Zeitsch. anorg. Chem. 1906, 50, 33; Gutbier and Bünz, Chem. Zentr. 1909, i. 732.). In contact with sodium it explodes violently.

Hydrogen peroxide oxidises organic sulphides into sulphoxides (Gazdar and Smiles, Chem. Soc. Trans. 1908, 1833). It also reacts with benzene in presence of ferrous sulphate, forming phenol (Young, Chem. Soc. Proc. 1899, 131), and with α -diketones, and generally with substances possessing a quinonoid structure, and can therefore be employed for oxidising phenolic substances like brazilin and aurin, without having to protect the hydroxyl group by methylation (Perkin, Chem. Soc. Proc. 1907, 166). Hydrogen peroxide reacts with a number of opium alkaloids forming crystalline bases (Freund and Speyer, Pharm. Zeit. 1907, 52, 115). According

¹ The reaction between hydrogen peroxide and potassium permanganate in acid solution may be utilised for preparing oxygen gas. In this way a good stream of tolerably pure KMnO_4 may be readily prepared. Crystals of the KMnO_4 should be placed in a Woulff's bottle containing 1:1 sulphuric acid, and the 3 p.c. solution of H_2O_2 allowed to drop regularly into the solution from a suitable reservoir.

to Schaer (Arch. Pharm. 1910, 248, 458), it may be used as a test for other alkaloids. A few milligrams of the alkaloid to be tested are added to a cooled mixture of the peroxide and sulphuric acid. Quinine gives a lemon or canary yellow colour; berberine a cherry red; hydrastine a chocolate; emetine a dark orange, and nicotine a blood-red colour.

In presence of ferrous sulphate hydrogen peroxide also reacts with a number of sugars, forming osones (Cross, Bevan, and Smith, Chem. Soc. Trans. 1898, 403; Morell and Bellars, *ibid.* 1905, 280; Chem. Soc. Proc. 1902, 55; Chem. News, 1904, 90, 158). It also reacts with other organic compounds (Cross, Bevan, and Heiberg, Chem. Soc. Proc. 1899, 130; Harden, *ibid.* 158; Wolfenstein, Ber. 1895, 28, 1459; Bevan and Heiberg, *ibid.* 1900, 33, 2015; Clover and Houghton, Amer. Chem. J. 1904, 32, 43).

Pure hydrogen peroxide reacts with potassium cyanide thus:

Potassium formate and ammonia are also produced, but if the peroxide contains acid, then oxamide is formed (Masson, Chem. Soc. Trans. 1907, 1449).

Chromic acid decomposes hydrogen peroxide in accordance with the equation:

With potassium persulphate it reacts thus:

an unstable intermediate compound is also formed (Friend, Chem. Soc. Trans. 1906, 1092).

With sodium thiosulphate it gives the reaction:

In presence of certain solid substances, especially when finely divided, hydrogen peroxide undergoes violent decomposition, the substances themselves remaining unchanged (Fillippi, Chem. Zentr. 1907, ii. 1890; Antropoff, Zeitsch. physikal. Chem. 1908, 62, 513; Bredig and Wilkie Biochem. Zeitsch. 1908, ii. 67). This is the case with carbon, many metals, and oxides, and iodine (Walton, Zeitsch. physikal. Chem. 1904, 47, 185; Abel, Zeitsch. Elektrochem. 1908, 14, 589). Gold, platinum, and particularly silver, act most violently and evolve great heat. The presence of acids retards this decomposition, whilst the presence of alkalis facilitates it.

This decomposition is still more readily brought about by these metals when in the colloidal state (Bredig and Reinders, Chem. Zentr. 1901, ii. 87; Bredig, Zeitsch. physikal. Chem. 1899, 31, 258; *ibid.* 1901, 37, 323; *ibid.* 38, 122; Price and Denning, *ibid.* 1903, 46, 89; Brossa, *ibid.* 1909, 66, 162; Spear, J. Amer. Chem. Soc. 1908, 30, 195; see also Kastel and Loevenhart, Amer. Chem. J. 1903, 29, 563; Liebermann, Ber. 1904, 37, 1519; Bredig, *ibid.* 798; Poppada, Gazz. chim. ital. 1907, 37, ii. 172).

Hydrogen peroxide is also decomposed by *catalases*, a class of organic ferments which are widely distributed in the animal and vegetable kingdoms (Senter, Proc. Roy. Soc. 1904, 74, 201;

Wender, Chem. Zeit. 1904, 28, 300, 322; Euler, Chem. Zentr. 1905, i. 941; Bach, Ber. 1904, 37, 3785; *ibid.* 1905, 38, 1878; Laer, Bull. Soc. chim. Belg. 1906, 19, 337; J. Inst. Brewing, 1906, 12, 313; Rywosch, Centr. Bakt. Par. 1907, i. 44, 295).

Hydrogen peroxide also acts as a deoxidising agent; thus silver oxide when brought in contact with it causes a mutual decomposition of the two compounds $\text{Ag}_2\text{O} + \text{H}_2\text{O}_2 = \text{H}_2\text{O} + \text{O}_2 + \text{Ag}_2$, an atom of oxygen is liberated from each compound, and a molecule of free oxygen is thus obtained. A similar reaction occurs when hydrogen peroxide and ozone are brought together, $\text{H}_2\text{O}_2 + \text{O}_3 = \text{H}_2\text{O} + 2\text{O}_2$ (Mulder, Rec. trav. chim. 1903, 22, 388; Baeyer and Villiger, Ber. 1902, 34, 749; 2769; Inglis, Chem. Soc. Trans. 1903, 1013).

Hydrogen peroxide is reduced by manganese dioxide and peroxide of lead in presence of an acid, $\text{H}_2\text{O}_2 + \text{MnO}_2 = \text{MnO} + \text{H}_2\text{O}$.

Alkaline mercury salts are reduced to the metallic state by hydrogen peroxide (Kolk, Chem. Zeit. 1901, 25, 21). Direct sunlight accelerates the decomposition of hydrogen peroxide. The effect of hydrogen peroxide on a photographic plate is similar to that of light, and is probably due to the hydrogen peroxide vapour itself, and not to a radiation from it (Russell, J. Soc. Chem. Ind. 1899, 516; Otsuki, *ibid.* 1905, 575; Precht and Otsuki, *ibid.* 290; Dony-Hénault, *ibid.* 1904, 138; Graetz, Chem. Zentr. 1904, ii. 1561; Dony-Hénault, *ibid.* 1906, ii. 203; Bull. Soc. chim. Belg. 1908, 22, 224; Soeland, Ann. Physik. 1908, [iv.] 26, 899).

Hydrogen peroxide forms molecular compounds with certain inorganic and organic salts in which it appears to play the same part as water of crystallisation (Tanatar, Chem. Zeit. 1901, 25; Rep. 326; J. Russ. Phys. Chem. Soc. 1908, 40, 376; Staedel, *l.c.*; Jones and Carroll, Amer. Chem. J. 1902, 28, 284; Willstätter, Ber. 1903, 36, 1828; De Forcerand, Compt. rend. 1902, 134, 601).

An acidified solution of potassium dichromate in presence of hydrogen peroxide gives rise to an unstable combination of chromic acid and the dioxide; this, on mixing with ether, can be extracted from the aqueous solution, imparting to it a beautiful and characteristic blue colour.

A solution of guaiacum mixed with a small amount of blood gives a blue coloration on addition of hydrogen peroxide. This is a delicate test for the compound, and serves also as a test for blood.

Hydrogen peroxide gives a blue-green coloration with an alcoholic solution of guaiacol and sulphuric acid, and an intense yellow colour with a solution of quinine sulphate in concentrated sulphuric acid (Denigès, Pharm. J. 1909, July 31st).

In the presence of hydrogen peroxide, chlorates, bromates, iodates, phosphates, sulphates, hypochlorites, also salts of organic acids, give a yellow-green coloration with 1 p.c. guaiacol solution. On addition of hydrochloric or sulphuric acid the colour changes to red (Baudran, Compt. rend. 1905, 141, 891). Solutions of vanadic and titanous acids are turned brown or red by the peroxide, and with a mixture of potassium chlorate and aniline in the presence

of acid a violet colour is formed after a short time (Bach, *Compt. rend.* 1894, 119, 1218); if dimethylaniline is used instead of aniline, a yellow colour is formed. By the latter reaction 1 part of peroxide in 5,000,000 can be detected.

When hydrogen peroxide is added to a solution of potassium iodide, even in presence of ferrous sulphate or copper sulphate, iodine is set free, which may be shown by the coloration of starch. Hydrogen peroxide is the only compound known which can liberate iodine in presence of ferrous sulphate (*cf.* Traube, *Ber.* 1884, 17, 1062), 1 part in 25,000,000 can thus be detected.

Tartaric acid added to hydrogen peroxide in presence of a ferrous salt gives on the addition of caustic alkali a violet coloration, due to the production of a ferric compound of deoxytartaric acid.

A very delicate reagent for hydrogen peroxide has been suggested by Charitschkoff (*Chem. Zeit.* 1910, 34, 50). It consists of the pinkish-red cobalt salts of the naphthenic acids obtained from the waste liquors from the refining of petroleum with alkali. A strip of filter paper is dipped into a petroleum solution of the cobalt salt, and, after drying, is moistened with the liquid to be tested. If the peroxide is present the colour changes immediately to olive-green. Ozone does not give this reaction.

An ammoniacal silver nitrate solution gives a characteristic grey opalescence or precipitate with hydrogen peroxide (von Sobbe, *Chem. Zeit.* 1911, 35, 898).

For other tests, *see* Denigès (*Bull. Soc. chim.* 1890, 797); Aloy (*ibid.* 1902, 27, 734); Precht and Otsuki (*Zeitsch. physikal. Chem.* 1905, 52, 236).

Technical applications.—Moistened lead sulphide in contact with hydrogen peroxide is quickly oxidised to lead sulphate. This fact has led to the employment of hydrogen peroxide as a *picture restorer*. The painting darkened by age or by exposure to air containing sulphuretted hydrogen, owing to the white lead employed as body colour being partially converted into lead sulphide, after careful treatment with an aqueous solution of the peroxide is found to be greatly improved in colour from the oxidation of the sulphide to the white sulphate.

Dilute solutions of hydrogen peroxide mixed occasionally with nitric acid, are also used as 'auricome,' 'golden hair water,' &c., for imparting a light colour to the hair (Schrötter, *Ber.* 1874, 7, 980; Lange, *Dingl. poly. J.* 1886, 259, 196).

It is also employed for removing the last traces of chlorine from vegetable fibres which have been bleached with the latter, and to remove the last traces of sulphur dioxide from bleached wool and silk.

Hydrogen peroxide may be used for bleaching in many cases where other agents, such as bleaching powder, sulphurous acid, chlorine, would be injurious. It is particularly valuable for bleaching ostrich feathers, bones, ivory, silk, wool, gelatin, straw, hair, parchment, wood, cotton, the teeth, &c.

The advantages of using hydrogen peroxide as a bleaching agent, particularly for wool, are claimed to be the following: a purer white can be obtained; the fibres are not tendered by it

to the same extent as by the sulphur bleach; the wool, after bleaching, does not turn yellow, does not emit an unpleasant odour when in contact with perspiration, and purer tones and more even colours can be obtained on dyeing the bleached wool. It is also stated to be more convenient to use, more pleasant for the workpeople, and less corrosive on the machinery. With care, the process, moreover, need not be much more expensive than with the older bleaches, and it is now used very extensively and with good results, both in England and on the Continent (Wachtel, *Färber-Zeit.* 1900, 11, 268; Russell, *Proc. Roy. Soc.* 1899, 64, 409).

In the case of wool the scoured article is first soaked thoroughly in a dilute solution of sodium silicate (2 lbs. to 10 gallons). After saturation the wool is wrung out and placed in the peroxide bath, which is prepared by adding 3½ gallons of 10 volume peroxide to 6½ gallons of water in which ½ lb. of sodium silicate has been dissolved. The wool is kept in the bath for about 24 hours (or a shorter or longer interval depending on the quality of the wool and on the whiteness desired) at 80°F. Occasionally the wool is turned over, and the solution tested whether it is alkaline, which it must be for satisfactory results. It is then pressed through a wringing machine and dried at a temperature of 15°–17°C., and preferably in the sunlight. When quite dry the wool is well washed and redried (Fawsitt, *J. Soc. Chem. Ind.* 1902, 229; Luttringhaus, *Färber-Zeit.* 1901, 12, 328; Dommergne, *Rev. Chim.* Ind. 1896, 7, 73).

With slight modifications this process is also applicable to cotton, straw and silk, but for the two last, the peroxide solution is made up of 1 part 10 volumes peroxide to 2 of water, and for every 10 volumes of peroxide, 4 ozs. of sodium silicate are employed (Fawsitt, *l.c.*; Koehlin, *J. Soc. Chem. Ind.* 1899, 1119). In the case of silk the bath may be made strongly alkaline with caustic soda from the beginning of the process.

Bone and ivory are first cleansed by treatment with light petroleum, ammonia or other solvent; they are then immersed in a bath containing 1 of 10 volumes peroxide to 2 of water made slightly alkaline with ammonia. Feathers are bleached similarly, but are washed after bleaching with a dilute solution of sulphuric acid.

On a small scale lace can be bleached conveniently in the following way: The material, after being moistened with water, is immersed in a solution of potassium permanganate for a few minutes. It is then rinsed and treated for about 10 minutes with a very dilute solution of hydrogen peroxide, after which it is treated with acid to remove the manganous oxide formed in the previous operation (Thomas, *J. Soc. Chem. Ind.* 1900, 734).

For bleaching delicate materials the hydrogen peroxide should not be too strong; a solution of 1 in 10 is strong enough, and a bleaching vat of this solution may be used for a long time if the strength be kept up by fresh additions of hydrogen peroxide. In bleaching dead hair, it is first digested for 12 hours in a solution of 3 parts of ammonium carbonate in 100 of water at a temperature of 30°C., rinsed, then washed with soap and treated with ammonium carbonate until all fatty matter is removed. Thus prepared

it is treated in a bath of hydrogen peroxide and water as in the first case.

Hydrogen peroxide has been used for tanning leather, also to disinfect hides that have been long stored, and to preserve extracts of tanning materials (Göhring, J. Soc. Chem. Ind. 1890, 84). It has also been recommended for use in photographic processes (Smith, J. 1873, 1131; Gros, D. R. PP. 147131; 153769; 158368; Otsuki, *l.c.*; Lüppo Cramer, Chem. Zeit. 1902, 26, Rep. 292, 336; Ebert, *ibid.* 27, Rep. 152).

Medicinal and surgical applications.—As an antiseptic and disinfectant it has the advantage of (1) being odourless; (2) yielding oxygen without leaving any residuum but pure water; (3) absence of injurious influence on the organism.

The antiseptic properties of hydrogen peroxide solution were first brought into notice by Richardson in 1860. They were also studied by Kingzett, and subsequently by Paul Bert and Regnard (Compt. rend. 1882, 94, 1383).

It is used in the treatment of syphilitic and scrofulous sores, alveolar abscesses, and purulent discharges. It is also of great value in cases of purulent discharge from the conjunctiva, and it is particularly efficient for destroying diphtheritic membranes.

Its behaviour is that of a powerful oxidising agent, but on healthy skin its action is slow. In contact with fistulous wounds or pus it is rapidly decomposed with effervescence, which continues till the wound is cleansed or the diseased secretion is destroyed (Kingzett, J. Soc. Chem. Ind. 1890, 3; Paneth, Chem. Zentr. 1890, 174; Schmidt, *ibid.* 1906, ii. 145; Jaubert, *ibid.* 1905, ii. 99).

Hydrogen peroxide may be used to bleach discoloured teeth. In cases where the teeth are covered with coloured matter (*Lichen dentalis*, &c.) peroxide of hydrogen in conjunction with finely levigated pumice-stone may be employed in place of water. A suitable liquid for cleansing the teeth and mouth is prepared by mixing 1 part of 3 p.c. peroxide of hydrogen with 9 parts of water (Chem. News, 45, 71; and Ch. Trade J. April 14, 1888).

It has been proposed to use mixtures of hydrogen peroxide containing starch, cooked or in viscid solution, with anhydrous calcium sulphate as dentrifices, the starch preventing loss of oxygen from the oxide and the latter preserving the starch from putrefaction (Queissier, Fr. Pat. 381924, 1907; J. Soc. Chem. Ind. 1908, 226).

Hydrogen peroxide has the power of freeing water from living organisms, a property which has been utilised in brewing. It also destroys the acid and mould ferments in the wort, and has been used in sterilising casks and filter pulp. In stronger doses it destroys the alcoholic ferment and stops fermentation (G. Reisenbichler, Chem. News, 56, 219; Miquel, Monit. Scient. 1884, [3] 14, 170; Chodat and Bach, Ber. 1902, 35, 1275; Loew, *ibid.* 2487; Bonjean, Compt. rend. 1905, 140, 50; Laer, J. Inst. Brewing, 1909, 15, 553).

Altenhöfer has recommended hydrogen peroxide as a disinfectant for drinking water (Zentr. Bakteriell. und Parasitenkunde, 1890, 129; Küster, Chem. Zentr. 1889, i. 411; 1891, ii. 272; 1895, i. 948; but see also Gourmont, Nagier, and Rochaix, Compt. rend. 1910, 150, 1453).

Hydrogen peroxide is one of the chief constituents of 'Sanitas,' which is a solution of the products of oxidation of turpentine oil in the presence of water and air (Kingzett).

It has been tried with success in the preservation of beer; after a month the taste and aroma of the beer remained good (Weingartner, Bied. Zentr. 1884, 428).

Hydrogen peroxide has been suggested as a useful and harmless preservative of milk (Jablin and Gounet, Ann. Chim. anal. 1901, 6, 129; J. Soc. Chem. Ind. 1902, 420; *ibid.* 1905, 1184; Fr. Pat. 355547; Amberg, J. Biol. Chem. New York, 1906, i. 219).

To test milk for hydrogen peroxide, 10 drops of a 2 p.c. alcoholic solution of benzidine and a few drops of acetic acid are added to 10 c.c. of the milk. If hydrogen peroxide is present a blue coloration appears. The peroxide can be detected in this way in other liquids if a little milk serum is added (Wilkinson and Peters, Zeitsch. Nahr. Genussm. 1908, 16, 172, 515, 589; for other tests, see Feder, *ibid.* 15, 234; Arnold and Mentzel, *ibid.* 1903, 6, 305).

Hydrogen peroxide is used in the laboratory in the valuation of bleaching-powder, the principle depending upon the fact that hypochlorites, when mixed with hydrogen peroxide, instantly evolve all their oxygen, at the same time liberating the oxygen of the peroxide (J. Soc. Chem. Ind. 1887, 391). It is also employed in estimating the amount of active oxygen in potassium permanganate and in manganese dioxide (Schlossberg, Zeitsch. anal. Chem. 1902, 41, 735; Carnot, Compt. rend. 1893, 116, 1295). The amount of sulphur in sulphides is also determined by first oxidising to sulphate and then proceeding as usual (G. Lunge, Ber. 18, 1872; see also Baumann, Zeitsch. angew. Chem. 1890, 72; Talbot and Moody, J. Soc. Chem. Ind. 1893, 780).

Hydrogen peroxide has been employed in the separation of a number of metals from one another (Rose, Ber. 1894, 27, 2227; Lesinsky, *ibid.* 1893, 26, 1496, 2331, 2908; Jannasch and Röttgen, Zeitsch. anorg. Chem. 1895, 8, 202; Friedheim and Brühl, Zeitsch. anal. Chem. 1899, 38, 681). Also for the separation of the halogens (Jannasch and Zimmermann, Ber. 1906, 39, 196, 3655). and for separating vanadium from ores and slags (Fr. Pat. 357397; J. Soc. Chem. Ind. 1906, 72).

Hydrogen peroxide has also been used as a solvent for Indian gum (Bull. Soc. Ind. Mulhouse, 1894, 36), but its use in the estimation of the quantity of flour in a mixture of the latter with bran, is considered to be untrustworthy by Bremer (Zeitsch. Nahr. Genussm. 1906, 11, 569).

Hydrogen peroxide has been employed with success in determining the amount of sulphur in coal gas. The solution used for this purpose consists of the commercial product diluted to a 1 p.c. solution. This solution is run into the Referees' 'apparatus,' through which the coal gas passes at a measurable rate, and the sulphurous acid gas in it is oxidised to sulphuric acid $\text{SO}_2 + \text{H}_2\text{O}_2 = \text{SO}_4\text{H}_2$. The amount of sulphur is then determined by titration or precipitation (J. Soc. Chem. Ind. 1887, 285).

Higher oxides of hydrogen.—The oxides H_2O_4 and H_2O_3 have been described (Bach,

Ber. 1900, 33, 1506, 3111; *ibid.* 1902, 35, 158; Berthelot, *Compt. rend.* 1900, 131, 637, but it is doubtful whether they really exist (Armstrong, *Chem. Soc. Proc.* 1900, 134; Ramsay, *Chem. Soc. Trans.* 1901, 1324; see also Baeyer and Villiger, 1900, 33, 2488; Clover, *Amer. Chem. J.* 1903, 24, 463; Brühl, *Chem. Zentr.* 1896, i. 86; Nagel, *Pharm. Zeit.* 1898, 43, 556). Kastner (*J.* 1820, 472) described a *suboxide*, but its existence has not been confirmed.

HYDROGEN SULPHIDES *v.* SULPHUR.

HYDROHÆMATITE *v.* TURGITE.

HYDROLITES *v.* AGATE.

HYDROLYSIS. The term hydrolysis (or hydrolytic dissociation) is given to a number of different chemical reactions, all of which consist in the addition of water to a complex, and the subsequent resolution of the product into simpler substances.

Some of the best-known types of hydrolysis are those of metallic salts, esters, acid chlorides, amides, &c., or generally acyl derivatives, complex carbohydrates, and glucosides, and finally, polypeptides and proteins.

1. **Hydrolysis of salts.** The hydrolysis of a salt by water may be represented by means of an equation of the type:

The reaction is a balanced one, and may be regarded as due to the incomplete neutralisation of the acid and base from which the salt is derived; in terms of the ionic theory the acid in question (HCN) does not yield sufficient hydriions to combine with the hydroxyl ions of an equivalent quantity of the strong base (KOH). When equivalent quantities of a strong acid and a strong base are brought together in aqueous solution complete neutralisation takes place, and a normal salt with a neutral reaction towards common indicators is formed. (Basis of methods of acidimetry and alkalimetry.) In the cases of such salts appreciable hydrolysis would not be expected even in dilute solution. The following are the common types of salts which are hydrolysed by water: (1) salts derived from feeble acids and strong bases; (2) salts from strong acids and feeble bases; (3) salts from feeble acids and feeble bases. As examples of the first type we have potassium cyanide and sodium phosphate,

Solutions of such salts invariably have an alkaline reaction towards common indicators, *e.g.* litmus, phenolphthalein. The water may be regarded as a feeble acid, which, like any other feeble acid, liberates a certain amount of acid from the salt with which it is brought into contact. In many cases acid salts are first formed, *e.g.* sodium phosphate, sodium carbonate, but free acid and free base may be liberated. The alkaline reaction of the solution can be accounted for by the fact that the feeble acid, or the acid salt formed, is ionised to a slight extent only, whereas with moderately dilute solutions the strong base is almost completely ionised, and thus there is a great excess of hydroxyl ions over hydriions. As examples of

the second type we have ferric chloride and cupric sulphate, which are derived respectively from the feeble bases, ferric hydroxide and cupric hydroxide. The aqueous solutions of such salts invariably give an acid reaction. The hydrolysis may be represented by means of the equations:

With moderately concentrated solutions basic salts, *e.g.* $\text{FeCl}_2 \cdot \text{OH}$ are almost certainly formed, and it is only in very dilute solution that the hydrolysis will proceed to the formation of the metallic hydroxide, and even when this is formed it is not precipitated, but remains in solution in the form of a colloid. A group of salts which belongs to this type is that of the salts derived from feeble organic bases such as aniline, and from the strong mineral acids, *e.g.*

As examples of the third type we have ferric phosphate, aluminium carbonate and sulphide, and aniline acetate. The hydrolysis in the first case is readily shown by washing finely divided ferric phosphate with distilled water, when it is found that the filtrate is always distinctly acid, owing to the free phosphoric acid which has been washed away by the water, and if the operation is continued nearly pure ferric hydroxide remains on the filter. In the case of the two aluminium salts, they are so readily hydrolysed that when brought into contact with water they yield the corresponding metallic hydroxide, and the free acids, carbonic acid and hydrogen sulphide, which escape and thus destroy the equilibrium.

In the case of salt formation we may regard the water as capable of acting as either a feeble base or a feeble acid. When in contact with equivalents of a strong acid and a feeble base the water competes with the base for the acid, and hence neutralisation is not complete, or, in other words, hydrolysis of the salt occurs and the feeble base the greater the degree of hydrolysis. The mechanism of salt hydrolysis according to the ionic theory is as follows: In aqueous solution the given salt, *e.g.* potassium cyanide is ionised in the ordinary manner into K^+ and CN^- ions, but water itself is ionised to a

certain extent, $\text{H}_2\text{O} \rightleftharpoons \text{H}^+ + \text{OH}^-$, and as hydrogen cyanide is a very feeble acid, and therefore ionised to only a very slight extent in aqueous solution, there is a tendency for the H^+ ions of

the water to combine with the CN^- ions from the cyanide, yielding undissociated HCN, the result is

that the equilibrium $\text{H}_2\text{O} \rightleftharpoons \text{H}^+ + \text{OH}^-$ is destroyed and more molecules of water are ionised, but this results in further combination between H^+ and CN^- ions, and by this means an excess of OH^- over H^+ ions is produced, and thus the

alkaline reaction. The changes continue until ultimately an equilibrium is established between the KCN, CN^- , K^+ , H^+ , OH^- , HCN , and H_2O present. The degree of hydrolysis, *i.e.* the fraction of the salt hydrolysed, cannot be determined by direct titration of the free acid or free base present in the solution; the addition of standard acid to the solution of potassium cyanide would immediately destroy the equilibrium which previously existed, and more salt would be hydrolysed in order to restore the equilibrium, and the point of neutrality would not be reached until acid sufficient to decompose the salt completely had been added. The methods commonly adopted for determining the degree of hydrolysis are (*cf.* Farmer, B. A. Report, 1901, 240): 1. Determination of the concentration of the free acid or free alkali present in the solution of the salt by its catalytic effect on the hydrolysis of an aqueous solution of ethyl acetate or on the inversion of a solution of cane sugar, and then determining the amount of pure acid or alkali required to produce the same effect (for acid, *cf.* Walker, Zeitsch. physikal. Chem. 1889, 4, 319; for alkali, *cf.* Shields, *ibid.* 1893, 12, 167; also Bruner, *ibid.* 1900, 32, 133; Ley, *ibid.* 1899, 30, 216; Walker and Aston, Chem. Soc. Trans. 1895, 67, 576). 2. Determination of the electrical conductivity of the solution (Walker, Zeitsch. physikal. Chem. 1889, 4, 333; Bredig, *ibid.* 1894, 13, 313; Lundy, J. Chim. Phys. 1907, 5, 574; Denham, Chem. Soc. Trans. 1908, 93, 41). The molecular conductivity of a hydrolysed salt of the type aniline hydrochloride is made up of two quantities: (*a*) conductivity due to the non-hydrolysed salt; (*b*) conductivity due to the free acid formed on hydrolysis—since the free base (aniline) is not an electrolyte. $M = (1-x)u_1 + xu_{\text{HCl}}$, where M = molecular conductivity, x = degree of hydrolysis, u_1 = molecular conductivity of non-hydrolysed salt. The various quantities in the equation with the exception of x can be determined and then x calculated. 3. By determining the partition coefficient (Farmer, Chem. Soc. Trans. 1901, 79, 863). In the case of aniline hydrochloride the hydrolysis of the salt leads to the formation of free aniline and hydrochloric acid, and the concentration of the free base is determined by shaking the aqueous solution at a given temperature with a known volume of benzene, and finding the concentration of the aniline in the benzene layer. Since C_B/C_{Aq} is always constant (C_B = concentration of aniline in benzene and C_{Aq} = concentration of aniline in water) for a given temperature the concentration of free aniline in the aqueous layer can be calculated directly, and thus the degree of hydrolysis determined. The assumption is made that the salt present does not affect the partition coefficient to an appreciable extent. 4. By the change in colour produced by a solution of the hydrochloride of an organic base on a solution of methyl orange of known concentration, and a comparison of this change with that produced by the addition of known quantities of hydrochloric acid (Veley, Chem. Soc. Trans. 1908, 93, 652, 2114, 2122; 1909, 95, 758; Trans. Far. Soc. 1908, 4, 19).

Most of the methods give only rough approxi-

mations (*cp.* Beveridge, Proc. Roy. Soc. Edin. 1909, 29, 648). A few of the results obtained are as follows:—

Salt	Temp.	P.c. of salt hydrolysed in 0.1 N solution	Method
Glycine hydrochloride	25	19.00	Hydrolysis of ester
Acetoxime "	25	36.00	" "
Urea "	25	90.00	" "
Urea "	60	81.00	Inversion of sugar
Sodium cyanide	25	1.10	Saponification of ester
" acetate	25	0.008	" "
" carbonate	25	3.17	" "
" phenate	25	3.05	" "
Aniline hydrochloride	60	2.60	Inversion of sugar
" chloride "	25	1.50	Conductivity
Zinc chloride "	100	0.10	Inversion of sugar
Aluminium chloride	100	6.10	" "
" "	25	0.50	Conductivity "
Ferric chloride "	25	10.00	Inversion of sugar
Lead "	25	0.50	Conductivity

The whole question becomes more complicated when the acid or base formed by hydrolysis is unstable and is transferred into an isomeric (pseudo-acid or pseudo-base).

The influence of concentration on hydrolysis is given by Guldberg and Waage's law of mass action. According to this $\frac{C_s}{C_A \times C_B} = \text{constant}$,

where C_s represents the concentration (molar) of the non-hydrolysed salt, C_A that of the acid formed by hydrolysis, and C_B that of the base. If originally 1 gram. mol. of salt was dissolved in v litres of solution and x gram mols. were hydrolysed, then

$$\frac{1-x}{v} \times \frac{x}{v} \times \frac{x}{v} = \text{constant, or } \frac{v(1-x)}{x^2} = \text{constant.}$$

It is obvious that as v increases, *i.e.* as the concentration is diminished, x , *i.e.* the degree of hydrolysis, must increase in order to keep the whole expression constant.

The relationships are not quite the same in the case of a salt derived from a feeble base and a feeble acid, *e.g.* aniline acetate.

If the reaction is represented as taking place between the ions of the salt and the water, and the salt is practically completely ionised, and the base and acid not appreciably, then $C_{\text{Cat}}\cdot C_{\text{An}}/C_A\cdot C_B = \text{constant}$, where C_{Cat} = concentration of the cation and C_{An} = concentration of the anion. But $C_{\text{Cat}} = C_{\text{An}} = C_{\text{Salt}}$. $\therefore C_{\text{Salt}}^2/C_A\cdot C_B = \text{constant, or } \left(\frac{s}{v}\right)^2 \frac{a}{v} \frac{b}{v} = \text{constant}$

where s , a , b are the gram mols. respectively of salt, acid, and base in v litres of solution. But this expression is independent of v , and hence dilution does not affect the degree of hydrolysis.

Another factor which affects the degree of hydrolysis is the addition to the solution of one of the products of hydrolysis, *e.g.* free acid or free base. Thus the hydrolysis of aniline hydrochloride in aqueous solution can be stopped

completely by the addition of hydrochloric acid or of aniline. This follows again directly from the equation $C_S/C_A \cdot C_B = \text{constant}$. If C_A , i.e. the concentration of the acid, is increased it is necessary, in order that the whole expression may remain constant, that either C_B should diminish or C_S increase or both, and the only way in which this can be effected is by a diminution in the degree of hydrolysis.

The velocity of salt hydrolysis has been determined in a few cases, e.g. ferric chloride (Goodwin, *Zeitsch. physikal. Chem.* 1896, 21, 1); potassium ruthenium chloride K_2RuCl_5 (Lind and Bliss, *J. Amer. Chem. Soc.* 1909, 31, 868).

A type of hydrolysis analogous to salt hydrolysis is that of the chlorides of certain non-metals, e.g. $PCl_3 + 3H_2O = 3HCl + P(OH)_3$. This reaction proceeds to completion in the presence of an excess of water, and, as a rule, the chlorides of non-metals are hydrolysed more readily than those of metals. Nitrogen trichloride and carbon tetrachloride are, however, stable in the presence of water and many metallic chlorides derived from feeble electropositive metals are appreciably hydrolysed, e.g. $FeCl_3$, $BiCl_3$, &c.

2. Hydrolysis of esters. The hydrolysis of an ester may be brought about by water alone, by solutions of neutral metallic salts, by aqueous solutions of strong alkalis or acids, by water in the presence of finely divided solids, such as charcoal, and also by means of enzymes.

The reaction with water may be represented by an equation of the type:

The reaction is the reverse of esterification, and is hence a balanced bimolecular reaction; in dilute solutions, however, the mass of the water may be regarded as remaining constant, and the reaction becomes practically non-reversible. The course of the reaction can be followed by estimating the amount of free acid in the solution after given intervals of time; this is accomplished by removing an aliquot part of the solution at the given time and titrating the free acid by means of standard alkali solution. In most cases it is necessary to use a feeble alkali for titration, e.g. ammonium hydroxide using litmus as indicator, as nearly all esters which are hydrolysed appreciably by water are decomposed very readily by strong alkalis, and it becomes impossible to tell the end point of the titration when sodium or barium hydroxide solutions are used. Comparatively few esters are hydrolysed to any appreciable extent by water at the ordinary temperature, the few that have been investigated are esters derived from comparatively strong acids, e.g. methyl sulphate, ethyl formate, ethyl trichloroacetate, and ethyl pyruvate. In these cases the velocity of the reaction does not correspond with that of a simple unimolecular reaction, the values for K calculated by means of the usual equation $K = 1/t \log a/a-x$, increase as t increases, and the probable reason is that the acid formed during the hydrolysis reacts catalytically on the reaction (see under hydrolysis by acids). Hydrolysis of natural glyceryl esters by means of

superheated steam is used as a commercial method for the production of stearic acid for the manufacture of candles.

The hydrolysis of esters by means of dilute mineral acids is slow and readily lends itself to study as a time reaction. The velocity is directly proportional to the concentration of the mineral acid, i.e. probably to the hydriions which act as a catalyst, and the reaction may be represented by the differential equation

$$dx/dt = K \cdot C_{\text{Ester}} \cdot C_{H^+}$$

In dilute solution, and most esters are somewhat sparingly soluble in water, C_{H_2O} can be regarded as not changing, and C_H is also constant, since the catalyst is not used up during the reaction. The process thus becomes a typical unimolecular reaction, and the velocity constant can be determined with the aid of the usual formula $K = 1/t \log_e a/a-x$.

The catalytic activity of the acid is not entirely due to the hydriions, but also to the unionised acid (cf. art. ESTERIFICATION). E. Remstedt (*Chem. Soc. Abstr.* 1915, ii. 541) gives the following formula:

$$v = K_h Ca' + K_m C(1-a)$$

where v = rate of hydrolysis, K_h and K_m are coefficients, characteristic of the hydriion and unionised acid respectively, C is the concentration of the acid, and a is the degree of ionisation. Experiments with ethyl acetate at 25° and using various organic acids as catalysts are described, the degree of ionisation of the acids being determined by measurements of electrical conductivities of the free acids and sodium salts over a considerable range of dilution.

The concentration of the organic acid at any given time is obtained by titrating a portion of the solution with standard barium hydroxide solution and phenolphthalein (unless the ester is derived from a strong acid when ammonia and litmus are used) and subtracting from the total alkali used the amount required by the mineral acid. The following relative values have been obtained at 25°, using 0.1 N-hydrochloric acid as catalyst working with the methyl, ethyl, and propyl esters of acetic, propionic, and butyric acids:

K methyl ester : K ethyl ester = 0.97
and K ethyl ester : K propyl ester = 1.01.
K acetate ester : K propionate ester = 1.07
K propionate ester : K butyrate ester = 1.75
K butyrate ester : K valerate ester = 2.93.

From these values it is clear that in the hydrolysis of an ester $R \cdot CO \cdot OR'$ by means of a strong mineral acid the acyl group $R \cdot CO$ has a much greater influence than the alkyl group R' on the velocity of hydrolysis (Hemphill, *Zeitsch. physikal. Chem.* 1894, 13, 562). Lowenherz (*ibid.* 1894, 15, 389) working at a temperature of 40° found that ethyl formate is hydrolysed much more readily than ethyl acetate (ratio 20 : 1); that methyl and ethyl monochloroacetates are hydrolysed at much the same rates, ratio 1.01 : 1, that the ratio K ethyl acetate : K ethyl monochloroacetate = 1.7 and that K ethyl dichloroacetate : K ethyl monochloroacetate = 1.6, and that ethyl benzoate is hydrolysed extremely slowly.

As the result of experiments on the hydrolysis

of the ethyl esters of propionic, acrylic, butyric, crotonic, β -phenylpropionic, and cinnamic acids with dilute hydrochloric acid at 20°. Williams and Sudborough (Chem. Soc. Trans. 1912, 101, 412) show that the rate of hydrolysis of the ethyl ester of an $\alpha\beta$ unsaturated compared with the rate for the corresponding saturated acid is about 1 : 30. The difference is, however, not nearly so marked when an alkali (barium hydroxide) is used as hydrolysing agent.

The majority of chemists are of opinion that the process of hydrolysis consists first of all in the formation of an additive compound between

the ester and the water, *e.g.* $R\cdot C \begin{smallmatrix} \nearrow OH \\ \searrow OH \\ \searrow OEt \end{smallmatrix}$ (*cp.*

Esterification), and the subsequent breaking up of this into acid and alcohol. The manner in which the complex dissociates, *e.g.* into water and ester, or into alcohol and acid, will depend largely on the relative amounts of water and alcohol present. A view put forward by Stieglitz, and supported by many chemists (*cp.* Acree and Johnson, Amer. Chem. J. 1907, 38, 335), is that the ester, being a feeble base, combines with the strong mineral acid used as catalyst, forming a salt, *e.g.* $R\cdot CO_2Et\cdot HCl$, only small amounts of such salts would be formed, as the base is an extremely feeble one. The salt would be ionised in the usual manner into \bar{Cl} ions and complex cations $R\cdot CO_2Et\cdot H^+$. It is these complex cations which then react with the water and undergo hydrolysis

and the assumption has to be made that the hydrolysis of the complex cations proceeds more rapidly than the hydrolysis of the ester molecules. The view that it is the complex cation and not the unionised salt (ester hydrochloride) which reacts with the water is supported by the fact that the rate of hydrolysis is directly proportional to the concentration of the mineral acid, *i.e.* to the concentration of the hydron and not to the square of the concentration of the hydron.

The hydrolysis of an ester by means of an alkali hydroxide can be represented by an equation of the type :

The reaction is non-reversible, as the alkali salt cannot react directly with the alcohol, and as both ester and alkali are used up as the hydrolysis proceeds the reaction should be bimolecular. Hydrolysis by alkalis proceeds more rapidly than that by mineral acids (*cp.* Van Dikjen, Rec. trav. chim. 1895, 14, 106), and is the common method used in the laboratory. The ester is boiled for some time with an excess of sodium (or potassium) hydroxide solution in a flask fitted with a reflux condenser. If the ester is an oil only sparingly soluble in water, the completion of the reaction is denoted by the disappearance of the oily layer, unless the alcohol formed is also insoluble in water. If, however, the ester itself is soluble in water, but has a characteristic odour, the disappearance of the odour indicates complete hydrolysis. In order to separate the acid and alcohol formed, the mixture is (*a*) boiled, when the alcohol passes over together

with water, provided the alcohol is a comparatively simple monohydric one; (*b*) extracted with ether if the alcohol is complex and is not readily volatile. To obtain the acid the alkaline solute left after treatment (*a*) or (*b*) is acidified with hydrochloric acid, when the organic acid is directly precipitated if it is sparingly soluble in water, or can be extracted with ether if soluble in water.

An alcoholic solution of potassium hydroxide is sometimes used for hydrolysing purposes, especially when the ester is practically insoluble in water.

The decomposition of esters by alkaline hydroxide solutions is the basis for the usual methods for the manufacture of hard and soft soaps (*see* SOAP; SAPONIFICATION), and hence a common name for the process is 'saponification.' The common fats are glyceryl esters of monobasic acids of high molecular weight, more especially of palmitic, stearic, and oleic acids, and on saponification yield the trihydric alcohol glycerol and the sodium or potassium salts of the acids, *e.g.*

Anderson and Brown (J. Phys. Chem. 1916, 20, 195) have studied the velocity of saponification of various fats in different media; they find that the velocity is practically independent of the molecular weight of the fat, but varies considerably with the solvent and of the three used, namely, methyl, ethyl, and amyl alcohols, is greatest in amyl alcohol.

The saponification of fat occurs in stages and if insufficient alkali is used, the product is a mixture of unaltered fat with mono- and diglycerides and free fatty acid (*cf.* Fortine Chem. Zeit. 1912, 36, 1117; Marcusson, Zeitsch. angew. Chem. 1913, 26, 173).

Reicher (Annalen, 1885, 228, 257) was one of the first to determine the velocity of saponification under varying conditions. When the alkali and ester are not used in equivalent quantities the differential equation is of the type

$$dx/dt = K(a-x)(b-x)$$

where *a* and *b* are the original concentrations, and *a* - *x* and *b* - *x* the concentrations at the time *t*. When integrated this gives an equation

$$K = \frac{1}{t(a-b)} \log_e \frac{b(a-x)}{a(b-x)}$$

for calculating *K*. The concentration of the alkali at any given time is determined by titration with standard acid and the concentration of the ester calculated from that of the alkali, as with an ester of the type of ethyl acetate, the disappearance of each gram molecule of alkali entails the disappearance of a gram molecule of ester (*cf.* Warder, Amer. Chem. J. 1882, 3, 340; Ber. 1881, 14, 1311). The velocity constant *K* can be calculated by means of the equation

$$K = \frac{1}{C_{\infty}t} \log_e \frac{C_t(C - C_{\infty})}{C(C_t - C_{\infty})}$$

where *C*, *C_t*, and *C_∞* denote the concentration of the alkali just after mixing, the concentration after time *t* and the concentration after complete hydrolysis (24-48 hours).

Reicher's experiments were carried out at 9.4°, and show that the velocity is practically the same whether sodium, potassium, or calcium hydroxide is used as saponifying agent. With strontium or barium hydroxide the velocity constants are somewhat smaller and with a feeble alkali, such as ammonium hydroxide, the value for K is much less, *e.g.*

$$\frac{K_{\text{NaOH}}}{K_{\text{NH}_4\text{OH}}} = 200 : 1.$$

The results obtained by using different esters show that the alkyl group R' in the ester $\text{R}\cdot\text{C}\overset{\text{O}}{\underset{\text{OR}}{\parallel}}$ influences the rate of hydrolysis to

a greater extent than it does when mineral acids are used for hydrolysing; thus the values for K using sodium hydroxide at 9.4° are: methyl acetate 3.49, ethyl acetate 2.31, propyl acetate 1.92, isobutyl acetate 1.62, and isoamyl acetate 1.64. The influence of the acyl group R·CO is also marked, as shown by the following values for K at 14.4°, using sodium hydroxide and ethyl esters: acetate 3.2, propionate 2.8, butyrate 1.7, isobutyrate 1.73, isovalerate 0.62, and benzoate 0.83. Later experiments by Sudborough and Feilmann (Chem. Soc. Proc. 1897, 13, 243) prove that the introduction of methyl groups into the ethyl acetate molecule retards hydrolysis by means of alcoholic potassium hydroxide, whereas the introduction of chlorine atoms facilitates the decomposition. The investigations of Gyr (Ber. 1908, 41, 4308) show that two or three phenyl groups in the ethyl acetate molecule also retard hydrolysis, whereas the ethyl ester of phenylacetic acid is hydrolysed more readily than ethyl acetate itself. The results obtained by Hjelt (Ber. 1896, 29, 1864) with substituted derivatives of ethyl malonate also show that the introduction of an alkyl group into the ethyl malonate molecule retards hydrolysis, and that when two such groups are present the effect is still more noticeable. The influence of the strength of the acid from which the ester is derived also appears to be a determining factor. The investigations of Kellas (Zeitsch. physikal. Chem. 1897, 24, 243) on the hydrolysis of ethyl esters of substituted benzoic acids show that the esters of many substituted benzoic acids are hydrolysed by alcoholic potash more readily than ethyl benzoate itself. This appears to be true of all esters derived from acids much stronger than benzoic acid, *e.g.* the bromo-, chloro-, and nitro-benzoic acids, but does not hold good when the esters are derived from acids with small dissociation constants, *e.g.* the toluic acids. Kellas's results also show that when the rates of hydrolysis of a group of three isomeric esters are compared the ortho-compounds are invariably hydrolysed more slowly than the isomeric, meta-, and para-compounds, even when the ortho-acid is a much stronger acid than the isomers.

Findlay and Turner (Chem. Soc. Trans. 1905, 87, 747) and Findlay and Hickmans (*ibid.* 1909, 95, 1004) show that an α -hydroxyl group increases the readiness with which the ester is hydrolysed by alkalis. The ratio K ethyl glycolate : K ethyl acetate = 11.5; and K ethyl lactate : K ethyl propionate = 11.9; and K methyl mandelate : K methyl phenylacetate = 5.7. The introduction of a phenyl group in the α -position does not necessarily increase the

rate of hydrolysis. The ratio K ethyl phenylacetate : K ethyl acetate = 1.9, but K ethyl mandelate : K ethyl glycolate = 0.88. It is shown that there is no direct proportionality between the affinity constant of the acid and the saponification constant of its ester, although in any given series of compounds the two constants follow the same order. Palomaa (Chem. Soc. Abstr. 1914, 1, 136) shows that with esters which contain an oxygen atom in the chain (whether as OH, OR, CO, or O) the velocity of hydrolysis by mineral acids is reduced to a minimum when the oxygen atom is in the β -position with respect to the ester group. On the other hand, a cyano group always has a retarding effect on the hydrolysis of an ester by dilute hydrochloric acid, and the effect is more pronounced in the α - than in the β -position (Amer. J. Sci. 1914, [iv.] 37, 514). Drushel and Dean (*ibid.* 1912, [iv.] 34, 293) show that in the case of acetic acid the rate of hydrolysis is increased by the introduction of the hydroxy group, but retarded by an alkoxy group. The introduction of hydroxy groups into the butyric acid, on the other hand, had a retarding effect (Dean, *ibid.* 1914, [iv.] 37, 331). For hydrolysis of halogenated esters, see Drushel, *ibid.* 1912, [iv.] 34, 69; for hydroxy and alkoxy derivatives of propionic acid, *ibid.* 1913, [iv.] 35, 486. When alkali is used for hydrolysing the esters of hydroxy acids (*ibid.* 605) the esters derived from strong acids are more readily saponified than those from weak. The results obtained by different authorities point to the general conclusion that two factors at least determine the rate of hydrolysis of ethyl esters by alkalis or acids. (a) The complexity of the acyl group, especially as regards the presence of substituents in close proximity to the carbonyl group, *e.g.* in the α -position in aliphatic, the ortho-position in aromatic, and probably the cis-position in unsaturated esters. (b) The strength of the acid from which the ester is derived. When mineral acids are used as hydrolysing agents the rate of hydrolysis appears to be determined largely by the first factor, although the second factor also has an effect, as shown by the fact that ethyl trichloroacetate is hydrolysed more readily than the dichloroacetate. When alkalis are used and also probably when water alone is used, the second factor has a much more marked effect than when acids are used; the effect is so marked in certain cases that the influence of the first factor is almost completely obscured, *e.g.* with the esters of the chloroacetic acids, of the α -hydroxy acids and of nitro substituted benzoic acids.

The generalisation drawn by V. Meyer (Ber. 1895, 28, 1263; *cp.* Wegscheider, *ibid.* 2356) viz. that there is a simple relationship between the rate of hydrolysis of an ester by alkalis and its rate of formation by the catalytic method of esterification does not hold. It is highly probable that there may be a relationship between the rate of esterification of an acid by the direct method and the rate of saponification of the ester, and also a relationship between the rate of hydrolysis of the ester by acids and the rate of esterification by the catalytic method. No relationship between the rate of saponification or by hydrolysis by acids and the

constitution of the alkyl group R' in the ester $R\cdot C \begin{smallmatrix} O \\ \diagup \\ \diagdown \end{smallmatrix} \begin{smallmatrix} OR' \\ \diagdown \\ \diagup \end{smallmatrix}$, can be deduced as the data available are not sufficiently numerous.

Since sodium, potassium, and calcium hydroxides as saponifying agents have practically the same effect when solutions of equivalent strengths are used, the conclusion has been drawn that the hydrolysis is due to the hydroxyl ions present. The reaction cannot be a simple addition of the alkali to the ester followed by the elimination of alcohol, as then the reaction with calcium hydroxide would be termolecular

whereas it can be shown to be bimolecular.

It is possible that the reaction consists in the addition of water (not alkali) to the ester and the subsequent resolution of this complex into acid and alcohol. The alkali in this case would act first as a catalyst, and secondly as a base for neutralising the acid formed. According to Acree (Amer. Chem. J. 1907, 38, 344) the ester can function as a feeble acid and form small amounts of salts with the alkali, *e.g.*

and it is the complex anion which reacts with the water yielding the anion of the acid and alcohol

Esters of dibasic acids. J. Meyer (Zeitsch. physikal. Chem. 1909, 66, 81, and 67, 257) by the study of the hydrolysis of esters of dibasic acids (tartaric, succinic, and camphoric) with hydrochloric acid as catalyst, has been able to prove that the reaction proceeds in two distinct stages: (a) normal ester + water \rightarrow acid ester + alcohol; (b) acid ester + water \rightarrow acid + alcohol. With the ethyl esters of symmetrical dibasic acids, *e.g.* tartaric and succinic, the whole reaction appears to be unimolecular as the velocity constant for the first stage is almost exactly double that for the second stage, and the whole is pseudo-unimolecular. In the case of ethyl camphorate, the ester of an unsymmetrical acid, the two stages proceed at very different

rates, the normal ester, $\begin{matrix} CH_2\cdot CMe(CO_2Et) \\ | \\ CH_2\cdot CH(CO_2Et) \end{matrix} \begin{matrix} \\ \\ \end{matrix} CMe_2$, is rapidly hydrolysed to the acid ester,

but this latter is fairly stable, and the method is a convenient one for the preparation of the acid ester. For different esters of the same acid the influence of the alcoholic group on the rate of esterification is scarcely noticeable, whereas the constitution of the actyl group has a marked effect. Experiments carried out with the same esters using alkali hydroxide as hydrolysing agent show that here also the reaction proceeds in two distinct stages, but the relationship between the velocity constants of the two is not so simple as when hydrochloric acid is used. With ethyl malonate the first stage proceeds

about 100 times as quickly as the second, but with ethyl succinate the ratio is about 10 : 1, and in neither case can the whole process be represented as a simple bimolecular reaction. With the esters derived from symmetrical dihydric alcohols, *e.g.* glycol diacetate $C_2H_4(OAc)_2$, although the saponification proceeds in two distinct stages the velocity constants of the two stages bear a simple relationship to one another, *e.g.* 2 : 1, and hence the whole appears to be a bimolecular reaction. The same holds good for the hydrolysis of glyceryl triacetate, where the three distinct stages proceed at the relative rates 3 : 2 : 2.

Esters of sulphonic acids. Esters of sulphonic acids can also be hydrolysed by water, mineral acids, or alkalis, and since most of the sulphonic acids are very strong acids, their esters are hydrolysed quite readily by water alone. The esters are also converted into the corresponding acids when heated with alcohol (Krafft and Roos, Ber. 1892, 25, 2225; Kastle and Murrill, Amer. Chem. J. 1895, 17, 290), a reaction in which an alkyl ether is also formed

This decomposition proceeds slowly at the ordinary temperature, and is brought about more readily by methyl than by ethyl alcohol.

Kastle, Murrill, and Frazer (Amer. Chem. J. 1897, 19, 894) have shown that 0.1 N-solutions of sulphuric and acetic acids have no effect on the hydrolysis of esters of sulphonic acids by water. Hydrochloric and hydrobromic acids, on the other hand, have an apparent retarding effect, but this is due to the fact that the halogen hydracids can react with the ester according to the equation:

a reaction which does not affect the total acidity of the solution. A more detailed investigation has proved that this second reaction proceeds more rapidly and to a greater extent than the hydrolysis of the ester by water. The hydrolysis of a sulphonic ester by means of a large excess of water or alcohol in acetone solution gives concordant values for K when the equation for a monomolecular reaction is used. Alkalis are much more efficient hydrolysing agents than water for sulphonic esters; this may be due to the alkali acting independently of the water or to the alkali catalytically affecting the hydrolysis by water. The constants at 25° for methyl benzenesulphonate, using water and N-potassium hydroxide solution, are 1 : 90 (Wegscheider and Furcht, Monatsh. 1902, 23, 1903). When the neutral ester of a mixed carboxylic sulphonic acid is hydrolysed, *e.g.* $OEt\cdot SO_2\cdot C_6H_4\cdot CO_2Et$, the $\cdot SO_2\cdot OEt$ group is hydrolysed much more readily than the $\cdot CO_2Et$ group, and an acid ester of the type $OH\cdot SO_2\cdot C_6H_4\cdot CO_2Et$ is formed.

Esters can also be hydrolysed by water with finely divided metals as catalysts, *e.g.* Neilson (Amer. J. physiol. 1903, 10, 191) has shown that platinum black accelerates the hydrolysis of ethyl butyrate by water. The reaction is, however, very slow, and increases with the amount of platinum present. The maximum effect is obtained at 50°, and the activity of the catalyst is readily destroyed by various 'poisons.' The reaction is reversible as platinum

black can also accelerate the esterification of butyric acid in ethyl alcoholic solution.

Sabatier and Maihle (Compt. rend. 1911, 152, 494) have shown that titanium dioxide is a good catalyst for the conversion of acids and alcohols into esters. The method adopted is to allow a mixture of molecular quantities of the vapours of the two compounds to pass over a column of the dioxide kept at 280°–300°. The yield of ester is much the same as in Berthelot and Menschutkin's experiments, but the process is extremely rapid. The reaction is reversible, and using equivalent quantities of acid and alcohol an approximately 70 p.c. yield of ester was obtained in most cases examined. A similar method may also be used for hydrolysis of esters. It consists in allowing a mixture of the vapour of the ester with an excess of steam to pass over the titanium dioxide at 280°–300°.

Similar results can be obtained with thorium oxide as catalyst provided aromatic acids of the type of benzoic are used (*ibid.* 358).

Certain neutral metallic salts also act catalytically on the hydrolysis of esters by water (Kellog, J. Amer. Chem. Soc. 1909, 31, 403, 886). The salts which have been investigated are potassium chloride, bromide, and iodide. The catalytic effects are comparatively small when compared with those of strong acids, the chloride has the greatest effect and the iodide the least, and when the concentration of the salt reaches a certain value the catalytic effect is negative.

Holmes and H. C. Jones (J. Amer. Chem. Soc. 1916, 38, 105), working with aqueous solution of methyl acetate and methyl formate, show that salts with water of crystallisation have a greater effect in increasing the velocity of hydrolysis than salts which crystallise anhydrous. Certain salts such as Li_2SO_4 , NaI , SrBr_2 , LiBr_2 , LiBr , and KI produce retarding effects. On dilution the effect with salts having water of crystallisation decreases more rapidly than with salts which crystallise anhydrous, and this shows that the decomposition of the esters cannot be due to the hydrolysis of the salts alone.

Hydrolysis of halogen derivatives. The hydrolysis of chloroacetic acid $\text{CH}_2\text{Cl}\cdot\text{CO}_2\text{H}$ and of its sodium salt to glycollic acid $\text{OH}\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$ has been studied. With water at high temperatures the reaction is unimolecular and non-reversible, and when salts of the acid are used the velocity appears to be independent of the base with which the chloroacetic acid is combined. The velocity coefficients of *N*-, 0.3 *N*-, and 0.1 *N*-solutions of salts of monochloro- and monobromoacetic acids are inversely proportional to the affinity constants of the two acids. The rate diminishes with dilution and reaches a minimum at about 0.1 *N*-, and from that point to $v=1000$ the velocity of decomposition is practically constant (Kastle and Keiser, Amer. Chem. J. 1893, 15, 471).

Senter (Chem. Soc. Trans. 1907, 91, 460) has shown that *N*-solutions of hydrochloric acid and neutral salts have but little effect, and that the hydrolysis of the monochloroacetic acid is directly proportional to the concentration of the acid within wide limits. At 102° it is shown that the reaction is strictly unimolecular in dilute solution, but that slight deviations are met with in more concentrated solutions. The reaction is presumably between unionised water

and unionised acid, and when the sodium salt is used the reaction is between unionised water and both unionised salt and the anion. When sodium hydroxide is used for hydrolysis at 102° the reaction is bimolecular in dilute solutions, although deviations are met with in more concentrated solution, and the reaction with the alkali proceeds some 10 times as fast as with water alone. For comparison of rates of various α -bromo acids and sodium salts, *cp.* Chem. Soc. Trans. 1909, 95, 1835. The velocity reaction between the sodium salt of the acid and water is appreciably increased by the introduction of methyl and ethyl groups into the acid molecule, whereas the reaction between the sodium salt and sodium hydroxide is retarded by the presence of alkyl substituents.

The esters of imino acids can be hydrolysed in two different ways :

The former reaction is enormously accelerated by acids and the latter by alkalis. According to Steiglitz (Amer. Chem. J. 1908, 39, 29, 166) the former reaction consists in the hydrolysis of the complex cation $\text{R}\cdot\text{C}(\text{NH})\cdot\text{OR}^+\cdot\text{H}$, and the latter in the decomposition of the anion $\text{R}\cdot\text{C}(\text{N})\cdot\text{OR}'$. The effect of alkalis is much more pronounced than that of acids. When water alone is used it is the non-ionised ester which is decomposed.

3. Hydrolysis of acyl derivatives. The chlorides, amides, anilides, and anhydrides of organic acids can be hydrolysed in much the same manner as esters, *e.g.*

As a rule the derivatives of aliphatic acids are hydrolysed more readily than those derived from aromatic acids, *e.g.* acetamide more readily than benzamide. The hydrolysis is usually effected by boiling with alkali hydroxide, but the presence of ortho- substituents in derivatives of benzoic acid retards hydrolysis to an appreciable extent (V. Meyer, Ber. 1894, 27, 2153; Sudborough, Chem. Soc. Trans. 1894, 65, 1030; 1895, 67, 587; 1897, 71, 229; Reed, Amer. Chem. J. 1899, 21, 281). When two such substituents are present the amide cannot be hydrolysed by boiling with potassium hydroxide solution, but the hydrolysis may be accomplished by heating with concentrated hydrochloric or hydrobromic acid under pressure in sealed tubes. One of the most convenient methods for converting a diortho- substituted benzonitrile into the corresponding acid is to hydrolyse to the amide $\text{R}\cdot\text{CN} + \text{H}_2\text{O} = \text{R}\cdot\text{CO}\cdot\text{NH}_2$ by heating at 120°–130° with 90 p.c. sulphuric acid, and when cold to replace the amino group by hydroxyl by the addition of sodium nitrite solution (Bouveault, Bull. Soc. chim. 1892, [iii.] 9, 368; Sudborough, Chem. Soc. Trans. 1895, 67, 602).

The hydrolysis of acetamide by hydrochloric acid has been studied by Acree and Nirdlinger (Amer. Chem. J. 1907, 38, 489). The amount of hydrolysis after given intervals of time was determined by introducing known volumes of the reaction mixture into a Lunge nitrometer

containing sodium hypobromite solution and measuring the nitrogen evolved. Their results show that at 65° the reaction is practically unimolecular when dilute solutions are used, but that the values for K tend to increase with the time, probably owing to a slight catalytic effect of the ammonium chloride formed on hydrolysis. These chemists conclude that the hydrolysis of an acid amide by mineral acids is analogous to the hydrolysis of an ester or the inversion of cane sugar by acids, and that the first stage consists in the formation of a small amount of salt between the acid and the amide, the final stage consisting in the hydrolysis of the complex cation derived from the salt.

Crocker and Lowe (Chem. Soc. Trans. 1907, 91, 593, 952) have studied the hydrolysis of the amides of the simple aliphatic acids with hydrochloric acid, and also with sodium hydroxide solution, using the electrical conductivity method in order to determine the amount of amide hydrolysed. The order of the amides when hydrochloric acid is used is formamide, propionamide, acetamide, isobutyramide, capronamide, butyramide, and valeramide; but with sodium hydroxide the order is formamide, acetamide, propionamide, capronamide, butyramide, isobutyramide, and valeramide, in both cases formamide is the amide most readily hydrolysed, and in every case the hydrolysis with alkali proceeds more rapidly than that with hydrochloric acid under similar conditions.

The hydrolysis of an aliphatic nitrile by either acids or alkalis occurs in two distinct stages, the intermediate product being the acid amide. The first reaction takes place much more slowly than the second, and is the one actually measured when hydrochloric acid is used as catalyst (Kilpi, Zeitsch. physikal. Chem. 1914, 86, 641; for alkaline hydrolysis *cf. ibid.* p. 740).

E. Fischer (Ber. 1898, 31, 3266) has pointed out that uric acid and similar cyclic nitrogen derivatives are less readily hydrolysed by dilute alkalis than their alkylated derivatives, *e.g.* 1:3:9-trimethyl uric acid. Similarly the amide and methyl ester of the methyl ether of salicylic acid are more readily hydrolysed than the corresponding derivatives of salicylic acid itself, and in all such cases the compounds most resistant to the hydrolysing agent are those which can form metallic salts with the alkalis.

These facts support Stieglitz's view that in hydrolysis by alkalis a salt of the alkali and amide (or ester) is formed and that the complex anion of this salt undergoes hydrolysis. When the amide or ester contains a replaceable hydrogen atom, salt formation of a different type occurs, and the characteristic complex anion is not formed.

Most compounds of the type of alkylated acid amides, *e.g.* compounds containing the grouping: $\text{C}\cdot\text{C}\equiv\text{N}\cdot\text{H}\cdot\text{C}$, can be hydrolysed.

Thus hippuric acid (benzoylglycine)

is hydrolysed to benzoic acid and glycine hydrochloride when boiled with concentrated hydrochloric acid. The hydrolysis of naturally occurring protein derivatives by means of acids or alkalis consists in the addition of water to such groups and the subsequent resolution into simpler cleavage products, ultimately into amino acids (*see* PROTEINS). (For hydrolysis of sulphonic acids, *cp.* Crafts, Bull. Soc. chim. 1907, [iv.] 1, 917.)

4. Hydrolysis of di- and poly-saccharoses. As a rule compounds of the ether type, *i.e.* compounds containing two alkyl or substituted alkyl groups attached to oxygen, are not readily hydrolysed when boiled with alkali or acid solutions.

All the carbohydrates of the di- or poly-saccharose type take up water when warmed with dilute mineral acid and are resolved into mono-saccharoses. The best known examples are:

All these reactions can be represented by the equation:

Starch is also hydrolysed by dilute mineral acids yielding as final product dextrose:

The hydrolysis of cane sugar (sucrose) by means of dilute mineral acid has been examined in detail; it is usually referred to as the inversion of sucrose, as the optical rotatory power changes from + to - during the reaction. The investigations of Wilhelm (Pogg. Ann. 1850, 81, 413, 499) proved that in dilute solution the amount of sugar inverted is proportional to the amount present, or, in other words, the reaction is unimolecular. The method of determining the concentration of the sucrose at any given time is based on polarimetric readings. If the original rotation of the sucrose solution be $+x^\circ$, and after complete inversion be $\frac{1}{2}-y^\circ$, then the total change is $x+y^\circ$. If after an interval of time t the rotatory power of the solution is $+z^\circ$, then the fraction of sucrose which has undergone inversion is $\frac{x-z}{x+y}$, and the velocity constant can be determined by substituting the values for t , C_0 , and C_t in the equation

$$K = 1/t \log_e C_0/C_t$$

where C_0 represents the concentration of the sucrose at the beginning, and can be expressed by $x+y$, C_t represents the concentration at time t , and is equal to $x-z$. The velocity of inversion is directly proportional to the concentration of the hydrochloric acid, and increases with rise in temperature. J. Meyer (Zeitsch. physikal. Chem. 1908, 62, 59) states that the reaction between sucrose and dilute mineral acid is not a simple unimolecular reaction, but is complicated by the mutarotation of the glucose and fructose.

Hudson (J. Amer. Chem. Soc. 1908, 30, 1165), on the other hand, claims that the reaction is typically unimolecular, and that the question

of mutarotation does not arise, as both the α -glucose and α -fructose first formed undergo mutarotation immediately in the presence of the acid, giving the usual rotatory values for invert sugar. Even in the earlier readings deviations from the unimolecular reaction are not encountered (*cf.* also Rosanoff, Clark and Sibley, *J. Amer. Chem. Soc.* 1911, 33, 1911).

The hydrolysis of other di-saccharoses, and even of glucosides by dilute mineral acids, also follows Wilhelm's Law, but the relative rates are very different; the following values have been obtained for *N*-sulphuric acid at 20°: lactose 1, maltose 1.27, sucrose 1240; or again α -methylglucoside 100, and β -methylglucoside 179. The hydrolysis of carbohydrates by means of dilute mineral acids is the basis of certain commercial methods for the manufacture of glucose. Large quantities of this carbohydrate are manufactured by boiling starch (*e.g.* potato or maize starch) with dilute sulphuric acid, removing the acid by precipitating as calcium sulphate and evaporating the clear solution under reduced pressure.

Neutral salt action. The investigations of Ostwald (*J. pr. Chem.* 1883, [ii.] 28, 460), Spohr (*ibid.* 1886, [ii.] 33, 265), and Arrhenius (*Zeitsch. physikal. Chem.* 1889, 4, 234; 1899, 31, 207) prove that the addition of a substance which is largely ionised in aqueous solution accelerates the hydrolysis of esters or of carbohydrates by aqueous solutions of strong acids. This has been proved by the addition of metallic chlorides to mixtures in which hydrogen chloride is the catalyst, the addition of bromides to hydrogen bromide, and of nitrates to nitric acid. The majority of chlorides have much the same effect if readily ionised, whereas a salt such as mercuric chloride, which is only partially ionised, has a much feeble action. Non-electrolytes, such as methyl and ethyl alcohols have but little effect on the hydrolytic activity of hydrogen ions. The neutral salt action has been shown to be independent of the concentration of the compound hydrolysed, and is stated to be proportionately greater the more dilute the acid solution, but Lunden (*Med. Nobel Institut.* 1910, 2) disputes this statement.

Caldwell (*Proc. Roy. Soc.* 1906, A, 78, 272), working with weight normal solutions, shows that the presence of metallic chlorides increases the catalytic activity of hydrogen chloride on the inversion of cane sugar, and that calcium chloride has the most pronounced effect. Similar effects on the activity of nitric acid are produced by nitrates (Whymper, *ibid.* 1907, A, 79, 576). Salts also tend to increase the activity of hydrogen chloride when used as a catalyst in the hydrolysis of methyl acetate (Armstrong and Watson, *ibid.* 1907, A, 79, 579), but their effect is not so marked as in the case of the inversion of sucrose (*cp.* Armstrong, *ibid.* 1908, A, 81, 90; Armstrong and Crothers, *ibid.* 102). According to Armstrong and Caldwell the salts act by removing part of the water in the form of definite hydrated compound, and in this manner increase the concentration of the reacting substance. Senter (*Chem. Soc. Trans.* 1907, 91, 462) is of opinion that this view cannot be correct, as the relative neutral salt action of different salts is not that of their ordinary degree of

hydration (*cf.* chlorides and nitrates), and as in equivalent solutions the effect is practically independent of the nature of the salt (*cp.* Jones, *Zeitsch. physikal. Chem.* 1906, 55, 355, 429). A further argument used by Senter is that whereas rise of temperature affects hydration to an appreciable extent, alteration of temperature has but little effect on neutral salt action. It is concluded that probably the earlier suggestion of Arrhenius is correct, namely, that the ions of the neutral salt have some action on the hydrons or hydroxyl ions of the catalyst.

Reed (*Amer. Chem. J.* 1899, 21, 342) states that neutral salts retard the hydrolysis of acid amides by alkalis; and Arrhenius (*Zeitsch. physikal. Chem.* 1887, 1, 110) and Spohr (*ibid.* 1888, 2, 1194) claim that the same effect is produced by salts on the rate of hydrolysis of esters by alkalis. Senter, on the other hand (*l.c.* 473), shows that they accelerate the hydrolysis of sodium chloroacetate by sodium hydroxide. Since neutral salts have no effect on the decomposition of sodium chloroacetate by water, it is claimed that the effect of the salts cannot be due to their action on the reacting substance (the chloroacetate), and probably is due to their action on the hydroxyl ions (*cf.* *Zeitsch. physikal. Chem.* 1910, 70, 517).

5. Hydrolysis by enzymes. Many of the hydrolytic processes induced by aqueous solutions of acids or alkalis can also be brought about by certain complex organic substances found in animal and plant tissues. Such substances are termed unorganised ferments or *enzymes*; they act not merely as catalysts in processes of hydrolysis, but certain of them induce processes of oxidation—the oxidases—and others can effect complex decompositions as exemplified by the decomposition of glucose into ethyl alcohol and carbon dioxide under the influence of zymase. The enzymes are somewhat unstable, nitrogenous, organic compounds of colloidal nature, but not necessarily proteins; they act as catalysts, in the majority of cases as positive, but in a few as negative catalysts. The catalytic nature is shown by the fact that the rate of reaction is directly proportional to the concentration of the catalyst, but that the total decomposition is the same whatever the amount of catalyst used, provided sufficient time is allowed, and provided the enzyme does not undergo decomposition owing to secondary reactions. One of the most characteristic proofs of their catalytic nature is due to Henri, who showed that when sugar was added after given intervals of time to a solution in which cane sugar was undergoing hydrolysis by invertase, the added sugar in each case began to be inverted by the enzyme at a rate irrespective of the amount already decomposed. Unlike most inorganic ferments the enzymes are sensitive to high temperatures; thus when heated to just below 100° their activity is completely destroyed; they are, however, resistant towards certain antiseptics which destroy protoplasm and kill fermenting organisms. A colloidal solution of an enzyme can often be prepared free from living organisms by treatment with a mild antiseptic, *e.g.* toluene, and filtration through a porous clay filter. Strong antiseptics such as formaldehyde are to be avoided, as they tend to destroy the enzyme also. A study of enzyme action is often

complicated by the fact that it is impossible to isolate, in a state of purity, the particular enzyme required, and it may be accompanied by another enzyme capable of causing the destruction (autolysis) of the first, and thus bringing the reaction to an end long before all the substrate is decomposed.

The name given to a particular hydrolysing enzyme usually indicates the substance it is capable of hydrolysing and in all cases the termination *ase* is used. Thus maltase is the enzyme which hydrolyses maltose, amylase the enzyme which hydrolyses starch; but in some cases older names which were in use before this scheme was adopted, are still retained, *e.g.* sucrose, the enzyme which inverts sucrose (cane sugar), is still called invertase or even invertin, the common digestive enzymes are termed trypsin and pepsin. The substance which is decomposed by the enzyme is usually termed the substrate.

Although the processes of hydrolysis by acids and by enzymes are frequently compared it should be borne in mind that the rate at which a given substance is hydrolysed by the two different types of catalysts is frequently quite different, *e.g.* sucrose is hydrolysed by invertase much more readily than by a *N*-solution of hydrochloric acid; in fact, with a concentrated solution of invertase at 0° the inversion is practically instantaneous. It is not essential that the products obtained by the two processes should be identical. Thus in the case of the inversion of cane sugar by invertase the products are α -glucose and α -fructose, whereas when mineral acids are used the products are equilibrium mixtures of α - and β -glucose and α - and β -fructose, as the α -glucose and the α -fructose undergo immediate mutarotation in the presence of the mineral acid. Another example of a similar type is met with in the tri-saccharose, raffinose; when hydrolysed by acids this yields galactose, fructose, and glucose, the same sugar with raffinase yields melibiose and fructose, and with emulsin it yields galatose and sucrose. Similarly natural products of protein character yield comparatively simple amino acids when hydrolysed with acids or alkalis, whereas with enzymes more complex intermediate products are formed.

An important point of difference between hydrolysis by means of acids or alkalis and hydrolysis under the influence of enzymes is that any particular enzyme has a very restricted use as a catalyst or the action of enzymes is essentially selective. Thus lipase can hydrolyse esters and not carbohydrates; maltase can hydrolyse maltose but not sucrose. That a slight difference in the configuration of two isomeric compounds is sufficient to affect their reactivities with a particular enzyme is shown in the case of the two stereoisomeric α -methylglucosides. (For further details, see art. FERMENTATION.) Further examples are met with among the numerous polypeptides prepared within recent years (*cp.* Fischer and Bergell, Ber. 1903, 36, 2592; 1904, 37, 3103; Fischer and Abderhalden, Zeitsch. physiol. Chem. 1905, 46, 52; 1907, 51, 264).

The behaviour of some of the natural and artificial glucosides (see GLUCOSIDES) towards the two enzymes maltase and emulsin has been

made use of in determining their configurations. Thus maltose, which is hydrolysed by maltase but not by emulsin, is regarded as an anhydride of α -glucose, having a configuration similar to that of the α -methylglucoside; most of the natural glucosides, on the other hand, are hydrolysed by emulsin, but not by maltase, and therefore are probably analogous to β -methylglucoside. As a rule a natural glucoside is accompanied in the plant tissue by the enzyme which is able to hydrolyse it. The commonest glucosidoclastic enzymes, *i.e.* enzymes capable of hydrolysing glucosides are emulsin (β -glucase), myrosin, which hydrolyses sulphur glucosides, rhamnase, and tannase.

The products formed by the hydrolysis of naturally occurring compounds by enzymes are various; thus the natural glucosides can give rise to sugars, alcohols, phenols, aldehydes, acids, mustard oils, anthracene derivatives, indigo, &c.

It has been proved in many cases that a specific enzyme can act not merely as a hydrolysing, but also as a synthesising agent. The process of hydrolysis is thus, in certain cases, a balanced reaction, but the equilibrium is mainly in the direction of analysis and not synthesis. The synthesising activity of an enzyme was first demonstrated by Croft Hill (Chem. Soc. Trans. 1898, 73, 634; 1903, 83, 578) in the case of maltase. The greater portion of the maltose is hydrolysed by the enzyme to glucose, but a certain proportion of di-saccharose is always present.

A series of alkyl- β -glucosides and galactosides has been synthesised by Bourquelot using emulsin or α -glucosides by an enzyme extracted from bottom yeast by means of water (Ann. Chim. 1913 [viii.], 29, 145; 1915 [ix.], 3, 287; 1915 [ix.], 4, 310; *cp.* also Bayliss, J. physiol. 1913, 46, 236).

Bayliss has synthesised arbutin from quinal and dextrose by means of emulsin in the presence of glycerol (Chem. Soc. Abs. 1912, 1, 328) The synthetic action of enzymes in forming polypeptides and proteins has also been demonstrated (Abderhalden, Chem. Soc. Abs. 1915, 1, 725).

According to Bayliss (J. physiol. 1915, 50, 85) the reaction occurs at the interface of contact between the solid enzyme phase and the liquid substrate phase, as when many of them are filtered the filtrate is inactive, but the solid active.

Emulsin and lipase have also been shown to possess synthesising properties; in the latter case natural fats have been synthesised by the action of lipases on mixtures of glycerol and the higher fatty acids in the absence of a large excess of water. The lipatic enzymes present in certain seeds are made use of on a commercial scale for the preparation of fatty acids from natural fats (*cp.* Welter, Zeitsch. angew. Chem. 1911, 24, 385; Pottevin, Bull. Soc. chim. 1906, [iii.] 35, 693). For details of the synthetic functions of enzymes, see art. FERMENTATION.

In some of these balanced actions between carbohydrates or esters and enzymes it has been shown that the equilibrium mixture is the same, whether mineral acid or enzyme is used, *e.g.* Visser's experiments using invertase and emulsin;

in other cases, however, the equilibrium mixture with the enzyme is quite different from that obtained when an acid is used, *e.g.* Dietz's experiments with lipase and *iso*-amyl *n*-butyrate (*Zeitsch. physiol. Chem.* 1907, 52, 279).

A considerable amount of work has been done on the velocities of different reactions in which enzymes play a part. Henri (Lois general de l'action des diastases, 1903) and others claim that the rate of inversion of sucrose by invertase, unlike that by mineral acids, does not agree with the unimolecular formula. The investigations of O'Sullivan and Tompson (*Chem. Soc. Trans.* 1890, 57, 834) and of Hudson (*J. Amer. Chem. Soc.* 1908, 30, 1160, 1564; 1909, 31, 655) prove conclusively that the unimolecular formula holds for any given solution, if the birotation of the α -glucose and α -fructose first formed is taken into consideration. The complications attending the mutarotation of the glucose and fructose can be avoided by adding a small amount of alkali, *e.g.* 10 c.c. of 0.4 *N*-sodium carbonate solution for each 100 c.c. of sugar solution, a short time before the polarimetric reading is taken. The alkali stops the hydrolysis and rapidly brings about equilibrium between the α - and β -glucoses and α - and β -fructoses, so that the normal rotatory power of invert sugar is given. Hudson's results clearly prove that the α -modifications of glucose and fructose are first formed, and that these are stable in the presence of enzyme, but rapidly undergo mutarotation in the presence of a little alkali. Hudson's experiments also show that a trace of hydrochloric acid, *e.g.* 0.0006 *N*-, accelerates the action of the invertase to an appreciable extent.

The decomposition of the cane sugar is directly proportional to the concentration of the enzyme, and in very dilute solutions (under 5 p.c.) is also proportional to the concentration of the sugar, but with more concentrated solutions it is not even approximately proportional, but decreases and becomes practically zero in the strongest solutions. According to O'Sullivan and Tompson, and to Hudson, the diminution in the velocity in concentrated solutions is due principally to the viscosity of the medium; it may also be partly due to the formation of a definite compound between the sugar and enzyme. According to A. J. Brown (*Chem. Soc. Trans.* 1902, 81, 373) a given quantity of invertase decomposes a nearly constant weight of sugar in unit time (*i.e.* the decomposition is independent of the sugar concentration), provided the solution is moderately concentrated; but after an appreciable amount of sugar is decomposed the further inversion is directly proportional to the concentration of the sugar. This change of velocity from a linear to a logarithmic period is in harmony with the view that the sugar unites with the enzyme, and that it is the additive compound which is hydrolysed, and that the enzyme thus liberated immediately combines with a further amount of sugar. *Cp.* the hydrolysis of milk sugar by enzymes (*E. F. Armstrong, Proc. Roy. Soc.* 1904, 73, 500).

The reaction between salicin and water in the presence of emulsin is also a unimolecular reaction (Hudson and Paine, *J. Amer. Chem. Soc.* 1909, 31, 1242), provided alkali is added to

bring about mutarotation of the β -glucose, which is the primary product

The ester splitting enzyme contained in castor seeds is probable a mixture of two distinct enzymes: (a) an esterase which is soluble in water and which hydrolyses ethyl butyrate more readily than glyceryl esters; (b) a true lipase which is almost insoluble in water and which hydrolyses glyceryl esters more readily than ethyl butyrate (Falk and Sugiura, *J. Amer. Chem. Soc.* 1913, 35, 1904; 1915, 37, 217).

The reaction between lipase and *iso*amyl butyrate or between the same enzyme and *iso*amyl alcohol and *n*-butyric acid in the presence of a large excess of alcohol is a normal unimolecular reaction, although it proceeds in a heterogeneous medium. Dietz concludes that the reaction takes place in the solid phase, and that the diffusion of the ester or acid into the colloidal enzyme takes place so rapidly when compared with the velocity of reaction that the rates of diffusion do not affect the determination of the velocity of the reaction.

The hydrolysis of ethyl butyrate by lipase (Pierce, *J. Amer. Chem. Soc.* 1910, 32, 1517) points to the formation of an additive compound of the ester and enzyme. In many other cases the velocity relationships are not so simple. In some of these the reaction is retarded after a certain time owing to the product or products formed combining with the enzyme, or to negative autocatalysis, or to the gradual destruction of the enzyme.

In the reaction between pepsin and albumen the amount of albumen transformed in given time by different amounts of pepsin is proportional to the square root of the pepsin concentrations. The same relationship holds good with regard to trypsin and albumen, and is due to the fact that the velocity is inversely proportional to the amount of substance transformed, and this points to the formation of a definite compound between the enzyme and one of the products.

Most decompositions by enzymes are characterised by a high temperature coefficient when compared with catalytic reactions in which acid or alkali is used. In the latter case the coefficient is about 2-3 for a rise of 10°; with emulsin, however, the coefficient is 7.14 for a rise from 60° to 70°, with trypsin 5.3 for a rise from 20° to 30°; but like most colloidal catalysts enzymes exhibit an optimum temperature, at which the activity is greatest, and then falls again with further rise of temperature. This may be due to the coagulating effects which a moderately high temperature usually has on the majority of colloids.

In certain cases it has been found possible to obtain by dialysis from a given enzyme two portions, a dialysate and a residue; neither portion alone is active, but the hydrolytic activity is restored when the dialysate is added to the dialysed residue. This residue is decomposed when boiled with water, and is the enzyme proper, whereas the dialysate is not decomposed when boiled and contains the co-enzyme (*see art. FERMENTATION*). In the case of liver lipases it has been proved that both

enzyme and co-enzyme are essential for the hydrolysis of esters, and it has also been proved that the co-enzyme is a metallic salt of taurocholic acid. In living tissues a number of complex substances are present which are capable of interfering with the specific action of an enzyme. These are termed anti-enzymes; some are normally present in tissues, others appear to be formed when an enzyme is injected into the tissue.

A view generally held with regard to the mechanism of enzyme reaction is that compounds perhaps of the type of 'absorption compounds' (Bayliss) are formed between the enzyme and substrate, and that the absorbed material then reacts with water (*see art. FERMENTATION*). The fact that a specific enzyme can hydrolyse only certain particular substrates is in harmony with this view, as it is known that chemical constitution plays an important part in absorption phenomena (Zung, *Arch. inter. Physiol.* 1907, 5, 245; Hedin, *Bio-Chem. J.* 1907, 2, 112; Acree, *J. Amer. Chem. Soc.* 1908, 30, 1755; *cp.* also Freundlich, *Zeitsch. physikal. Chem.* 1907, 57, 385).

6. Alcoholysis. Reactions in which alcohols play much the same part as water in hydrolysis are usually grouped together under the name alcoholysis. The reaction with methyl alcohol is termed '*methanolysis*,' and that with ethyl '*ethanolysis*.'

The ethanolysis of an acid amide in the presence of a mineral acid is analogous to the hydrolysis of the amide by dilute mineral acids as shown by the two equations:

The latter reaction has been studied in detail by Reed (*Amer. Chem. J.* 1909, 41, 483). The reaction is bimolecular as the catalyst is gradually neutralised by the ammonia formed in the reaction, and proceeds at an easily measurable rate at 50° in the case of benzamide. A comparison of the values of K for *p*- and *m*-nitrobenzamide shows that this is 1.16, a value practically identical with the ratio for the hydrolysis of the two amides. The ratio of the constants for benzamide and *m*-nitrobenzamide varies considerably with the concentration of the hydrogen chloride. The presence of small amounts of water on the rate of alcoholysis is also marked, just as in the case of the esterification of an acid, and similarly ortho-substituents appear to have inhibiting effects. The general conclusion drawn is that the mechanism of alcoholysis is analogous to that of hydrolysis, and consists in the formation of salts between the amide and the mineral acid and the reaction of the complex cation with the alcohol.

Another common type of alcoholysis met with is the conversion of an ester of a given acid into another ester of the same acid by means of an alcohol, *e.g.* :

This change does not take place readily except in the presence of a catalyst, the most efficient

being sodium alkyl oxide (Purdie, *Chem. Soc. Trans.* 1885, 47, 862; 1887, 51, 627; 1888, 53, 391; Claisen, *Ber.* 1887, 20, 646), hydrogen chloride (Patterson and Dickinson, *Chem. Soc. Trans.* 1901, 79, 280), sodium hydroxide (Henriques, *Zeitsch. angew. Chem.* 1898, 338; Pfannl. *Monatsh.* 1910, 31, 301; Kommenos, *ibid.* 1910, 31, 111, 687; 1911, 32, 77; Kremann, *ibid.* 1905, 26, 783; 1908, 29, 23) or ammonia (Leuchs and Theodorescu, *Ber.* 1910, 43, 1239). As a rule only a small amount of the catalyst need be used, but with the esters of aromatic acids saturation with hydrogen chloride is necessary. The reaction appears to be reversible, as it is possible to transform an ethyl into a methyl and conversely a methyl into an ethyl ester. The reaction is not limited to methyl and ethyl esters, but can be applied to more complex esters, such as benzyl and phenyl, and also to glyceryl esters (*cp.* Haller, *Compt. rend.* 1906, 143, 657; 1908, 146, 259; Fanto and Stritar, *Monatsh.* 1908, 29, 299), and is a most convenient laboratory method for the conversion of a given ester into another ester derived from the same acid. The esters of the great majority of aliphatic and aromatic acids react in this manner, but Sudborough and Edwards have shown that when the esters are derived from diortho-substituted benzoic acids the transformation cannot be affected by using either sodium alkyl oxide or saturating with hydrogen chloride and boiling for some time. Even when several substituents are present transformation occurs, provided the ortho-positions are free. This indicates that the transformation of esters under the influence of hydrogen chloride is analogous to the esterification of an acid by the same catalyst.

This analogy has been further confirmed by determining the rates of alcoholysis of various esters. These changes cannot be measured by a simple chemical method as in the case of esterification or hydrolysis, but use has been made of the volume changes which occur and the results obtained by dilatometric readings at constant temperature indicate that with an excess of the alcohol and using hydrogen chloride as catalyst the reaction

is practically unimolecular. The steric effects are very similar to those met with in the case of catalytic esterification (Kolhatkar, *Chem. Soc. Trans.* 1915, 107, 921). (*See ESTERIFICATION.*)

Similar transformations can be brought about in the case of the alkyl ethers of carbonium

Chem. 1890, [ii.] 45, 182), and of the oxygen ethers of substituted thiocarbamides, *e.g.*

(Johnson and Guest, *J. Amer. Chem. Soc.* 1910, 32, 1279). *Comp.* also Kuntze (*Arch. Pharm.* 1908, 246, 110). An interesting case of alcoholysis observed by Willstätter and Stoll (*Annalen*, 1910, 378, 18) is the conversion of amorphous chlorophyll into crystalline chlorophyll by ethyl alcohol in the presence of an enzyme 'chlorophyllase,' which accompanies chlorophyll in plant tissues. The reaction consists in the

replacement of the complex phytyl group by the simpler ethyl group

For alcoholysis of acid amides and thioamides using mercaptans instead of alcohols, see Reed, Chem. Soc. Abstr. 1913, 1, 975.

J. J. S.

HYDROMAGNESITE. Hydrated basic carbonate of magnesium, $3\text{MgCO}_3\cdot\text{Mg}(\text{OH})_2\cdot 3\text{H}_2\text{O}$, occurring as small, acicular, or bladed (orthorhombic or monoclinic) crystals, but more often as white, earthy, or chalky masses. It is a mineral of secondary origin, and usually occurs as veins in serpentine, from which it has been derived. It is softer and less heavy (sp.gr. 2.16) than magnesite. When calcined it can be used for the same purposes as magnesite (*q.v.*). A large deposit is quarried at Atlin, in British Columbia (for analyses, see G. A. Young, Sum. Rep. Geol. Survey, Canada, 1915); and there is a considerable quantity available at a spot 93 miles north of Ashcroft, in the Lillooet district of British Columbia. Several occurrences are known in California. It is also found with the massive magnesite of Eubœa in Greece.

HYDROMETER *v.* SPECIFIC GRAVITY.

HYDROPHANE *v.* OPAL.

HYDROPYRIN. A trade name for sodium acetylsalicylate. *v.* SYNTHETIC DRUGS.

HYDROQUINONE, HYDROTOLUQUINONE *v.* PHENOL AND ITS HOMOLOGUES.

HYDROQUINONE CARBOXYLIC ACID *v.* PROTOCATECHUIC ACID.

HYDROSOLS *v.* COLLOIDS.

HYDROSULPHITES *v.* SULPHUR.

HYDROXYACETOPHENONES *v.* KETONES.

HYDROXY ACIDS. *Oxy acids.* The organic hydroxy acids are derived from the corresponding non-hydroxylated acids by the replacement of one or more hydrogen atoms in the hydrocarbon radicle of the acid by the same number of hydroxyl groups. According as the hydroxyl group is introduced into a fatty radicle or into a benzenoid radicle, the resulting acid is an alcohol-acid or a phenol-acid.

HYDROXY ACIDS OF THE ALIPHATIC SERIES.

There are several groups of hydroxy acids of the aliphatic series and these will be discussed *seriatim*.

I. Monohydroxymonocarboxylic acids

$\text{C}_n\text{H}_{2n}\text{OH} \cdot \text{CO}_2\text{H}$. The most important members of this group are glycollic, lactic, hydracrylic, hydroxybutyric, and hydroxystearic acids (*q.v.*). They occur naturally, *e.g.* glycollic acid in unripe grapes and in the leaves of *Ampelopsis* (*Vitis*) *hederacea* (D. C.), lactic acid in the juice of the muscles, in sour milk, in pickles and in the gastric juice.

General methods of preparation.

(i) By the careful oxidation of diprimary, primary secondary, and primary tertiary glycols with dilute nitric acid or with platinum black and air, *e.g.* lactic acid from glycol.

(ii) By the reduction of aldehyde acids, ketonoids, and dicarboxylic acids with sodium amalgam or with zinc and hydrochloric or sulphuric acids, *e.g.* lactic acid from pyro-

racemic acid and glycollic acid from oxalic acid.

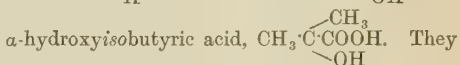

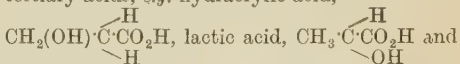

(iii) By boiling monohalogen fatty acid with silver oxide, alkali, or with water or by distilling them, *e.g.* glycollic acid from monochloroacetic acid; hydracrylic acid from β -chloropropionic acid; γ -butyrolactone from γ -chlorobutyric acid.

(iv) By the action of nitrous acid on amino acids of the fatty series, *e.g.* glycollic acid from glycine.

(v) By the action of hydrogen cyanide followed by hydrochloric acid on aldehydes, ketones, and glycolchlorhydrins, *e.g.* lactic acid from acetaldehyde; hydracrylic acid from glycolchlorhydrin.

(vi) By treating unsaturated acids with hydrobromic acid, or with dilute sulphuric acid or by distilling them, *e.g.* γ -valerolactone from allylactic acid.

Properties.—These acids may be subdivided into three groups, primary, secondary, and tertiary acids, *e.g.* hydracrylic acid,

also exhibit differences in their properties depending on the position of the hydroxyl group in the molecule, *i.e.* whether they are α -, β - or γ -hydroxy-acids. They are more soluble in water, but less soluble in ether than the corresponding fatty acids. They are also less volatile and, as a rule, cannot be distilled unchanged.

General reactions.

(i) Like the fatty acids they yield through change in the carboxyl group normal salts, esters, amides, and nitriles.

(ii) Like the alcohols, the hydrogen of the hydroxyl group may be replaced by alkali metals or by alkyl groups; also by the action of acyl chlorides or of a mixture of concentrated nitric and sulphuric acids, acid radicles or the nitro group may be substituted for it.

(iii) Phosphorus pentachloride replaces the two hydroxyl groups by chlorine, *e.g.* glycollic acid yields chloracetylchloride.

(iv) Hydriodic acid reduces the hydroxy acids to the corresponding fatty acids, *e.g.* propionic acid from lactic acid.

In the above reactions the hydroxy acids behave similarly, but on oxidation or by the application of heat, these acids show great differences.

(v) On oxidation these acids yield different products, according to whether they are primary, secondary, or tertiary acids.

(a) Primary acids yield aldehyde acids and dibasic acids, *e.g.* glycollic acid yields glyoxylic and oxalic acids.

(b) Secondary acids yield ketonic acids; the α -ketonic acids change to aldehyde and carbon dioxide, the β -ketonic acids to ketones and carbon dioxide, *e.g.* lactic acid yields pyruvic acid, which changes into acetaldehyde and carbon dioxide.

(c) Tertiary α -hydroxy acids yield ketones, *e.g.* α -hydroxyisobutyric acid yields acetone.

(vi) By the application of heat, differences

in deportment are shown by these acids, according as they are α -, β -, or γ -hydroxy acids.

(a) α -Hydroxy acids lose water and become cyclic double esters—the lactides, e.g. lactic acid becomes lactide, two molecules of the acid condensing with the loss of two molecules of water.

(b) β -Hydroxy acids lose water and become unsaturated acids, e.g. hydracrylic acid becomes acrylic acid.

(c) γ - and δ -Hydroxy acids lose water at the ordinary temperature and change more or less completely into simple cyclic esters—lactones.

II. Aldehyde acids. Formic acid is the simplest member of this group of acids, and also of the fatty acid series. The next member is glyoxylic acid, $\text{CHO} \cdot \text{CO}_2\text{H}$. Its claim to be considered here lies in the fact that all the salts are derived from the dihydroxy formula of glyoxylic acid $(\text{OH})_2\text{CH} \cdot \text{CO}_2\text{H}$, and thus it behaves both as an aldehyde acid and as a dihydroxy acid. For details as to this group of acids *v.* GLYOXYLIC ACID.

III. Monohydroxydicarboxylic acids

Various groups of monohydroxydicarboxylic acids are known, corresponding to the several groups of dibasic acids (*q.v.*). The most important acids of this type are tartronic, malic, α -glutanic and paraconic acids. They occur in nature; thus malic acid in unripe gooseberries, and in rhubarb; α -hydroxyglutaric acid in molasses. The acids in which the hydroxyl group occupies the γ position with reference to the carboxyl group, when separated from their salts, readily part with water and become lactones, e.g. paraconic acid. The methods of preparation are very similar to those of the monobasic acids.

IV. Dihydroxydicarboxylic acids. The most important acid of this group is tartaric acid (*q.v.*). Mesoxalic acid, which is ketomalonic acid, exhibits tautomerism and behaves both as a keto-acid and as a dihydroxy acid.

V. Hydroxytricarboxylic acids. The most important acid of this group is citric acid (*q.v.*).

HYDROXY ACIDS OF THE AROMATIC SERIES.

If the hydroxyl group is attached to the benzene nucleus of a carboxy acid derived from benzene or its homologues, the acid thus formed is a phenol acid. Examples of this class are the three isomeric hydroxybenzoic acids, which have the formula $\text{C}_6\text{H}_4(\text{OH})\text{COOH}$. On the other hand, in the case of carboxy acids derived from homologues of benzene, a hydroxyl group may be introduced into a fatty lateral chain, and in such a case the resulting acid is an alcohol acid; such an acid is mandelic acid

I. Monohydroxyaromatic acids. The most important members of this group of acids are salicylic, *m*- and *p*-hydroxybenzoic and anisic acids (*q.v.*). They occur in nature; thus salicylic acid is found in the buds of *Spiræa Ulmaria* (Linn.) and as the methyl ester in oil of winter-green.

General methods of preparation.

(i) By the action of nitrous acid on the amino-acids, e.g. salicylic acid from anthranilic acid,

(ii) By fusing the sulphonic acids with alkalis, e.g. salicylic acid from *o*-toluenesulphonic acid.

(iii) By fusing the homologous phenols with alkalis, when the methyl group attached to the benzene nucleus will be oxidised to the carboxyl group, e.g. salicylic acid from *p*-cresol.

(iv) By fusing the phenol aldehydes with potash, e.g. salicylic acid from salicylaldehyde.

(v) By the action of carbon dioxide on the dry sodium salts of the phenols at high temperatures when the carbonic acid usually enters the ring in the position ortho to the hydroxyl group, e.g. salicylic acid from sodium phenate.

(vi) By boiling the phenols with carbon tetrachloride and caustic potash, the carboxyl group entering the ring generally in a position para to the hydroxyl groups: *o*-acids are formed in small amounts, e.g. *p*-hydroxybenzoic acid from phenol, carbon tetrachloride, and caustic potash.

Properties.—When these acids react with carbonates only the hydrogen of the carboxyl group is replaced by metal; but with alkaline hydroxides they behave like feeble dibasic acids, and the hydrogen of the phenolic hydroxyl is also replaced: e.g. in disodium salicylate $\text{C}_6\text{H}_4(\text{ONa})\text{COONa}$. Carbon dioxide will convert the latter into the former. The *o*-acids, unlike the *m*- and *p*-acids, volatilise in aqueous vapour, are coloured violet by ferric chloride and dissolve in chloroform. The *m*-acids are coloured red brown when heated with concentrated sulphuric acid and are converted into hydroxyanthraquinones: they are usually more stable than the *o*- and *p*-acids. Boiling hydrochloric acid decomposes the *p*-acids into carbon dioxide and phenols. All the hydroxy acids decompose into phenol and carbon dioxide when distilled with lime.

II. Dihydroxyaromatic acids. The most important member of this class is protocatechuic acid (*q.v.*). These acids may be prepared by the same methods as were used for the monohydroxy acids (*v. supra*). The carboxyl group is more readily introduced into the dihydroxybenzenes than into the monohydroxybenzenes. This may be effected by heating the compounds with a solution of ammonium or sodium carbonate at 100° – 130° . The dihydroxybenzoic acids break down when heated, into carbon dioxide and dihydroxybenzenes.

III. Trihydroxyaromatic acids. The most important members of this group are gallic and tannic acids (*q.v.*).

HYDROXYANTHRAQUINONE *v.* ALIZARIN AND ALLIED COLOURING MATTERS.

HYDROXYBENZALDEHYDE *v.* SALICYL-ALDEHYDE.

HYDROXYBENZENES *v.* PHENOL AND ITS HOMOLOGUES.

HYDROXYBUTYRIC ACIDS $\text{C}_4\text{H}_5\text{O}_3$.

α -Hydroxybutyric acid

Prepared by treating α -chloro- or α -bromobutyric acid with baryta (Markownikow, *Annalen*, 153, 242) or with moist silver oxide (Naumann, *Annalen*, 119, 115; Friedel and Machuca, *ibid.* 120, 279); by treating the cyanhydrin of propionaldehyde with hydrochloric acid and saponifying the nitrile thus produced (Przbzybek, *J. Russ. Chem. Soc.* 8, 335); by heating ethyltartronic acid at 180° (Guthzeit, *Annalen*, 209,

234); by boiling 100 grams of α -bromobutyric acid, 500 c.c. of water and 1 molecular proportion of potassium carbonate for 5 to 6 hours (Bischoff and Walden, *ibid.* 279, 104). Forms white crystals, m.p. 43° - 44° , sublimes at 60° - 70° and boils at 225° . Chromic acid oxidises it to acetic and propionic acids, whilst electrolysis of a concentrated solution of the sodium salt results in the production of propionaldehyde and formic acid (Miller and Hofer, Ber. 1894, 468). It has been resolved into its optically active components by fractional crystallisation of the brucine salts (Guye and Jordan, Compt. rend. 120, 562, 632, 1274).

β -Hydroxybutyric acid

Prepared by the reduction of aceto-acetic ester with sodium amalgam (Wislicenus, Annalen, 149, 205); by the action of potassium cyanide on α -propylenechlorhydrin and saponification of the nitrile thus formed (Markownikow, *ibid.* 153, 237). It forms a thick syrup, which is volatile in steam and on heating decomposes into water and crotonic acid. It has been resolved into its optically active components by fractional crystallisation of the quinine salts (McKenzie, Chem. Soc. Trans. 1902, 1402). l - β -Hydroxybutyric acid occurs in the urine in considerable quantities in cases of *diabetes mellitus* (Laud, Chem. Zentr. 1899, ii. 63; Bergell, Zeitsch. physiol. Chem. 1901, 33, 310; Minkowski, Chem. Soc. Abstr. 1885, 413; Kulz, Zeitsch. Biol. 20, 165). (For estimation in urine *v.* Schaffer, J. Biol. Chem. 1908, 5, 211; Black, *ibid.* 207.) The liver cells contain an enzyme, β -hydroxybutyrase, which converts β -hydroxybutyric acid into aceto-acetic acid (Wakeman and Dakin, *ibid.* 1909, 6, 373).

γ -Hydroxybutyric acid

readily loses water even at the ordinary temperature passing into the cyclic ester, butyrolactone

$\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}\cdot\text{O}$. Butyrolactone was discovered by Saytzeff in 1873, but he regarded it as the dialdehyde of succinic acid. He prepared it by the reduction of succinyl chloride in acetic acid with sodium amalgam (Annalen, 171, 261). It may also be prepared by the distillation of γ -chlorobutyric acid at 180° - 200° (Henry, Bull. Soc. chim. [ii.] 45, 341); by the interaction of ethylene chlorhydrin and acetoacetic ester and decomposing the resulting product with baryta (Chanlaroff, Annalen, 226, 325); by treating a solution of succinic anhydride in ether with sodium amalgam and gradually adding hydrochloric acid to the product (Fichter and Herbrand, Ber. 1896, 1192); by heating γ -phenoxybutyric acid with fuming hydrobromic acid (Bentley, Haworth and Perkin, Chem. Soc. Trans. 1896, 168); by the reduction of aldehydopropionic acid with sodium amalgam (Perkin and Sprankling, *ibid.* 1899, 17). It is a colourless oil, b.p. 206° (Fittig and Roeder, Annalen, 227, 22); sp.gr. 1.1286 $15^{\circ}/0^{\circ}$; it is volatile in steam. Chromic acid oxidises it to succinic acid; heating with hydriodic acid converts it into iodo-butyric acid (Saytzeff, J. pr. Chem. 25, [ii.] 70). It reacts with magnesium methyl iodide, forming

δ -methylpentane- α -diol (Henry, Compt. rend. 1906, 143, 1221).

α -Hydroxyisobutyric acid (*Butyl-lactic acid*, *Acetonic acid*, *Dimethyl oxalic acid*)

Prepared by treating acetone with prussic and hydrochloric acids (Staedeler, Annalen, 111, 320; Markownikow, *ibid.* 146, 339); by treating dimethylloxalic ester with zinc and methyl iodide (Frankland and Duppa, *ibid.* 135, 25); by heating acetonechloroform to 180° with water or by boiling with caustic soda (Willgerodt and Schiff, J. pr. Chem. 41, [ii.] 519; Ber. 1882, 2307); by heating α -bromo- or α -chloroisobutyric acid with water to 180° , with baryta, or with caustic soda (Markownikow, Annalen, 153, 228; Fittig, *ibid.* 200, 70; Ostropjatow, J. Russ. Phys. Chem. Soc. 28, 51); by treating α -aminoisobutyric acid with sodium nitrite (Tiemann and Friedländer, Ber. 1881, 1973); by treating isobutyric acid with potassium permanganate (Meyer, Annalen, 219, 240). It forms hygroscopic prisms which sublime at about 50° , and when freshly sublimed melt at 79° ; b.p. 212° ; volatile in steam. Oxidation with chromic acid converts it into acetic acid, acetone, and carbon dioxide; fusion with caustic soda yields acetone; heating with phosphorus pentoxide yields acetaldehyde, acetone, acetic acid, and other products (Bischoff and Walden, Annalen, 279, 111). *Acetone chloroform* (q.v.)

is an interesting derivative of this acid.

HYDROXYCODEINE *v.* OPIUM.

HYDROXYETHYLANILINE

Prepared by heating a mixture of aniline, water, and ethylenechlorhydrin. B.p. 286° , sp.gr. 1.11 at 0° , slightly soluble in water; readily soluble in alcohol and ether. Used in the manufacture of indigo.

HYDROXYLAMINE NH_2OH . Discovered by Lossen (Annalen, Suppl. 1868, 6, 220) in 1865, but until 1891 only known in the form of salts or in aqueous solution. Obtained by the reduction of nitric acid with metals under suitable conditions (Divers, Chem. Soc. Trans. 1883, 443 *et seq.*; 1885, 597 *et seq.*); by the reduction of nitrates, nitro bodies, &c., with finely divided metals (Wohl, Eng. Pat. 11216; J. Soc. Chem. Ind. 1895, 595); by the electrolytic reduction of nitric acid, nitrous acid, or their salts or other derivatives in the presence of a second acid electrolyte at a low temperature (Boehringer and Söhne, D. R. PP. 133457, 137697; Fr. Pat. 319187; J. Soc. Chem. Ind. 1902, 1458; Compagnie Parisienne de Couleurs d'Aniline, Fr. Pat. 322943; J. Soc. Chem. Ind. 1903, 425; Tafel, Zeitsch. anorg. Chem. 1902, 31, 289; Schoch and Pritchett, J. Amer. Chem. Soc. 1916, 38, 2042); by the reduction of nitrites with sodium amalgam (Divers, Chem. Soc. Trans. 1899, 89) or with sulphites (Raschig, Eng. Pat. 3028; J. Soc. Chem. Ind. 1888, 210; Eichkoff, Arch. Pharm. 27, [iii.] 713; Lidoff, J. Russ. Chem. Soc. 1884, 751; Divers and Haga, Chem. Soc. Trans. 1887, 661; 1896, 1665). It is best prepared by taking a concentrated aqueous solution of commercial

sodium nitrite (2 mols.) and sodium carbonate (1 mol.) and passing in sulphur dioxide at -2° to -3° with constant stirring until it is just acid. The solution is warmed gently with a few drops of sulphuric acid and then kept at 90° – 95° for two days. It is then neutralised with sodium carbonate, evaporated until the solution weighs about $10\frac{1}{2}$ –11 times as much as the sodium nitrite originally taken, when on cooling nearly all the sodium sulphate crystallises out. The hydroxylamine sulphate is obtained from the mother liquors and purified by recrystallisation (Divers and Haga, *l.c.*). Jouve (Compt. rend. 128, 434) has prepared hydroxylamine synthetically by the direct union of hydrogen and nitric acid in the presence of spongy platinum at 115° – 120° . The anhydrous compound may be obtained by dissolving hydroxylamine hydrochloride in absolute methyl alcohol, adding a solution of sodium methoxide in the same solvent, separating the sodium chloride so formed and distilling off the greater part of the methyl alcohol under 100 mm. pressure. The residue is distilled in small portions under 20 mm. pressure with the addition of a little vaseline to prevent frothing. When the solid hydroxylamine begins to come over, the receiver is changed and cooled to 0° , care being taken that the hydroxylamine vapour does not come in contact with air at 60° – 70° , as then explosions occur (Lobry de Bruyn, Rec. trav. chim. 10, 100; 11, 18; v. also Brühl, Ber. 1894, 1347). Crismer (Bull. Soc. chim. 6, [iii.] 793) obtains it by heating zinc dihydroxylamine chloride, and Uhlenhuth (Annalen, 311, 117) by the distillation of the phosphate under reduced pressure; the solid thus obtained may be purified by crystallisation from absolute alcohol at -18° (Ebler and Schott, J. pr. Chem. 1908, 78, [ii.] 289).

According to Baudisch and Jenner (Ber. 1916, 49, 1182) hydroxylamine may be obtained by cautiously adding the finely powdered dry sulphate to liquid ammonia in a quartz tube, removing the ammonia by evacuation, and extracting the free hydroxylamine by alcohol.

Hydroxylamine forms white inodorous scales or hard needles, sp.gr. 1.3 (*circa*), m.p. 33.05° , b.p. 58° under 22 mm. Heated to 100° it decomposes, ammonia, nitrous and hyponitrous acids being the first products of decomposition and these then interact with the formation of nitrogen and nitrous oxide. Readily soluble in water, and to a less extent in ethyl and methyl alcohols, and in boiling ether (De Bruyn, Ber. 1894, 967). When pure it is stable below 15° , but alkali decomposes it. The aqueous solution is colourless and odourless, has a strong alkaline reaction, and gives precipitates, insoluble in excess, with salts of Zn, Ni, Fe, Al, Cr, but not with those of the alkaline earths. In its general reactions resembles a solution of ammonia, although it is less basic than that substance. It acts as a strong reducing agent, e.g. with CuSO_4 solution it gives a red precipitate of Cu_2O ; it reduces HgCl_2 to HgCl , and precipitates the metals from solutions of AgNO_3 , AuCl_3 , and PtCl_4 . It can also act as an oxidising agent being itself reduced to ammonia (Haber, Ber. 1896, 2444; Biltz, *ibid.* 1896, 2080; Dunstan and Dymond, Chem. Soc. Trans. 1887, 646). Thus in alkaline solution it converts ferrous

hydroxide into ferric hydroxide, whilst in acid solution it reduces ferric chloride to ferrous chloride. Oxidation converts hydroxylamine into nitrous oxide and nitric oxide (Arndt, Ber. 1900, 33) and caustic soda decomposes it into nitrogen, nitrous oxide, nitrous acid and water (Kolotoff, J. Russ. Phys. Chem. Soc. 25, 295).

The salts of hydroxylamine are readily soluble in water and alcohol; they crystallise well and are anhydrous.

By treating hydroxylamine sulphate in the cold with sodium nitrite and then adding silver nitrate, a yellow precipitate of silver hyponitrite is obtained (Wislicenus, Ber. 1893, 771; Tanatar, J. Russ. Phys. Chem. Soc. 25, 342; Ber. 1894, 187). By passing sulphur dioxide through a solution of the hydrochloride or sulphate, ammonium sulphate is produced (Tanatar, Ber. 1899, 241, 1016). Elber and Schott (J. pr. Chem. 1908, ii. 78, 289) have prepared metallic salts of the type $\text{R}(\text{ONH}_2)_2$, where R is any divalent metal: alkyl hydroxylamines have been prepared by the action of alkyl halides on hydroxylamine (Dunstan and Goulding, Chem. Soc. Trans. 1899, 792; v. also *ibid.* 1896, 839; De Bruyn, Rec. trav. chim. 15, 185).

Detection and estimation.—Hydroxylamine may be detected by its action in reducing Barreswil's solution with the formation of cuprous oxide (Adams and Overman, J. Amer. Chem. Soc. 31, 637); by adding sodium nitroprusside to a neutral solution and then a little caustic soda, when a magenta red coloration is produced (Angeli, Gazz. chim. ital. 23, ii. 102); or by treating it with sodium acetate and benzoyl chloride with the formation of benzhydroxamic acid which gives a violet-red coloration with ferric chloride (Bamberger, Ber. 1899, 1805). It may be estimated by titration in alkaline solution with mercury acetamide, which is reduced to metallic mercury (Forster, Chem. Soc. Trans. 1898, 785); by oxidation with vanadic sulphate, measuring the nitrogen evolved and titrating the vanadous sulphate with potassium permanganate (Hofmann and Küspert, Ber. 1896, 64); by adding excess of standard titanium trichloride and titrating back the excess with potassium permanganate (Stähler, *ibid.* 1904, 4732; v. also *ibid.* 1909, 2695); by titrating the solution with potassium permanganate after the addition of sodium oxalate (Simon, Compt. rend 135, 1339); by reducing ferric sulphate and titrating the ferrous salt by permanganate (Raschig); by boiling with excess of N/10 silver nitrate solution, ammonia, and caustic soda and estimating the silver nitrate unacted upon (Denigés, Ann. Chim. Phys. 7, [vi.] 427). Jones and Carpenter (Chem. Soc. Trans. 1903, 1394) add the solution containing the hydroxylamine to a hot solution of potassium copper carbonate or tartrate with stirring. The solution is boiled, filtered, the precipitate washed with hot water and dissolved in ferrous sulphate in an atmosphere of carbon dioxide. The ferrous salt is titrated back with potassium permanganate.

4 mols. $\text{K}_2\text{MnO}_8 = 10$ mols. NH_2OH

Rupp and Mäder describe volumetric processes depending on the oxidising action of bromine (Arch. der Pharm. 1913, 251, 295; Analyst, 1913, 437).

Bray, Simpson, and Mackenzie (J. Amer. Chem. Soc. 1919, 41, 1363) have investigated three methods for the estimation of hydroxylamine: (1) reduction to ammonia by excess of titanous salt in acid solution; (2) oxidation to nitrous oxide by excess ferric sulphate in sulphuric acid solution, with titration of the ferrous salt by permanganate solution; and (3) oxidation to nitrous oxide by iodine in a solution kept neutral by means of disodium hydrogen phosphate. The titanous salt and ferric salt methods were found to be accurate, but the iodine method was unsatisfactory.

Schaeffer (Bull. Mulhouse, 1883) has applied the reducing properties of hydroxylamine in order to discharge manganese brown. The hydrochloride $\text{NH}_2\text{OH}\cdot\text{HCl}$ must be used. On printing this upon a manganese ground the latter is instantly reduced to manganese chloride. A very dark indigo, blue-dyed on manganese, is lowered to a lighter and brighter blue by the elimination of the MnO_2 . In like manner nankin, chamois, and similar colours can be discharged white (J. Soc. Chem. Ind. 3, 166).

Hydroxylamine and its salts have been used as developers in photography, and for recovering silver from fixing bath solutions and waste liquors (Lainer, J. Soc. Chem. Ind. 1890, 890). It is a powerful antiseptic (Marpmann, Pharm. Centr. N.F. 10, 245) and has been used as a substitute for chrysarobin and pyrogallol acid, as it does not discolour the skin or bandages and has a strong reducing action (Schwarz, Pharm. Zeit. 33, 659).

Ethylhydroxylamines v. ETHYL.

β -Phenylhydroxylamine $\text{C}_6\text{H}_5\text{NHOH}$. Prepared by the reduction of nitrobenzene (1) in water with zinc (Bamberger, Ber. 1894, 27, 1348, 1548; Wohl, *ibid.* 1432); (2) in alcohol with zinc (Wohl, *ibid.* 1434; D. R. P. 84138; Frdl. iv. 44), or the zinc-copper couple (Wohl, D. R. P. 84891; *ibid.* 46) in the presence of anhydrous calcium chloride; (3) in aqueous alcohol with zinc amalgam in the presence of aluminium sulphate (Bamberger and Knecht, Ber. 1896, 29, 864); (4) in ether with zinc in the presence of anhydrous calcium chloride (Goldschmidt, *ibid.* 2307); (5) in aqueous ether with aluminium amalgam (Wislicenus, *ibid.* 494; J. pr. Chem. [ii.] 54, 57); (6) in ammonium chloride with zinc (Kalle & Co. D. R. P. 89978; Frdl. iv. 47); (7) electrolytically in acetic acid (Haber, Zeitsch. Elektrochem. 1898, 5, 77) or in alcoholic ammonia (Schmidt, Zeitsch. physikal. Chem. 32, 272); by the oxidation of aniline in ethereal solution with Caro's acid (Bamberger and Tschirner, Ber. 1899, 32, 343).

Baudisch (Chem. Zeit. 1911, 35, 913) gives the following details for the preparation of phenylhydroxylamine with a view to its conversion to 'cupferron' (*q.v.*). Sixty grams of nitrobenzene, 1000 c.c. of water, and 30 grams of ammonium chloride are well stirred, and to the white emulsion is added 80 grams of zinc dust in very small quantities, so that the temperature keeps between 16° and 18° . When the odour of nitrobenzene has completely disappeared, the solution is drawn off from the zinc hydroxide, and after cooling to 0° by means of ice, the liquid is saturated with salt, which causes an abundant crystalline precipitate of

phenylhydroxylamine. Great care must be taken not to let this substance come in contact with the skin, as it is very poisonous (Chem. Soc. Abtr. 1911, ii. 939). For further details, see Marvel and Kamm, J. Amer. Chem. Soc. 1919, 41, 276; Analyst, 1919, 142. The yield depends on the quality of the zinc dust, but consistently good yields may be obtained by previously treating the zinc dust with 2 p.c. mercurous nitrate solution slightly acidified with nitric acid (Kasanof, J. Ind. Eng. Chem. 1920, 12, 799).

β -Phenylhydroxylamine forms colourless needles, m.p. 81° – 82° ; soluble in 10 parts of hot and 50 of cold water, readily soluble in alcohol, ether, carbon disulphide, and chloroform, sparingly so in petroleum. It dissolves in sulphuric acid with a deep blue colour. By heating at 100° azobenzene together with aniline, azoxybenzene, and other products are formed. Oxidation with potassium permanganate gives first nitrosobenzene, then nitrogen and azoxybenzene (Bamberger and Tschirner, Ber. 1899, 32, 342); in dilute neutral solution hydrogen peroxide yields azoxybenzene, in alkaline solution azoxybenzene and nitrobenzene (Bamberger, *ibid.* 1900, 33, 119). In the presence of hydroxylamine and air it is partly oxidised to azoxybenzene and partly reduced to aniline, phenylazoimide, and benzeneazohydroxylanilide also being formed (Bamberger, *ibid.* 1902, 35, 3893). It dissolves in sodium hydroxide forming a sodium salt which in the absence of air yields azoxybenzene, and in the presence of air azoxybenzene and nitrobenzene; alcoholic potash yields azobenzene (Bamberger and Brady, *ibid.* 1900, 33, 271). Mineral acids yield *p*-aminophenol and azoxybenzene; alcoholic sulphuric acid gives azoxybenzene, *o*- and *p*-phenetidine, *o*- and *p*-aminophenols, aniline and other compounds (Bamberger and Lagutt, *ibid.* 1898, 31, 1501). With aromatic aldehydes

it yields phenylaldoximes of the type $\begin{matrix} \text{CHR} \\ \diagup \\ \text{NPh} \end{matrix} > \text{O}$

(Plancher and Piccinini, Atti. R. Acad. Lincei. 1905, [v.] 14, ii. 36). (For constitution, v. Bruhl, Zeitsch. physikal. Chem. 1898, 26, 47.)

Nitrosophenylhydroxylamine $\text{C}_6\text{H}_5\text{N(NO)OH}$. Prepared by the action of sodium nitrite and dilute sulphuric acid on β -phenylhydroxylamine (Wohl, Ber. 1894, 27, 1435; Bamberger, *ibid.* 1553); or by the interaction of hydroxylamine and nitrobenzene in alcoholic solution in the presence of sodium ethoxide (Angeli, *ibid.* 1896, 29, 1885; Angelico, Atti. R. Accad. Lincei, [v.] 8, ii. 28).

It crystallises from petroleum in colourless needles, melting at 58° – 59° and decomposing at 75° ; sparingly soluble in water, readily so in most organic solvents. On heating it decomposes into nitrosobenzene and other substances (Bamberger, Ber. 1898, 31, 574, 1507). Alcoholic or ethereal solutions give a brownish-red coloration with a few drops of dilute ferric chloride (Bamberger and Ekecrantz, *ibid.* 1896, 29, 2412). Reduction with sodium amalgam yields phenylhydrazine; oxidation with potassium permanganate or sodium hypochlorite, nitrosobenzene. By heating with dilute mineral acids nitrosobenzene is formed, whilst nitrous acid yields benzenediazonium nitrite.

Cupferron, *Ammonium nitrosophenylhydroxylamine*, $C_6H_5(NO)N\cdot ONH_4$ is prepared by dissolving β -phenylhydroxylamine in ether at 0° , passing in dry ammonia and adding excess of amyl nitrite, when a snow-white crystalline mass of ammonium nitrosophenylhydroxylamine is formed (Baudisch and King, J. Ind. Eng. Chem. 1911, 3, 629; Marvel and Kamm, J. Amer. Chem. Soc. 1919, 41, 276; Analyst, 1919, 142).

Cupferron is used in quantitative analysis for separating copper and iron from most of the metals. The iron and copper are precipitated in strongly acid solution with cupferron, the precipitate filtered, washed with water, and finally with ammonium hydroxide. The latter dissolves the copper, but not the ferric salt. The ferric salt is soluble in chloroform, ether, acetone, &c., and may be dissolved and separated from other salts, such as those of lead, silver, or tin, which may have been precipitated with it (Baudisch, Chem. Zeit. 1909, 33, 1298; 1911, 35, 913; Biltz and Hödtke, Zeitsch. anorg. Chem. 1910, 66, 426; Hanus and Soukup, *ibid.* 68, 52; Fresenius, Zeitsch. anal. Chem. 1911, 50, 35). It precipitates titanium as a bright yellow salt $[C_6H_5(NO)NO]_4Ti$, which on ignition yields TiO_2 . This reagent may be used to separate titanium from aluminium, chromium, nickel, cobalt, and manganese (Bellucci and Grassi, Gazz. chim. ital. 1913, 43, 570), or for the quantitative separation of zirconium, titanium, iron, manganese, and aluminium, or in the analysis of zircon and baddeleyite (Brown, J. Amer. Chem. Soc. 1917, 39, 2358). The reagent can be used for the accurate estimation of iron, copper, titanium, zirconium, thorium, and vanadium; the presence of other metals may interfere. Hence the cupferron method is only applicable when the qualitative composition of the material is known (Lundell and Knowles, J. Ind. Eng. Chem. 1920, 12, 344). For a bibliography of cupferron and its applications in analysis, see Analyst, 1920, 58.

HYDROXY-2-NAPHTHOIC ACID

Obtained by the action of carbon dioxide on sodium- α -naphthoxide at 120° – 145° under pressure. The product dissolved in water is treated with hydrochloric acid and recrystallised. Needles, m.p. 187° .

2-Hydroxy-3-Naphthoic acid

Prepared by acting on sodium- β -naphthoxide by carbon dioxide at 200° – 250° under pressure and treating the product dissolved in water with hydrochloric acid. Yellow scales, m.p. 216° .

β -HYDROXYPHENYLETHYLAMINE v. ERGOT.

HYDROXYQUINOL v. PHENOL AND ITS HOMOLOGUES.

HYDROXYQUINOLINE v. QUINOLINE.

HYDROXYQUINONE COLOURING MATTERS. The hydroxyquinones form an im-

portant group of mordant colouring matters which are characterised by containing at least one hydroxyl group adjacent (ortho- or peri-) to an oxygen atom of a quinone, but usually two hydroxyl groups in the ortho- position with respect to one another. They possess the property of forming insoluble, coloured salts with certain metallic oxides, and therefore, when dyed on a fabric impregnated (mordanted) with such oxides, for example, the oxides of aluminium, chromium, and iron, lakes are formed which are extremely fast. The simplest compound possessing the above requirements is tetrahydroxy- p -benzoquinone

but its dyeing properties are not sufficiently intense for it to be of practical value. This desideratum is first reached in the naphthalene series in the case of dihydroxynaphthaquinone or

Naphthazarin, which comes on the market in the form of its sodium bisulphite compound, Alizarin black (see under NAPHTHALENE).

By far the most valuable and important hydroxyquinones are those belonging to the anthracene series, of which a large number are manufactured. The simplest and best known of these is dihydroxyanthraquinone or alizarin

(See ALIZARIN COLOURING MATTERS.) J. C. C.

HYDROXYSTEARIC ACIDS $C_{18}H_{36}O_8$ α -Hydroxystearic acid

Prepared by treating α -bromostearic acid with aqueous potash. Separates from a mixture of benzene and petroleum as a crystalline powder, m.p. 91° – 92° (Hell and Sadomsky, Ber. 1891, 2391; Le Seur, Chem. Soc. Trans. 1904, 827). By heating it to 270° , it yields margaric aldehyde $C_{16}H_{33}\cdot CHO$, a lactide $C_{36}H_{68}O_4$, formic acid, water and carbon dioxide.

β -Hydroxystearic acid

Prepared by treating β -bromostearic acid with aqueous potash. Crystallises from chloroform in white plates, m.p. 89° (Ponzio, Atti. R. Accad. Sci. Torino, 1905, 40, 970).

γ -Hydroxystearic acid exists only in the form

of a lactone $CH_3[CH_2]_{13}CH \begin{matrix} \nearrow CH_2\cdot CH_2 \\ \searrow O\cdot CO \end{matrix}$ Ob-

tained by treating the anhydride of γ -hydroxyoleic acid with potash (Geitel, J. pr. Chem. 37, [ii.] 85). Prepared by heating oleic acid with anhydrous zinc chloride. Oxidation with chromic acid in glacial acetic acid converts it

into liquid monobasic and small quantities of di-basic acids, including succinic acid and γ -keto-stearic acid $\text{CH}_3[\text{CH}_2]_{13}\text{CO}[\text{CH}_2]_2\text{CO}_2\text{H}$, m.p. 97° (Shukoff and Schestakoff, J. Russ. Phys. Chem. Soc. 1903, 35, 1).

ι -Hydroxystearic acid

This acid was formerly described as β -hydroxystearic acid (A. C. and M. Saytzev, J. Russ. Phys. Chem. Soc. 1886, 328; 17, 426; J. pr. Chem. 35, [ii.] 369, 384; Fremy, Annalen, 19, 296; 20, 50; 33, 10; Ann. Chim. Phys. 65, [ii.] 113; Sabanejew, J. Russ. Phys. Chem. Soc. 18, 41; Geitel, J. pr. Chem. 37, [ii.] 81; Leichti and Suida, Ber. 1883, 2458). Shukoff and Schestakoff (J. Russ. Phys. Chem. Soc. 1903, 35, 1) have shown that its constitution is that of ι -hydroxystearic acid. It is prepared from the sulpho or iodo derivative of oleic acid, or best by the action of sulphuric acid on oleic acid; m.p. 83°–85°. It may also be obtained from elaidic acid by the action of sulphuric acid and subsequent treatment with alcoholic potash (Tscherbakow and Saytzev, J. pr. Chem. 57, [ii.] 27). By heating to 100° it yields an anhydride; oxidation with chromic acid in glacial acetic acid converts it into sebacic, azelaic, and traces of suberic and liquid monobasic acids and ι -keto-stearic acid $\text{CH}_3[\text{CH}_2]_7\text{CO}[\text{CH}_2]_8\text{CO}_2\text{H}$, m.p. 76°. Molinari and Barosi (Ber. 1908, 2794) have obtained an acid by the decomposition of the ozonide of oleic acid and consider it to be formed by the aldol condensation of nonaldehyde with nonoic acid, and hence they consider it to be ι -hydroxystearic acid; it melts at 41°, and hence is either impure or a hydroxystearic acid containing the hydroxyl group in some other position.

κ -Hydroxystearic acid

This acid was formerly described as α -hydroxystearic acid (Saytzev, J. pr. Chem. 37, [ii.] 277, 284). Shukoff and Schestakoff (J. Russ. Phys. Chem. Soc. 1903, 35, 1) have shown that its constitution is that of κ -hydroxystearic acid; m.p. 84°–85°. Prepared by the action of sulphuric acid on *isoleic* acid. Oxidation with chromic acid in glacial acetic acid yields sebacic acid, nonylene- α -dicarboxylic acid (m.p. 124°), and κ -ketostearic acid,

m.p. 65°.

λ -Hydroxystearic acid (12-Hydroxystearic acid)

Prepared from the methyl ester which is obtained by the reduction of the methyl ester of ricinoleic acid; m.p. 78° (Grün and Woldenberg, J. Amer. Chem. Soc. 1909, 31, 490). Kasansky (J. Russ. Phys. Chem. Soc. 1900, 32, 149), by acetylating ricinoleic acid, followed by bromination and reduction, obtained a hydroxystearic acid (m.p. 81°–82°) which is possibly identical with the above.

HYDROXYTHIONAPHTHEN (thioindoxyl)

Phenylthioglycol-o-carboxylic acid is introduced
Vol. III, —T.

into an aqueous solution of caustic soda, and heated to 170°–200°. The product is treated with water and the 2-hydroxythionaphthen-1-

carboxylic acid is pre-

cipitated by the addition of hydrochloric acid. By heating the acidified solution so long as carbon dioxide is evolved 2-hydroxythionaphthen is produced and separates out on cooling (Kalle & Co. D. R. P. 192075). Acetic anhydride may also be used to convert the phenylthioglycol-o-carboxylic acid in hydroxythionaphthen (*idem*, D. R. P. 198712), or the acid may be heated alone at 230° so long as gas is evolved (*idem*, D. R. PP. 188702, 198713) or with paraffin, glycerol (with or without sulphuric acid), or aniline. In the last case the aniline compound is boiled with a dilute acid when 2-hydroxythionaphthen distills with steam and forms white needles (*idem*, D. R. P. 202351). May also be formed by condensing chloroacetic acid with o-aminothiophenol and converting the o-aminophenylthioglycol-o-carboxylic acid in the cyano-compound by diazotising and boiling with dilute sodium hydroxide solution: the 2-aminothiophenol-1-carboxylic acid is transformed into 2-hydroxythionaphthen by boiling with dilute acid (Kalle & Co. D. R. P. 184496), or more directly by converting the cyano-derivative by treating with sulphuric acid (*idem*, D. R. P. 190291) or caustic soda solution (*idem*, D. R. P. 190674).

Esters and alkali salts of methylthiosalicylic acid may also be transformed into 2-hydroxythionaphthen (Farbw. vorm. Meister, Lucius and Brüning, D. R. PP. 200200, 200428, 200593).

Thiosalicylic acid treated with dichlorethylene (acetylene dichloride) $\text{CHCl}:\text{CHCl}$ yields acetylene-bisthiosalicylic acid,

which when heated with a mixture of caustic potash and soda at 220°–230°, dissolved in water, acidified, and steam-distilled, yields 2-hydroxythionaphthen (Bad. Anilin und Soda Fabrik, D. R. P. 221465). M.p. 71°. Used in the manufacture of thioindigo dyes.

HYDROXYTHIONAPHTHEN-1-CARBOXYLIC ACID (thioindoxyl carboxylic acid). Melts at 213°. Sparingly soluble in water, benzene, or light petroleum; more soluble in alcohol, acetone, or ethyl acetate. For preparation, see foregoing article.

HYDROZINCITE. Hydrated basic carbonate of zinc, $\text{ZnCO}_3\cdot 2\text{Zn}(\text{OH})_2$, containing Zn 60.5 p.c., of common occurrence as an alteration product of other ores of zinc. It is found in the upper levels of most zinc mines as soft, snow-white encrustations often in stalactitic, botryoidal, or other forms. Large masses with an earthy or chalky texture are not uncommon; sp.gr. 3.6–3.8. Much of the material often regarded as smithsonite (ZnCO_3) is really hydrozincite, as shown by its lower degree of hardness (H. 2–2½, that of smithsonite being 5) and the presence of water. Large quantities have been obtained from the zinc mines of province Santander in Spain, Bleiberg in Carinthia, Sardinia, &c. It has been observed as a mineral of recent formation in the old galleries of lead-zinc mines in North Wales.

L. J. S.

2 P

HYDURILIC ACID $C_8H_6O_6N_4 \cdot H_2O$ or $2H_2O$;

was first prepared by Schlieper (Annalen, 1845, 56, 11), who obtained the acid ammonium salt together with alloxan by the action of nitric acid (sp.gr. 1.25) on uric acid. It is also prepared (2) in the form of its ammonium salt by prolonged boiling of alloxan or alloxantin with very dilute sulphuric acid (Finch, Annalen, 1864, 132, 303); (3) by heating crystallised alloxantin in a tube at 170° when it is converted quantitatively into hydurilic acid, according to the equation

or alloxan is similarly decomposed (Murdoch and Doebner, Ber. 1876, 9, 1102); (4) in the form of its acid ammonium salt by heating dialuric acid with glycerol at 150° , formic acid and carbon dioxide being formed at the same time (Baeyer, Annalen, 1863, 127, 14; cf. Biltz and Heyn, Ber. 1919, 52 [B] 1298); (5) together with glycine and carbon dioxide by heating uric acid with twice its weight of concentrated sulphuric acid (Schultzen and Filehne, Ber. 1868, 1, 150), by oxidation of barbituric acid in aqueous solution with potassium permanganate (Biltz and Heyn, *l.c.*); (6) by reducing dibromobarbituric acid with hydrogen iodide (Baeyer, Annalen, 1864, 130, 133); and it is also formed to a small extent by reducing alloxantin with sulphuretted hydrogen (Murdoch and Doebner, *l.c.*); (7) by the condensation of ethyl ethanetetracarboxylate with carbamide in the presence of sodium ethoxide at 60° – 70° , or by the hydrolysis of ethanetetracarboxylguanide

by means of dilute hydrochloric acid at 150° (Conrad, Annalen, 1907, 365, 24; cf. Roeder, Ber. 1913, 46, 2560); whereas ethyl ethanetetracarboxylate and carbamide yield only a trace of hydurilic acid, *dithiohydurilic acid* is readily obtained from the ester and thiocarbamide; this compound remains unaltered at 250° , and can be desulphurised to hydurilic acid by heating at 100° with concentrated sulphuric acid. Hydurilic acid is most conveniently purified by precipitating the sparingly soluble copper salt from a solution of the neutral ammonium salt, and decomposing this with hot hydrochloric acid, in which the hydurilic acid is only slightly soluble (Baeyer, Annalen, 1863, 127, 15).

Hydurilic acid crystallises from hot water in small four-sided prisms containing $2H_2O$, or is precipitated as a fine crystalline powder containing $1H_2O$ by the addition of hydrochloric acid to a hot aqueous solution. It is sparingly soluble in alcohol or cold water, more readily so in hot water; its heat of combustion is 658.5 Cal. (Matignon, Ann. Chim. Phys. 1893, [vi.] 28, 328).

Hydurilic acid bears the same relation to dialuric and barbituric acids that alloxantin bears to alloxan and barbituric acid. Conrad (Annalen, 1907, 365, 24) has shown that its constitution is correctly represented by the formula

by its synthesis from ethyl ethanetetracarboxylate and carbamide (*v. supra*), and also by the fact that on hydrolysis with concentrated hydrochloric acid at 200° – 230° it is converted almost quantitatively into carbon dioxide, ammonia, and succinic acid; barbituric acid when similarly treated yields carbon dioxide, ammonia, and acetic acid.

Hydurilic acid is not attacked by reducing agents; it yields alloxan and dibromobarbituric acid when treated with bromine water (Biltz, Heyn, and Hamburger, Ber. 1916, 49, 662).

Fuming nitric acid oxidises it into alloxan, whilst weaker acid converts it into nitrobarbituric acid (dilituric acid), *isonitrosobarbituric acid* (violuric acid) and violentin. Ferric chloride or silver oxide oxidises it to oxyhydurilic acid, which gives a blood-red coloration with ferric chloride. Hydurilic acid has marked acidic properties, and decomposes most metallic chlorides and acetates, yielding the corresponding hydrogen hydurate (for the basicity of the acid, see Biltz and Hamburger, Ber. 1916, 49, 655). The heat of neutralisation of hydurilic acid with 2 mols. potassium hydroxide is 21.8 Cal.; but on adding a further quantity of alkali (up to 16 mols.) there is a further evolution of 4.2 Cal. of heat, thus pointing to the existence of a third very feeble acid function. The following salts have been described: the *ammonium hydrogen salt* $NH_4 \cdot C_8H_6O_6N_4$, small octahedral sparingly soluble crystals precipitated by acetic acid from solutions of the *normal ammonium salt* $(NH_4)_2C_8H_4O_6N_4$ which crystallises in needles with $1H_2O$ or in large monoclinic crystals with $4H_2O$, $a : b : c = 1.0821 : 1 : 0.7003$. *Sodium salt* $Na_2C_8H_4O_6N_4 \cdot 4H_2O$ crystallises in prisms; *potassium hydrogen salt* $KC_8H_5O_6N_4$ forms sparingly soluble microscopic needles; the *normal salt* $K_2C_8H_4O_6N_4 \cdot 3H_2O$ is soluble and crystallises in prisms (Matignon). The *calcium salts* $Ca(C_8H_5O_6N_4)_2 \cdot 8H_2O$ and

are crystalline and almost insoluble; the *barium salt* $BaC_8H_4O_6N_4 \cdot H_2O$, the *zinc salts* $Zn(C_8H_5O_6N_4)_2$ and $ZnC_8H_4O_6N_4 \cdot 2H_2O$ are crystalline; the *copper salt* $Cu(C_8H_5O_6N_4)_2 \cdot 8H_2O$ forms fine yellow needles or prisms, which become red on heating with loss of water. The *silver salt* is unstable; the *ferric salt* is a dark green precipitate, and the formation of a dark green colour with ferric chloride is a characteristic reaction of the salts of hydurilic acid; the *ferrous salt* is white becoming green; the *lead salt* is insoluble in acetic acid.

5: 5'-Dichlorohydurilic acid

is obtained by the action of potassium chlorate on an intimate mixture of hydurilic and concentrated hydrochloric acids (Baeyer, Annalen, 1863, 127, 26); a quantitative yield is obtained by chlorinating hydurilic acid in alcohol, Biltz and Hamburger (*l.c.*). It is a sparingly soluble powder, soluble in concentrated sulphuric acid and precipitated therefrom by the addition of water, in small rhombic crystals containing $2H_2O$; it is readily decomposed by alkalis yielding the metallic chloride. The *potassium salt* $K_2C_8H_3Cl_2O_6N_4 \cdot 2H_2O$ is a sparingly crystalline soluble powder.

5-bromo-5'-methoxyhydruilic acid,

is formed on brominating hydruilic acid in presence of methyl alcohol; it crystallises in stout, hexagonal tablets which decompose above 360°; in presence of ethyl alcohol 5-bromo-5'-ethoxyhydruilic acid is formed which crystallises in stout, elongated prisms decomposing above 360°: these compounds yield 5-methoxyhydruilic acid and 5-ethoxyhydruilic acid on reduction, which lose alcohol when heated and yield dehydrohydruilic acid: Biltz, Heyn, and Hamburger (Ber. 1916, 49, 662; *ibid.* 1919, 52 [B], 1298; cf. Baeyer, Annalen, 1863, 127, 26), who found that hydruilic acid broke down under the action of bromine water into dibromobarbituric acid and alloxan.

Tetramethylhydruilic acid (deoxyamalic acid)

is obtained by the dry distillation of amalic acid (Fischer and Reese, Annalen, 1883, 221, 339), or more conveniently by heating it in a sealed tube for 3 hours at 180°–185° (Matignon, Compt. rend. 1893, 116, 642); has also been obtained by heating dimethylpseudouric acid with fused oxalic acid at 170° (Fischer and Ach, Ber. 1895, 28, 2473). Deoxyamalic acid is crystalline, has m.p. 260°, with decomposition and can be distilled, although with partial decomposition. It is almost insoluble in hot or cold water; readily soluble in chloroform or acetic acid; its heat of combustion is 1321.8 Cal. (Matignon, Ann. Chim. Phys. 1893, [vi.] 28, 327). Its chemical properties are similar to those of hydruilic acid, it reduces ammoniacal silver nitrate solution on warming, and gives a beautiful green coloration with ferric chloride; on gentle oxidation it yields a product that gives a blood-red coloration with ferric chloride; but when oxidised by nitric acid it forms dimethyl-alloxan.

5:5'-Dichlortetramethylhydruilic acid may be obtained by chlorinating tetramethylhydruilic acid in alcohol; it forms transparent crystals with rectangular section, m.p. 266°. It is devoid of acidic properties, Biltz and Hamburger (*l.c.*).

5-bromo-5'-methoxy (or ethoxy) tetramethylhydruilic acid is formed on brominating tetramethylhydruilic acid in presence of methyl or ethyl alcohol. The bromomethoxy derivative forms elongated rhombic tablets and has m.p. 245°–247° (decomp.) and the bromoethoxy analogue forms elongated hexagonal tablets, m.p. 199°–200° (decomp.).

5:5'-dibromotetramethylhydruilic acid is formed by the action of bromine on tetramethylhydruilic acid in carbontetrachloride in complete absence of water; it crystallises in snow-white lancet-shaped leaflets and yields alkyloxy compounds on treatment with alcohols. It loses both atoms of bromine on heating at 140°–180°, forming tetramethyldehydrohydruilic acid

a highly reactive compound which melts at 284°. With boiling methyl alcohol it forms

5-methoxy-tetramethylhydruilic acid which crystallises in stout, four-sided prisms, m.p. 284° (decomp.).

5-aminotetramethylhydruilic acid

m.p. 295°–300° (decomp.) is prepared by acting upon dehydrotetramethylhydruilic acid with aqueous ammonia; it crystallises in silky rhombic leaflets. It is reduced by hydriodic acid and phosphonium iodide to 1:3-dimethyluramil and, on brominating it in alcohol, yields 5:5-dibromo-1:3-dimethyl barbituric acid.

5-methyl-amino-tetramethylhydruilic acid crystallises in rhombic plates.

5-anilinotetramethylhydruilic acid has m.p. 160°–161° (decomp.) and forms an aniline salt $\text{C}_{18}\text{H}_{19}\text{O}_6\text{N}_5\text{NH}_2\text{Ph}$ which melts at 134°.

Deoxyamalic acid has only two acidic functions; the potassium $\text{K}_2\text{C}_{12}\text{H}_{12}\text{O}_6\text{N}_4$ and the sodium salt $\text{Na}_2\text{C}_{12}\text{H}_{12}\text{O}_6\text{N}_4$ are sparingly soluble (Matignon, *l.c.*; Fischer and Ach, *l.c.*).

For the preparation of s-dimethyl-hydruilic acid and derivatives, see Biltz and Heyn (Ber. 1919, 52 [B], 1298).

M. A. W.

HYENANCHIN $\text{C}_{15}\text{H}_{18}\text{O}_7$.

A substance, probably a dilactone, found in *Hyenanche globosa*, Lamb (*Toxicodendron capense*, Thun.), a member of the N.O. *Euphorbiaceæ*, growing in S. Africa. Existence of active principle first indicated by Henkel (Arch. Pharm. 1858, 144, 16), and first isolated by Engelhardt (Arch. Pharm. Inst. Dorp. 1892, 8, 5). Further investigated by Henry (Chem. Soc. Trans. 1920, 117, 1619), who gives details of its mode of extraction. Slender, colourless needles, or hexagonal prisms. When heated becomes yellow at 200°, then darkens and finally decomposes with effervescence at 234°. Slightly soluble in water, alcohol, ethyl acetate, or acetone. $[\alpha]_D^{15} + 14.7^\circ$ in water. Reduces Barreswil's (Fehling's) solution on boiling, decolorises permanganate solution and gives an amorphous yellow precipitate with bromine water.

Iso-Hyenanchin crystallises from boiling water in long, slender needles. Has no melting-point, and is decomposed at 299° with effervescence. Is less soluble in water than hyenanchin, but its solution also reduces Barreswil's solution. Both modifications are toxic, and resemble picrotoxin in action but are much weaker, especially the *iso*-variety. They are isomeric with picroten.

Hyenanche globosa contains also a saturated alcohol $\text{C}_{23}\text{H}_{45}\text{OH}$; minute needles, m.p. 82°–83° (corr.); a *lævo*-rotatory phytosterol, lustrous needles, m.p. 265° (corr.), readily soluble in chloroform or boiling ethyl acetate, sparingly so in alcohol, together with a yellow colouring matter; microscopic yellow needles, m.p. 270°–280° (decomp.), probably belonging to the flavone group (Henry, *l.c.*).

HYGRINES v. COCAINE.

HYMENODICTYONINE (*Hymenodictine*)

crystals, m.p. 66°, occurs in the bark of *Hymenodictyon excelsum* (Wall.), used in India as an antipyretic. It is bitter and slightly toxic (Naylor, Pharm. J. 1883, [iii.] 13, 817; 1885, [iii.] 15, 195).

HYOSCINE v. TROPEINES.

HYOSCYAMINE AND HYOSCYAMUS v.

HENBANE; TROPEINES.

HYPAPHORINE *v.* BETAINES.

HYPEROL. Trade name for a mixture of urea and hydrogen peroxide stabilised by a trace of citric acid.

HYPERSTHENE. A rock-forming mineral belonging to the orthorhombic series of the pyroxene group, and consisting of metasilicate of magnesium and iron (Mg,Fe)SiO₃. With less iron it passes isomorphously into bronzite and enstatite (*q.v.*). It is a common constituent of basic igneous rocks, especially norite. The very coarse-grained norite found as boulders on the coast of Labrador consists of labradorite (*v.* FELSPAR) and hypersthene, the former showing brilliant coloured reflections and the latter a bright coppery sheen. This material is therefore sometimes used as an ornamental or precious stone. The mineral is opaque, with a dingy, brownish-black body-colour, and the metallic reflection is due to the presence of minute crystalline enclosures arranged parallel to one plane. Sp.gr. 3.4. L. J. S.

HYNAL *v.* SYNTHETIC DRUGS.

HYPNOGEN. Syn. for veronal.

HYPNONE *v.* KETONES; SYNTHETIC DRUGS.

HYPONITRITES *v.* NITROGEN.

HYPOPHOSPHITES *v.* PHOSPHORUS.

HYPOPHYSIS *v.* PITUITARY BODY.

HYPOQUEBRACHINE *v.* QUEBRACHO ALKALOIDS.

HYPORIT. Trade name for calcium hypochlorite containing about 80 p.c. available chlorine, forming a stable powder which can be compressed into tablets of accurate dosage. It is readily soluble in water, giving a faintly alkaline solution and may be used as a substitute for Dakin's solution as an antiseptic.

HYPOSCROME *v.* COLOUR AND CHEMICAL CONSTITUTION.

HYOSULPHITES *v.* SULPHUR.

HYPOXANTHINE or **SARCINE**, 6-oxypurine

discovered by Scherer (Annalen, 1850, 73, 328) in milk, spleen, and blood, is widely distributed both in the animal and vegetable kingdoms. Strecker (Phil. Trans. 1858, 10, 121) isolated it from meat juice, and hence called it *sarcine*; it was afterwards found to be identical with Scherer's hypoxanthine (*see* Salkowski, Biochem. Zeitsch. 1913, 55, 250; Yoshimura, *ibid.* 1911, 37, 481). It is a normal constituent of bone marrow (Heymann, Pflüger's Archiv. 6, 184), glands, muscles, liver, brain (Salomon, Ber. 1878, 11, 574; Kossel, Chem. Zentr. 1881, 486; Buglia and Costantino, Zeitsch. physiol. Chem. 1913, 83, 45; Smorodinzew, Chem. Zentr. 1914, 2, 797), blood (Scherer, *l.c.*; Salomon, Chem. Zentr. 1878, 681; Bass, Arch. f. exp. Path. u. Pharm. 76, 40), and urine (Strecker, *l.c.*; Salomon, Zeitsch. physiol. Chem. 1887, 11, 410), the amount varying from 0.024 p.c. in the grey matter of the brain (Kossel, *l.c.*) to 0.218 p.c. in the calf's thymus (Schindler, Zeitsch. physiol. Chem. 1889, 13, 432). Piccard found 5.8 p.c. of hypoxanthine and guanine in salmon roe (Ber. 1874, 7, 1714), whilst ox testis and the spermatozoa of carp contain 0.281 and 0.309 p.c. respectively of the former base (Schindler, *l.c.*). In the vegetable kingdom hypoxanthine occurs

in beer yeast (Schutzenberger, Chem. Zentr. 1877, 73); in fungi (Winterstein and Jegorow, Landw. Versuchs. Stat. 79 and 80, 541; Buschmann, Pharm. Post. 45, 453, from Chem. Zentr. 1912, 2, 613); and in hops (Chapman, Chem. Soc. Trans. 1914, 105, 1895); potato juice to the extent of 0.0037 gram per 1 c.c. (Schulze, Landw. Versuchs. Stat. 1882, 28, 111); in the leaf buds of plane and maple, bark of plane, in lupines, young grass, red clover, oats, vetch, in sugar beet (Schulze and Bosshard, Zeitsch. physiol. Chem. 1885, 9, 420; Von Lippmann, Ber. 1896, 29, 2645). It is present in heated soils (Schreiner and Lathrop, J. Amer. Chem. Soc. 1912, 34, 1242; Schreiner and Shorey, J. Biol. Chem. 1910, 8, 385).

The chief source of hypoxanthine in the animal economy appears to be nucleic acid, which, under the action of certain tissue enzymes, most abundant in the liver and spleen, is decomposed; thus *nuclease* liberates the purine bases adenine and guanine, and these are further changed by the deamidising enzymes *adenase* or *guanase* into hypoxanthine and xanthine respectively, and finally *oxydases* convert hypoxanthine into xanthine and xanthine into uric acid (Halliburton, Chem. Soc. Reports, 1909, 168; Amberg and Jones, Zeitsch. physiol. Chem. 1911, 73, 407; Long, J. Biol. Chem. 1913, 15, 449). Salomon (Ber. 1887, 11, 574; 12, 95) obtained hypoxanthine from blood fibrin by the action of pancreas ferment, by simple decay, or by digestion with dilute hydrochloric acid (8 parts in 1000 parts of water); and Kossel (Zeitsch. physiol. Chem. 1881, 5, 152) found that the nuclei from pus cells and goose blood yielded on prolonged boiling 1.03 and 2.64 p.c. respectively of hypoxanthine. On the other hand, Leathes (J. Physiol. 1906, 35, 125, 205), Leonard and Jones (J. Biol. Chem. 1909, 6, 453), and Vögtlin and Jones (Zeitsch. physiol. Chem. 1910, 66, 250), have shown that uric acid excretion is related in some way to muscular exercise, and the most important purine base which contributes to the endogenous uric acid is muscular preformed hypoxanthine. According to Frank and Przedborski (Arch. exp. Path. u. Pharm. 68, 349) 50 p.c. of ingested hypoxanthine is utilised in the formation of uric acid. This is not directly connected with nucleic metabolism, since it may occur in the absence of adensae, an essential factor in the passage from nucleic acid to hypoxanthine. Hypoxanthine has therapeutic properties (Funk, J. of Physiol. 45, 489). It raises the blood pressure (Backmann, Zentr. blatt. f. Physiol. 26, 166; Degrez and Dorléans, Compt. rend. 1913, 156, 93).

Fischer (Ber. 1897, 30, 2226; D. R. P. 1898, 17673) has synthesised hypoxanthine from trichloropurine by the following reactions: trichloropurine when heated with normal aqueous potassium hydroxide yields 6-oxy-2:8-dichloro-

to hypoxanthine by the action of hydrogen iodide. Hypoxanthine is also obtained from adenine (6-aminopurine) by the action of nitrous acid, or from uric acid by reduction with alkali and chloroform (Sundvik, Zeitsch. physiol. Chem. 1897, 23, 476; 26, 13; *ibid.* 1912, 76, 486).

A further synthesis of hypoxanthine from

ethyleyanacetate and thiourea is described by Traube (Annalen, 1904, 331, 64); 4-amino-6-

hydroxy-2-thiopyrimidine $\begin{array}{c} \text{NH}\cdot\text{CO}\cdot\text{CH}_2 \\ | \\ \text{CS}\cdot\text{NH}\cdot\text{C}\cdot\text{NH} \\ | \\ \text{NH}\cdot\text{CO}\cdot\text{C}\cdot\text{NOH} \end{array}$ obtained by the condensation of ethyleyanacetate and thiourea in the presence of sodium ethoxide, forms an isonitroso derivative

which on reduction yields 4:5-diamino-6-oxy-2-thiopyrimidine $\begin{array}{c} \text{NH}\cdot\text{CO}\cdot\text{C}\cdot\text{NH}_2 \\ | \\ \text{CS}\cdot\text{NH}\cdot\text{C}\cdot\text{NH}_2 \end{array}$. When the

sodium salt of the formyl derivative of this compound is heated at 250°-255° it is converted into 6-oxy-2-thiopurine $\begin{array}{c} \text{NH}\cdot\text{CO}\cdot\text{C}\cdot\text{NH} \\ | \\ \text{CS}\cdot\text{NH}\cdot\text{C}\cdot\text{N} \end{array} \text{CH}$, which

loses its sulphur on treatment with dilute nitric acid (25 p.c.) at 100°, yielding hypoxanthine $\begin{array}{c} \text{NH}\cdot\text{CO}\cdot\text{C}\cdot\text{NH} \\ | \\ \text{CH}\cdot\text{N}\cdot\text{C}\cdot\text{N} \end{array} \text{CH}$.

Hypoxanthine is a white crystalline powder, crystallising in two modifications, one form consisting of needles containing water of crystallisation, which spontaneously and readily lose their water yielding anhydrous octahedra (Micko, Zeitsch. Nahr. Genussm. 1904, 8, 225); it decomposes without melting at 150°, and dissolves in 69.5 parts of boiling water or 1400 parts at 19° (Fischer, Ber. 1897, 30, 2226).

Hypoxanthine exhibits both acid and basic properties, and combines with one equivalent of an acid, or two equivalents of a base; the following salts are described: the hydrochloride $\text{C}_5\text{H}_4\text{N}_4\text{O}\cdot\text{HCl}\cdot\text{H}_2\text{O}$, crystalline plates or needles, yields a sparingly soluble platinichloride

and a crystalline aurichloride

the hydrobromide $\text{C}_5\text{H}_4\text{N}_4\text{O}\cdot\text{HBr}$ and nitrate $\text{C}_5\text{H}_4\text{N}_4\text{O}\cdot\text{NH}_3$ are crystalline; the picrate dissolves in 450-500 parts of water at the ordinary temperature (Krüger and Salomon, Zeitsch. physiol. Chem. 1898, 26, 362). The barium derivative $\text{C}_5\text{H}_4\text{N}_4\text{O}\cdot\text{Ba}(\text{OH})_2$ is crystalline, the silver salt $\text{C}_5\text{H}_2\text{N}_4\text{OAg}_2\cdot\text{H}_2\text{O}$ loses $\frac{1}{2}\text{H}_2\text{O}$ at 100°; in the presence of excess of ammonia the salt crystallises with $3\text{H}_2\text{O}$, and loses $2\frac{1}{2}\text{H}_2\text{O}$ at 120°. The phosphotungstate forms straw-coloured cubical plates (Drummond, Biochem. J. 1918, 12, 5).

Hypoxanthine-d-glucoside crystallises in long needles, m.p. 245°, $[\alpha]_D^{20} -34.5^\circ$ in N/1-sodium hydroxide and $+12.92^\circ$ in N/1-hydrochloric acid

solution (Fischer and Helferich, Ber. 1914, 47, 210).

Hypoxanthine forms characteristic sparingly soluble derivatives with certain metallic salts, and these are used for separating and estimating the base. The compound with mercuric chloride $\text{C}_5\text{H}_3\text{N}_4\text{O}\cdot\text{HgCl}_2\cdot\text{H}_2\text{O}$ is crystalline; the compound with silver nitrate $\text{C}_5\text{H}_4\text{N}_4\text{O}\cdot\text{AgNO}_3$ is a flocculent precipitate, crystallising from hot nitric acid (sp.gr. 1.1), 1 part dissolves in 4960 parts cold nitric acid; according to Salkowski (Pflüger's Archiv. 4, 91), the presence of gelatin prevents the precipitation of hypoxanthine by silver nitrate; the picrate $\text{AgC}_5\text{H}_3\text{N}_4\text{O}\cdot\text{C}_6\text{H}_3\text{N}_3\text{O}_7$ is a lemon-yellow crystalline salt, insoluble in cold water, precipitated from a hypoxanthine salt by sodium picrate and silver nitrate (Bruhns, Zeitsch. physiol. Chem. 1890, 14, 555).

Bromohypoxanthine $\text{C}_5\text{H}_3\text{BrN}_4\text{O}\cdot 2\text{H}_2\text{O}$ is sparingly soluble in cold water, and is obtained by the action of bromine (1 mol.) on hypoxanthine (1 mol.) at 120°, or by the action of sodium nitrite on a solution of bromadenine at 70°; on heating hypoxanthine for 6 hours at 100°-150° with excess of bromine, bromohypoxanthine-tetrabromide hydrobromide $\text{C}_5\text{H}_3\text{BrN}_4\text{O}\cdot\text{HBr}\cdot\text{Br}_4$ is obtained (Krüger, Zeitsch. physiol. Chem. 1894, 18, 449).

Urethane of hypoxanthine $\text{C}_5\text{H}_3\text{N}_4\text{O}\cdot\text{COOEt}$, prepared by the interaction of ethylchloro-carbonate and hypoxanthine, crystallises in plates, m.p. 185°-190°, and is sparingly soluble (Bruhns and Kossel, Zeitsch. physiol. Chem. 1892, 16, 1). Hypoxanthine combines with adenine to form the crystalline compound

(Bruhns, Ber. 1890, 23, 225); and like other purine derivatives containing an imino group in position 7 it yields coloured derivatives with diazobenzene salts (Burian, Ber. 1904, 37, 696).

Separation and estimation.—From mixtures of the xanthine bases, adenine and hypoxanthine are separated from xanthine and guanine by means of their sparingly soluble derivatives with silver nitrate in nitric acid solution. The mixed silver compounds are decomposed by hydrochloric acid, the filtrate nearly neutralised with sodium carbonate and the adenine precipitated as picrate. The filtrate is neutralised with ammonia, and the hypoxanthine precipitated with ammoniacal silver nitrate (Bruhns, Ber. 1890, 23, 225; cp. also Kossel, Zeitsch. physiol. Chem. 1883, 8, 404; Schindler, *ibid.* 1889, 13, 432; Krüger, *ibid.* 1894, 20, 170). M. A. W.

HYRGOL v. SYNTHETIC DRUGS.

HYRGOLUM. Trade name for a form of colloidal mercury.

HYSTARAZIN v. ALIZARIN AND ALLIED COLOURING MATTERS.

I

IACHIOL. Trade name for silver fluoride.

IBIT v. SYNTHETIC DRUGS.

IBOGA. A plant *Tabernanthe iboga* (Baill.), natural order *Acanthaceae*, found in the Congo, the root of which is chewed by the natives and which is said to possess properties similar to

those of coca and kola. It enables persons to withstand fatigue, is used as a remedy for sleeping sickness and acts as an aphrodisiac.

Ibogaïne $\text{C}_{26}\text{H}_{32}\text{O}_2\text{N}_2$ (*Ibogine*), an alkaloid occurring in 'iboga' (*Tabernanthe iboga*) obtained from the French Congo. Orthorhombic crystals,

m.p. 152°, levo-rotatory (Dybowski and Landrin, *Compt. rend.* 1901, 133, 748; Haller and Heckel, *ibid.* 1901, 133, 850). The alkaloid produces anaesthesia, and in large doses causes convulsions and death due to stoppage of respiration (Lambert and Heckel, *ibid.* 1901, 133, 1236).

ICACIN *v.* OLEO-RESINS.

ICE BLACK *v.* AZO-COLOURING MATTERS.

ICE COLOURS. Colours formed on the fibre by treating it with a phenol and then with a diazotised amine in presence of ice. Known also as ingrain colours; *v.* AZO-COLOURING MATTERS.

ICELAND MOSS. *Cetraria islandica*. Yields on extraction with ether *proto-a-lichesteric acid*, which when subjected to a temperature higher than 45° is converted more or less into *a-lichesteric acid* $C_{15}H_{30}O_5$, m.p. 124°, which again is converted into *dilichesteric acid*. Acetone extracts from Iceland moss the potassium salt of *fumaroprotocetraric acid*, which is readily split up into acid potassium fumerate and *cetraric acid*; the latter does not occur in the free state. The cold-water soluble carbohydrates of Iceland moss include *lichenin*, *d-lichenidin* $[\alpha]_D = +15.4$, and *lichenoin* $C_{12}H_{20}O_{10}$, $[\alpha]_D = +20.7$, which on hydrolysis yields dextrose and a carbohydrate $C_6H_{10}O_5$, which gives a crystalline derivative with barium hydroxide. On boiling with water and a little sodium carbonate the lichen loses about 61 p.c., and the residue is largely hydrolysable by dilute acid, yielding mainly dextrose, some galactose and a very little mannose (Hesse, *J. prakt. Chem.* 1916, 94, 227; *J. Soc. Chem. Ind.* 1917, 566); *v.* LICHENS.

ICELAND-SPAR *v.* CALCITE; CALCIUM.

ICE-SPAR *v.* CRYOLITE.

ICHTHALBIN. Syn. for ichthylol aluminate.

ICHTHARGAN *v.* SYNTHETIC DRUGS.

ICHTHERMOL. Trade name for a mercury compound of ichthylol.

ICHTHOFORM. Trade name for a combination of ichthylol and formaldehyde. Used as an intestinal antiseptic.

ICHTHOSULPHOL (*ichthynal*). Syn. for ichthylol (*q.v.*).

ICHTHYOL. A pharmaceutical product distilled from fossilised fish remains, found in the Tyrol and on the coasts of the Adriatic. Similar deposits are found in the valley of the Isar and the Loisach; in Switzerland north of Meride, and in various parts of Italy.

Crude ichthylol from the Seefeld district between Southern Bavaria and the Tyrol has long been used as an antiseptic remedy. The crude 'rock oil' is obtained by simple distillation from the shale or 'stinkstein', a bituminous substance of a grey or black colour occurring in the upper dolomites. The amount of oil obtained varies from 1 to 10 p.c. An installation of nine stills yields, on an average, 15 to 20 kilos. of oil per charge. In one works the output of crude oil is over 3000 kilos. per annum. As found in pharmacy, the substance consists mainly of the ammonium sulphonate. It is not a simple substance but a mixture of ammonium ichthylol sulphonate with about 1 p.c. of a powerful-smelling empyreumatic oil, 5 to 7 p.c. of ammonium sulphate, and about 50 p.c. water.

According to Baumann and Schotten, ichthylol-sulphonic acid has the formula

An odourless ichthylol has been prepared by Knorr & Co. which has the therapeutic activity of the original strong-smelling product (*J. Soc. Chem. Ind.* 1903, 1304; 1910, 44, 174, 264).

The purification of the crude oil is effected by heating it with soda lime, washing with dilute sulphuric acid, drying and heating with sodium in a current of ammonia gas. It then contains only a small quantity of a ketonic substance from which it may be freed by magnesium methyl chloride. After fractionation over sodium it becomes colourless and acquires a pleasant, fragrant smell (Scheibler, *Ber.* 1919, 52, 1903). According to the same authority (*Archiv. et Pharm.* 258, p. 70), the typical sulphur compounds of ichthylol and similar tar oils are derivatives of thiophen.

For ichthylol preparations *v.* SYNTHETIC DRUGS.

ICHTHYOLIDIN. Trade name for piperazine ichthyolate.

ICHTHYOL-SALICYL. Trade name for a mixture of ichthylol and sodium salicylate.

ICICA and ICACIN *v.* OLEO-RESINS.

ICOSANE $C_{20}H_{42}$. A hydrocarbon found in paraffin. M.p. 36°; b.p. (under 15 mm. pressure) 205°; sp.gr. 0.778 at 37°/4°. Formed by the action of sodium on normal decyl iodide.

ICOSONENE *v.* RESIN OIL.

IDAEIN *v.* ANTHOCYANINS.

IDOCRASE *v.* VESUVIANITE.

IDRYL *v.* FLUORANTHENE.

IGNATIUS BEANS *v.* NUX VOMICA.

IGNOTINE *v.* CARNOSINE.

ILEX VOMITORIA (Aiton). The leaves of this tree growing in the South Eastern States of America, and used by the Indians, under the name of 'Yaupon' on account of their medicinal and stimulating properties, have been found by Power and Chesnut (*J. Amer. Chem. Soc.* 1919, 41, 1307) to contain notable amounts of caffeine.

ILICIC and ILICYLIC ALCOHOLS *v.* BIRDLIME.

ILLIPÉ-NUT FAT. Illipé-nuts yield a considerable quantity of a fat which is imported from the Dutch East Indies, and used in conjunction with palm-kernel oil in the manufacture of candles. It is well adapted for the saponification method of stearin manufacture. In the autoclave it yields about 10 p.c. of glycerol of 28°B. (*J. Soc. Chem. Ind.* 1898, 161, 358); *v.* BASSIA OIL.

ILMENITE, or titaniferous iron-ore. A common mineral with approximately the formula $FeTiO_3$, but of variable composition. Analyses show TiO_2 22-59, FeO 20-46, Fe_2O_3 1-59 p.c. In its rhombohedral crystalline form it shows a close agreement with hematite, and it has consequently, until recently, been regarded as an isomorphous mixture of ferric oxide and titanium sesquioxide, the formula being written as an oxide $(Fe,Ti)_2O_3$. The discovery of the rhombohedral titanates of magnesium and manganese, geikielite ($MgTiO_3$) and pyrophanite ($MnTiO_3$), and the frequent presence of magnesium (and manganese) in ilmenite, suggest, however, that the mineral is really a titanate of

ferrous iron, FeTiO_3 (S. L. Penfield, Amer. J. Sci. 1897, 4, 108). In the variety *microilmenite* a considerable amount of iron is replaced by magnesium, the formula then being $(\text{Fe}, \text{Mg})\text{TiO}_3$ (T. Crook and B. M. Jones, Min. Mag. 1906, 14, 165).

Ilmenite is black with a sub-metallic lustre, and often a smooth and lustrous conchoidal fracture, sp.gr. 4.5-5; H. 5-6. The massive mineral somewhat resembles magnetite in appearance, from which it is readily distinguished by its feeble magnetic character. It is of constant occurrence as isolated grains in the more basic igneous rocks (gabbro, diabase, basalt, &c.); and in certain instances it forms rich segregations in such rocks. Enormous deposits of ilmenite are found under these conditions at several places in Norway, Sweden, Canada, and the United States. With the weathering and breaking down of these igneous rocks, grains of ilmenite (*Manaccanite*, from Manaccan in Cornwall) collect in the beds of streams, sometimes forming considerable deposits of 'black iron-sand.'

Although large deposits of ilmenite are available for mining, the mineral has not yet found any important applications. It has been used for the preparation of titanium paints and enamels; and in the future it may be more utilised for the manufacture of titanium-steel, which possesses great ductility and a high limit of elasticity. (See J. T. Singewald, The Titaniferous Iron Ores of the United States, their Composition and Economic Value, U.S. Bureau of Mines, 1913, Bull. 64.) L. J. S.

ILMENORUTILE *v.* STRÜVERITE.

ILVAITE, LIEVRITE, or YENITE. Acid silicate of iron and calcium, $\text{H}_2\text{CaFe}''_2\text{Si}_2\text{O}_9$, crystallised in the orthorhombic system. It contains theoretically FeO 35.2, Fe_2O_3 19.6 p.c. (Fe 41 p.c.), but the ferrous oxide is partly replaced by an equivalent amount of manganous oxide (up to 8.6 p.c.). Sp.gr. 3.9-4.1, H. 5½-6; gelatinises with hydrochloric acid. The mineral is found somewhat abundantly as brilliant black crystals and as compact masses in the iron mines at Río Marina and Cape Calamita in Elba. It is also known from Campiglia Marittima in Tuscany, Hebron in Nassau, British Columbia, Greenland, and Japan. L. J. S.

IMIDES. Nitrogenous compounds obtained by the action of gaseous ammonia on the anhydrides of dibasic acids and resulting in the substitution of the bivalent $>\text{NH}$ group (imidegen) for the oxygen atom uniting the two carbonyls, *e.g.*:

Phthalic anhydride.

β-IMINAZOLYETHYLAMINE *v.* ERGOT.

IMINES. Bases derived from aldehydes or ketones by the substitution of $>\text{NH}$ (imidegen) for oxygen. Imines derived from aldehydes are known as *aldimines*; those derived from ketones are called *ketimines*.

IMOGEN, eikonogen modified by the intro-

duction of another amino group; used as a photographic developer.

IMPERIALINE $\text{C}_{35}\text{H}_{60}\text{NO}_4$. An alkaloid discovered by K. Fragner in *Fritillaria Imperialis* (Linn.). Short needles, m.p. 254° (approx.) $[\alpha]_D -35.4^\circ$ in chloroform; yields a crystalline hydrochloride (Ber. 1885, 21, 3284). It is a heart-poison, and is probably closely related to the older alkaloid *Tulipine*, discovered by Gerard in *Tulipa Gesneriana* (Linn.).

IMPERIAL GREEN. *Emerald Green v.* PIGMENTS.

IMPERIAL SCARLET v. AZO-COLOURING MATTERS.

IMPERIAL YELLOW v. AURANTIA.

INACTIVE CAMPHOR v. CAMPHORS.

INCANDESCENT MANTLES v. GAS MANTLES.

INCARNATRIN v. GLUCOSIDES.

INCENSE, *see* Olibanum, art. GUM-RESINS; OLEO-RESINS.

INDACONITINE v. ACONITINE.

INDALIZARIN v. OXAZINE COLOURING MATTERS.

INDAMINES and INDOPHENOLS.

Constitution and mode of formation.—The indamines and indophenols are colouring matters most of which are too unstable to be of great practical value, but many of them are interesting as intermediate products in the manufacture of other more important dyestuffs. From a theoretical point of view they can claim great importance, as they form the starting-point of the modern 'quinonoid' structural formulæ now universally adopted for the majority of colouring matters. This is due to the fact that the indamines and indophenols are the simplest real colouring matters derived from the quinones, which are now considered as prototypes of chromogens.

All aromatic hydrocarbons are capable of forming quinonoid derivatives by the displacement of 2 hydrogen atoms by 2 atoms of oxygen. These may stand either in *o*- or in *p*-position to each other, whilst no quinones have ever been discovered which contain the oxygen atoms in *m*-position. The divalent nature of oxygen forces us to consider the quinones either as peroxides of aromatic hydrocarbons or as alicyclic diketones. The first of these possibilities was formerly considered as more probable and was made the basis of this article in the first edition of this dictionary. Since then the diketone formula has come to be generally adopted and it will therefore have to be used in this revision of the article.

The following formulæ represent the two different constitutions which may be given to *p*-quinone, the prototype of all the substances to be mentioned in this article:

Peroxide formula.

Diketone formula.

All other quinones, no matter from what aromatic hydrocarbon they are derived and whether they belong to the *o*- or *p*-series, may be similarly formulated and neither of

these two different constitutions can be claimed as undoubtedly preferable to the other. It is very probable that the quinones are tautomeric and possessed of both constitutions according to the circumstances under which they react.

If the oxygen of *p*-quinone be replaced by divalent imino groups =NH, two compounds may be obtained, *p*-quinoneimide and *p*-quinonediimide, which for many years have been considered as hypothetical but have recently been prepared by Willstätter (Ber. 37, 1494, 4605). They are very unstable substances the constitution of which is expressed by the following formulæ (based, as all the subsequent formulæ of this article, on the diketonic constitution of the quinones)

The iminic hydrogen of these compounds may be replaced by halogen atoms, and we thus obtain substances of a comparatively stable nature which have been known for a long time and may be used for the preparation of various derivatives. It was by treating quinonedichlorodiimide, dissolved in ether, absolutely free from moisture, with the theoretical quantity of dry hydrogen chloride that Willstätter first succeeded in preparing *p*-quinonediimide. Later on he found a general method for the production of both these imides in the oxidation of either *p*-phenylenediamine or *p*-aminophenol with dry silver oxide. They are slightly basic substances, capable of forming unstable hydrochlorides. In a free state they are white, but they resemble quinone in their reactions. Their great tendency to polymerisation is the cause why previous attempts at their isolation have failed.

by Schmitt and Bennewitz (J. pr. Chem. [ii.] 8, 2). It is prepared by allowing a solution of 43 grams *p*-aminophenol hydrochloride in 500 c.c. water and 100 c.c. concentrated hydrochloric acid to flow into a solution of sodium hypochlorite prepared by introducing 35 grams of chlorine into an ice-cold solution of 45 grams sodium hydroxide. The imide settles out and may be recrystallised from light petroleum (Willstätter, Ber. 37, 1499). It forms yellow crystals, melting at 85°; it is slightly explosive, volatile with aqueous vapour, and resembles quinone in many of its properties.

prepared in the same manner from trichloroaminophenol hydrochloride (Schmitt and Andersen, J. pr. Chem. [ii.] 23, 438; 24, 429). Yellow needles, m.p. 118°, similar to quinonechloroimide,

obtained by adding a solution of bleaching-powder to an aqueous acidulated solution of the double salt of dibromaminophenol hydrochloride and tin chloride. It separates in flesh-coloured crystals, melting at 80° (R. Möhlau, Ber. 16, 2845).

by acting with a solution of bleaching-powder upon a solution of *p*-phenylenediamine hydrochloride (Krause, Ber. 12, 47). Willstätter (Ber. 37, 1498) prepares it by allowing a solution of 54 grams *p*-phenylenediamine hydrochloride in 120 c.c. hydrochloric acid and 600 c.c. water to flow into a hypochlorite solution prepared by introducing 75 grams of chlorine into the solution of 90 grams sodium hydroxide in 500 c.c. of water. The imide separates in whitish flakes and may be recrystallised from light petroleum. White needles, insoluble in water, soluble in alcohol, benzene, &c., and exploding at 126°.

pared by acting with bromine water upon *p*-phenylenediamine hydrochloride (Krause, Ber. 12, 50). It is similar to the chloro derivative, and explodes at 86°.

These substances are not colouring matters, as may be seen from the above description. They cannot be colouring matters, because they are indifferent, whilst every dyestuff must be either an amine or a phenol (Witt, Bau und Bildung färbender Kohlenstoffverbindungen, Ber. 9, 522). Their chromophoric character, however, becomes apparent in those of their derivatives which are endowed with either basic or acid properties. Nitrosodimethylaniline and nitrosophenol, which, as their constitutional formulæ show, are closely related to quinonediimide and quinoneimide:

are by virtue of their basic and phenolic nature, colouring matters possessing some affinity for fibres, although they have no practical value as dyestuffs.

We may, however, obtain real colouring matters, many of which have proved useful and interesting, by preparing substitution products of the quinoneimides in which the substituting radicle is attached to nitrogen. Such products may be prepared by acting with amines or phenols upon quinoneimides, or their equivalents, quinonamidoximes (nitroso bases) and quinoneoximes (nitrosophenols). Various cases may here be cited :

1. By acting with aromatic amines upon quinonedichlorodiimides, indamines are formed, thus :

2. By acting with aromatic amines upon quinone-amidoximes (nitroso bases) indamines are formed likewise :

In this case, as in many similar ones in this group, the quinonoid character may in the formation of the dyestuff be shifted from one benzene ring to the other. This has been indicated in the formula, although we have no positive proof that such shifting takes place in the formation of tolylene blue.

3. By acting with aromatic amines upon quinonechloroimides normal indophenols are formed :

4. By acting with phenols upon quinone-dichlorodiimides indophenols of a more complicated nature may be formed :

5. By acting with phenols upon quinonamidoximes (nitroso bases) normal indophenols are formed :

Normal naphthindophenol.

In this case again, as in No. 2, a migration takes place and the quinonoid nature is shifted from the benzene to the naphthalene nucleus. This can be proved to be the case by the fact that the resulting dyestuff is a weak base but entirely devoid of phenolic properties. It cannot therefore contain an OH group.

6. By acting with phenols upon quinone-chloroimides colouring matters are formed, which although practically belonging to the indophenols are distinguished by the presence of a free hydroxyl group, by which they assume phenolic properties, dissolve in alkalis and have therefore been designated by the name of 'acid indophenols.'

7. The same result takes place if the equivalents of quinoneimide, viz. the quinoneoximes or nitrosophenols be acted upon with phenols :

8. If, however, amines be acted upon with nitrosophenols, a normal indophenol is the result :

9. The quinones themselves may be utilised for the production of these dyestuffs by being

acted upon with suitable diamines or aminophenols:

This reaction makes it evident that the indamines and indophenols are nothing else than a certain group of the larger family of quinone anilides, viz. those of these anilides which contain the auxochromic groups necessary for developing their nature as dyestuffs.

For the production of indamines and indophenols it is, however, not necessary to start from ready-formed quinones, quinoneimides, diimides, or quinoneoximes. It is possible to prepare these substances by the joint oxidation of amines or phenols with compounds which are capable of producing a quinoneimide or diimide.

In this process we may assume that the hypothetical quinoneimides and -diimides are formed as intermediate products which immediately react upon the amines or phenols present in the mixture, forming indamines or indophenols, as the case may be. Every *p*-aminophenol or *p*-diamine is capable of being used for this reaction, and a large variety of colouring matters may thus be produced. The following combinations may take place:

10. *p*-Diamines simultaneously oxidised with aromatic amines give rise to the formation of indamines.

11. *p*-Diamines oxidised with aromatic phenols produce normal indophenols:

12. *p*-Aminophenols oxidised with aromatic amines produce normal indophenols:

13. *p*-Aminophenols oxidised with aromatic phenols produce acid indophenols:

From the above it will be seen that all the various colouring matters prepared by these reactions and built up on the quinone type may be subdivided into three varieties:—

a. True *indamines* containing no oxygen, and having the generic formula:

strong bases, forming stable salts with mineral acids.

b. Normal *indophenols*, containing oxygen in their chromophoric group, being amino derivatives of substituted quinoneimides of the generic formula:

very weak bases, incapable of forming stable salts. With these the hydroxy derivatives of quinonediimides:

are practically identical, being transformed into normal indophenols *in statu nascendi* by the shifting or migrating process already mentioned.

c. Acid *indophenols*, hydroxyl derivatives of quinonimides of the generic formula:

distinct phenols, dissolving in caustic alkali solutions with intense colorations.

Like all colouring matters the indamines and indophenols are capable of being reduced by the action of nascent hydrogen, of which two atoms are taken up. Colourless 'leuco-' compounds are formed which stand in the same relation to the original dyestuff as hydroquinone stands to quinone:

It will be clearly seen that these formulæ of the leuco derivatives are identical with the

formulae of paradiamino, aminohydroxy, and *p*-dihydroxy derivatives of secondary aromatic bases. Now as the leuco derivatives of indamines and indophenols are capable of reoxidation into the original dyestuff, it is apparent that we have by this means three additional methods for the production of such colouring matters:

14. *Di-p*-amino derivatives of secondary aromatic bases may be oxidised into indamines.

15. *p*-Amino-*p*-hydroxy derivatives of secondary aromatic bases may be oxidised into normal indophenols.

16. *Di-p*-hydroxy derivatives of secondary aromatic bases may be oxidised into acid indophenols.

The conditions under which these various reactions should be performed are stated below.

The remarkable relations existing between dyestuffs and their leuco compounds were recognised and studied by chemists at an early period. In no group are they so clearly defined as in that of the indamines and indophenols. Their complete elucidation in this group very naturally sheds light upon analogous phenomena observed in other colouring matters, and thus the study of this class of substances greatly facilitated the introduction of the modern views of the 'quinonoid' constitution of colouring matters.

Literature on the Constitution of Indamines and Indophenols, Otto N. Witt, J. Soc. Chem. Ind. 1882, 255; R. Möhlau, Ber. 16, 2843; Otto N. Witt, British Association, 1887; Journ. Soc. Dy. Col. 1887; R. Nietzki, Organische Farbstoffe, 5th ed. 1906, 197 *et seq.*

History.—The first indamine observed was the intermediate product obtained in the production of safranine, of which, however, no account was published. In 1879, Otto N. Witt prepared the first indamine in a state of purity by acting with nitrosodimethylaniline hydrochloride upon *m*-tolylendiamine (Ber. 12, 931; Chem. Soc. Trans. 1879, 1, 356). In 1881, Otto N. Witt and Horace Köchlin obtained patents for the production of normal indophenols. The production of 'acid indophenols' by the reaction of quinonechloroimide upon phenol was first mentioned by Hirsch (Ber. 13, 1909), and discussed by Möhlau (*ibid.* 16, 2845). The normal indophenols only have found a practical application in dyeing and calico-printing. Owing, however, to their insufficient resistance to the action of acids and to the difficulties in their application, they did not make very rapid progress in the favour of practical dyers and colourists. A change for the better took place, when it was shown that the typical indophenol is a good vat-dye and capable of being used in combination with indigo. The consumption of indophenol became considerable for a while, but went down again as rapidly as it had gone up when the introduction of synthetic indigo lowered the prices of this 'king of dyestuffs' and the invention of many indigoid colouring matters overwhelmed the dyer with dyes suitable for the vat-process.

In later years some of the indophenols have become important as raw materials for the production of some valuable sulphur dyes, which are prepared from them by the well-known process of boiling or melting with alkaline sulphides. This new application of the indophenols had been first indicated in D. R. P. 132212 of the

Gesellschaft für Chemische Industrie, in Basle (14 Dec. 1898), and the corresponding Fr. Pat. 284387 and Amer. Pat. 665547.

Properties.—The properties of the indamines and indophenols are more uniform than those of other classes of colouring matters. It has consequently been necessary to prepare only a small number from the host of possible members of this group in order to obtain a fair notion of the properties of the whole group. With very few exceptions their shade is blue or violet; in some cases a bluish-green. The shade of the dyestuff is exhibited:

a. In the indamine group by the normal salts of the indamine bases.

b. In the group of normal indophenols by the free bases.

c. In the group of acid indophenols by the alkaline salts of the dyestuffs.

All the indamines and indophenols possess the generic character of the quinone group. They are therefore capable of acting as oxidising agents if brought together with oxidisable substances. In such reactions they take up hydrogen and are transformed into their leuco derivatives. So considerable is their tendency to act as oxidising agents that, under suitable conditions, an indamine or indophenol will attack its own molecules, when a mixture of its oxidation products and its leuco compounds is the result (*v. Safranines*, art. AZINES). The conditions under which such reactions take place are, an elevated temperature and the presence of mineral acids. The indamines and indophenols are consequently unstable in the presence of acids, whilst in alkaline and neutral solution they display but little tendency to decompose. A similar decomposition is caused, especially in the indamines, by the action of sunlight; the normal indophenols may, on the contrary, be called rather fast.

The following is an account of those members of this group of dyestuffs which have been more closely examined or proved important from a technical point of view:—

I. INDAMINES.

Phenylene-blue $C_{12}H_{11}N_3$

Constitution $C_6H_4-NH_2$

This compound is best prepared by oxidising a mixture of *p*-phenylenediamine and aniline hydrochloride in equal molecules in the cold, with the theoretical quantity of potassium dichromate. A greenish-blue liquid is formed, from which the iodide of phenylene-blue may be precipitated by the addition of potassium iodide solution. This salt forms long needles with a green metallic lustre. It is soluble in water with a greenish-blue colour, which turns into green on the addition of mineral acids. Acid solutions decompose very rapidly, a considerable quantity of *p*-quinone being formed in this decomposition. On reduction phenylene-blue yields di-aminodiphenylamine, from which phenylene-blue may be regenerated by simple oxidation. Phenylene-blue is transformed into safranine on being boiled in a neutral solution with aniline hydrochloride (*v. Safranine*).

Literature.—R. Nietzki, Ber. 1883, 16, 464; R. Nietzki, Organ. Farbstoffe, 5th ed. 1906, 200.

Tetramethyl derivative of Phenylene-blue (*Dimethylphenylene-green*).

This interesting compound, which is the completely methylated derivative of the preceding one, is formed by the joint oxidation of *asym*-dimethyl-*p*-phenylenediamine with dimethylaniline, in equal molecules, with potassium dichromate in the presence of zinc chloride (Bindschedler, Ber. 13, 207). The zinc double salt is at once deposited from the liquid. According to the quantity of zinc chloride present the crystals are either of a copper colour or have a metallic green lustre. These crystals are freely soluble in pure water, with a fine green coloration. Potassium iodide precipitates from this solution the phenylene-green iodide $\text{C}_{15}\text{H}_{20}\text{N}_3\text{I}$ in beautiful green needles, which are easily soluble in pure water, very insoluble in the presence of an excess of potassium iodide. The platinum double chloride has the composition $(\text{C}_{15}\text{H}_{20}\text{N}_3\text{Cl})_2\text{PtCl}_4$; dimethylphenylene-green is more stable than the majority of indamines. On reduction it yields tetramethyldiaminodiphenylamine from which the green may be regenerated by oxidation.

Dimethylphenylene-green dyes silk and other fibres a yellowish shade of green. It has, however, found no application as a colouring matter, being rather unstable to light.

Its solution, on being boiled with the solution of an equal molecule of the hydrochloride of a primary amine, yields the corresponding safranine. (Also *Safranine*.)

Literature.—Bindschedler, Ber. 13, 207; R. Nietzki, *ibid.* 16, 464; Bindschedler, *ibid.* 16, 865.

Diethylphenylene-green $\text{C}_{20}\text{H}_{28}\text{N}_3\text{Cl}$ is obtained by oxidising diethyl-*p*-phenylenediamine with diethylaniline in the presence of mercuric chloride. Very similar to the methyl derivative, but less stable.

Literature.—Bindschedler, Ber. 16, 867.

Homologues of phenylene-blue. These are formed by the joint oxidation of *p*-phenylenediamine and the homologues of aniline or of *p*-tolylenediamine with aniline and its homologues. They play an important part in the manufacture of the commercial safranines, in which they are obtained as intermediate products.

Literature.—O. N. Witt, J. Soc. Chem. Ind. 1882, 256.

Witt's phenylene-violet $\text{C}_{12}\text{H}_{12}\text{N}_4\cdot\text{HCl}$. This substance is obtained by the joint oxidation of *p*-phenylenediamine with *m*-phenylenediamine. Its aqueous solution, which exhibits a fine purple shade, is decomposed on boiling, when a corresponding diamino-azine or eurhodine is formed. Similar compounds are obtained by the joint oxidation of other *p*-diamines with *m*-phenylenediamine. This reaction is, therefore, applicable as a test for both *p*- and *m*-diamines.

Witt's phenylene-blue $\text{C}_{14}\text{H}_{16}\text{N}_4\cdot\text{HCl}$. The dimethyl derivative of the preceding substance

is formed either by the joint oxidation of dimethyl-*p*-phenylenediamine and *m*-phenylenediamine hydrochloride, or by mixing together lukewarm solutions of nitrosodimethylaniline hydrochloride and *m*-phenylenediamine, both dissolved in glacial acetic acid. It forms bronze-coloured crystals, readily soluble in water, with a purplish-blue shade. On the addition of mineral acids unstable diacid salts of a yellowish-brown colour are formed. The aqueous solution is decomposed by prolonged boiling, yielding neutral violet, a colouring matter of the eurhodine group (*v. Safranine*).

Literature.—Otto N. Witt, D. R. P. 15272, 1880; Eng. Pat. 4846, 1880.

Tolylene-blue $\text{C}_{15}\text{H}_{18}\text{N}_4\cdot\text{HCl}$

This is the most thoroughly investigated member of the group. It is formed by the action of oxidising agents upon a mixture of dimethyl-*p*-phenylenediamine and *m*-tolylenediamine, or by the direct combination of nitrosodimethylaniline hydrochloride and free *m*-tolylenediamine. It is best prepared by the latter method. On mixing lukewarm aqueous solutions of the two ingredients in the proportion of equal molecules the blue is formed at once, and on cooling settles out in the shape of glistening bronze-coloured crystals which have the composition $\text{C}_{15}\text{H}_{18}\text{N}_4\cdot\text{HCl}$. On adding hydrochloric acid to an aqueous solution of this compound a much more soluble diacid salt

$\text{C}_{15}\text{H}_{18}\text{N}_4\cdot\text{HCl}$

of a reddish-brown colour, is formed. By the action of reducing agents, especially stannous chloride, the leuco derivative of tolylene-blue, dimethyltriaminotolylphenylamine $\text{C}_{15}\text{H}_{20}\text{N}_4$ is formed. An aqueous solution of the blue is decomposed by prolonged ebullition. The products of this decomposition are leucotolylene-blue and dimethyldiaminotoluphenazine (*Tolylene red*, *v. AZINES*).

Literature.—Otto N. Witt (Ber. 12, 931; Chem. Soc. Trans. 1879, 356; D. R. P. 15272, 1880; J. Soc. Chem. Ind. 1882, 256); R. Nietzki (Ber. 16, 1883, 475).

II. INDOPHENOLS.

The simplest *indophenol* $\text{C}_{12}\text{H}_{10}\text{N}_2\text{O}$

was prepared in 1880 and described by the inventors, Horace Köchlin and Otto N. Witt in their fundamental patents: D. R. P. 15915,

Amer. Pat. 261518, Fr. Pat. 141843, Eng. Pat. 1373, 5249, 1881. It may be obtained by any of the processes indicated for the purpose by theory (see above, modes of formation). The best method for its preparation is the joint oxidation of *p*-phenylenediamine and phenol dissolved in water in equimolecular proportions with oxidising agents, which act in a neutral or alkaline solution, such as sodium ferricyanide, potassium persulphate, or hypochlorites. The last-named are exclusively used in industrial work. The dyestuff, which is of a reddish-blue shade, settles out at once. It is, however, very impure and contains other colouring matters which are formed by the condensation of part of the indophenol formed into more complicated indophenols of a higher molecular weight. According to the D. R. PP. 179294 and 179295, this is not the case if lead or manganese peroxides be used as an oxidising agent. Another method, indicated in the D. R. PP. 160710 and 168229 consists in oxidising a mixture of phenol with the monoacetyl or the monoaryl sulphonic derivatives of *p*-phenylenediamine and subsequent decomposition with alkali.

This dyestuff is insoluble in water, easily soluble in alcohol, ether, or benzene. Acids dissolve it readily with a yellow colour. The solution is quickly decomposed on standing.

A very similar dyestuff of a bluer shade may be obtained by the joint oxidation of a mixture of *p*-phenylenediamine and *p*-xylenol in molecular proportions.

Other nearly allied indophenols are prepared by the joint oxidation of *o*-tolidine and *p*-aminophenol (Cassella and Co., D. R. P. 199963, 1901); and by the action of nitrosophenol upon *p*-chloro-*o*-nitrodiphenylamine (Kalle & Co., D. R. P. 205391, 1907).

All these indophenols are extremely similar in their properties. Notwithstanding the intensity and beauty of their blue coloration they have not acquired any importance as practical dyestuffs, probably because they are so easily attacked and decomposed by mineral acids. But in later years they have assumed great importance as raw materials for the manufacture of very fast blue sulphur dyes, and this has caused the appearance of numerous patents for the production of such indophenols, the more important of which only can be mentioned in this article.

Dimethyl derivative of simplest indophenol,
 $C_{14}H_{11}N_2O$,

is obtained like the preceding compounds by joint oxidation from a mixture of phenol and dimethyl-*p*-phenylenediamine or by oxidising a mixture of dimethylaniline and *p*-aminophenol; it crystallises from alcohol in glistening green needles. Its alcoholic solution is of a brilliant greenish-blue colour.

Literature.—Horace Köchlin and Otto N. Witt, D. R. P. 15915, 1881. Leop. Cassella & Co., second addition to D. R. P. 15915.

Dimethyl-trichloroindophenol $C_{14}H_{11}Cl_3N_2O$,

is obtained by mixing alcoholic solutions of trichloroquinonechloroimide (1 mol.) and dimethylaniline (2 mols.), according to the equation:

Recrystallised from alcohol, it forms long green glistening needles, which have the general character of the indophenols and are comparatively stable. On reduction it yields the corresponding leuco compound, dimethylaminohydroxytrichlorodiphenylamine, $C_{14}H_{13}Cl_3N_2O$.

Literature.—Schmitt and Anderson (J. pr. Chem. [ii.] 24, 435).

Carbazole indophenol. This curious substance, which has been obtained by Cassella & Co. according to mode of formation No. 8 from carbazole and nitrosophenol has evidently the constitution:

It is of great importance because on being heated with polysulphides it yields *hydron blue*, a sulphur dye insoluble in sodium sulphide solution, but capable of being used in the vat in exactly the same way as indigo and giving deep blue shades which are quite as fine and fast as those obtained with indigo itself. It is therefore expected to become a serious competitor of indigo blue. (See INDIGO, ARTIFICIAL, and INDIGOID DYESTUFFS; VAT DYES, MODERN.)

All the indophenols mentioned so far have this in common, that they are derivatives of *p*-quinone, and this accounts for the similarity of their properties and chemical behaviour.

A marked difference in this respect is shown by the indophenols which are derived from naphthaquinone which is itself less reactive and consequently more stable than the benzene derivative. This stability also shows itself in the naphthindophenols which can therefore claim to be applicable and even valuable dyestuffs.

Although a large number of these substances is foreseen by theory, the only well-known member of the group is the one first discovered, the typical indophenol of commerce $C_{18}H_{18}N_2O$ (vat blue, Küpenblau), the structure of which is expressed by the constitutional formula

It was discovered in 1880 by Horace Köchlin and Otto N. Witt and described in their fundamental indophenol patents already mentioned.

It is prepared from an alkaline mixture of dimethyl-*p*-phenylenediamine and α -naphthol in molecular proportions by oxidation. On a small scale potassium ferricyanide or ammonium persulphate is the most convenient oxidising agent, whilst on the manufacturing scale air is blown through the liquid, or a solution of sodium hypochlorite is employed. It may also be prepared by adding potassium chromate to the alkaline mixture of the ingredients and acidifying with acetic acid. Another process consists in simply heating on the water-bath an alcoholic solution of free nitrosodimethylaniline and sodium α -naphthoxide; or in bringing together, in an aqueous solution, α -naphthol, nitrosodimethylaniline, and caustic soda; this mixture is rapidly transformed into indophenol if a small quantity of a reducing agent, such as sodium stannite or glucose, be added.

Indophenol forms a dark-blue microcrystalline powder with a coppery metallic lustre, exactly resembling indigo. It is quite insoluble in water, sparingly soluble in spirit, ether, or benzene. It dissolves in dilute mineral acids, forming salts of a yellow colour, which are, however, quickly decomposed. In this decomposition α -naphthaquinone is formed as one of the products. Indophenol is slightly volatile; on being strongly heated it forms a sublimate resembling sublimed indigo. By reducing agents it is transformed into its leuco derivative

dimethylaminophenylhydroxynaphthylamine. This has been an article of commerce under the name of indophenol-white. It is quite stable in an acid state, but in the presence of alkalis it rapidly absorbs the oxygen of the air, indophenol being regenerated.

The application of indophenol to dyeing and calico-printing is based either on the formation of the dyestuff on the fibre, or on the oxidation of its ready-formed leuco derivative after fixing the latter on the fibre. The first method is rarely employed. As an example the following description, taken from the patent specification, may serve: Bleached calico is printed with a thickened mixture of aminodimethylaniline and sodium α -naphthoxide; after drying and steaming it is passed through a solution of potassium dichromate, when the blue is instantaneously developed. As a rule ready-formed indophenol is

employed for printing, reduced by being mixed with a solution of stannous acetate, then thickened with starch paste and printed on the fibre. The colour is developed by steaming and exposure to the air. Indophenol-blue on calico is very fast to the action of soap, fairly so to the action of light, but rather susceptible to acids.

In spite of its many good qualities, indophenol at first did not meet with an enthusiastic reception in the tinctorial world. This was changed by an interesting and for its time (about 1885-1895) important discovery of the Swiss manufacturing firm L. Durand, Huguenin & Co. It is based on the fact that indophenol, mixed with indigo, assumes the properties of the latter and may consequently be used in the vat process, especially with hydrosulphite as a reducing agent.

It is more than probable that the two leuco compounds of indigo and indophenol are capable of combining chemically and that the resulting substance is endowed with strong affinities for the fibre, especially cotton. It is thus easily taken up from the vat and, on being reoxidised on the fibre, deposits in the molecular interstices of the latter an intimate mixture or even a chemical combination of the two dyestuffs, indigo and indophenol.

An intimate mixture of indigo and indophenol, ground together into an impalpable powder is the 'vat blue' or 'küpenblau' of commerce, which may still occasionally be met with, although it has lost many of its advantages by the great reduction in the price of indigo and by the introduction of the cheap and excellent dark-blue sulphur dyes, many of which are also capable of being applied in the vat.

Literature.—Otto N. Witt and Horace Köchlin, D. R. P. 15915, 1881, with several additions; and corresponding patents in England, France, the United States, Sweden, Belgium, and Austria; Otto N. Witt, J. Soc. Chem. Ind. 1882, 144, 225, 405; R. Möhlau, Ber. 16, 2845.

III. ACID INDOPHENOLS.

It has already been mentioned that these substances are not true acids, containing no carboxyl groups in their molecule. They owe their name to the fact that, containing no amino and several hydroxyl groups, they readily combine and form stable salts with metallic oxides. Of these only the alkali salts are known. In a solid state they form crystalline powders with a green or copper-coloured metallic lustre. They are easily soluble in water with an intense blue coloration. By the addition of acids the free indophenols are deposited in the shape of brown or reddish flakes, which are soluble with a dark-red colour in spirit, ether, benzene, and analogous solvents.

The acid indophenols show in even a higher degree the tendency of the whole group to polymerise into colouring matters of a more complex molecule. It is therefore extremely difficult to prepare them in a state of purity. On the other hand, they do not show the susceptibility to acids so characteristic of the indamines and typical indophenols. It is therefore possible to prepare them not only in alkaline

but also in acid solutions and by means of oxidising agents which act in such. Their modes of formation are given above under methods 4, 6, 7, 12, and 15.

Typical acid indophenol $C_{12}H_9NO_2$,

The possibility of preparing this compound by the joint oxidation of *p*-aminophenol and phenol is mentioned in Köchlin and Witt's fundamental indophenol patents, but its manufacture seemed at first to offer no interest. It is formed if quinoneimide is brought into contact with phenol, and R. Hirsch observed it on adding caustic potash to a solution of quinone-chloroimide in phenol, but did not succeed in isolating it (Ber. 13, 1909). The cause of these difficulties was revealed by the D. R. P. 157288 of the Actiengesellschaft für Anilinfabrikation of Berlin. The formation of the dyestuff must take place at unusually low temperatures if its tendency for polymerisation in a nascent state is to be overcome. According to this patent, the product may be prepared with a good yield if an equimolecular mixture of phenol and *p*-aminophenol be oxidised with sodium hypochlorite at a temperature of -15° to -18° , preferably in solutions saturated with sodium chloride so that the sodium salt of the dyestuff is at once salted out of the liquid. It is thus obtained in the shape of glistening metallic green needles.

These dyestuffs become more stable and are therefore more easily prepared if their molecule be weighted by the introduction of various substituents:

Acid dibromindophenol $C_{12}H_7Br_2NO_2$,

(See remarks on migration under 2 and 5.) has been prepared in various ways by R. Möhlau (Ber. 16, 2843). It may be obtained either by the joint oxidation of a mixture of dibromo-aminophenol and phenol in molecular proportions, or by adding dibromo-quinonechloroimide, suspended in alcohol, to an alkaline solution of phenol. The sodium salt of the indophenol separates out in green glistening needles, which are soluble in water and alcohol with a pure blue colour. On adding acetic acid to the solution the free indophenol settles out in dark-red, almost black prisms with a metallic lustre. It is soluble in alcohol with a magenta colour. Mineral acids decompose this compound into dibromo-aminophenol and *p*-quinone. If a current of sulphur dioxide be introduced into the solution of the sodium indophenolate, the corresponding leuco compound $C_{12}H_9Br_2NO_2$, dihydroxydibromodiphenylamine, is formed. It crystallises in white glistening needles, melting at 170° .

Acid dimethylindophenol $C_{14}H_{13}NO_2$,

is also much more stable and therefore more easily prepared than the typical acid indophenol. This was shown in 1902 by L. Cassella & Co. in their D. R. P. 191863 and the corresponding Eng. Pat. 4653, 1902; 2617, 1902. According to these patents, 1:4:5-(*p*-) xylenol and *p*-aminophenol give a good yield of this dyestuff if subjected to joint oxydation in equimolecular proportions.

All these acid indophenols have assumed a new interest and are being largely investigated, since it has been shown that they are valuable raw materials for the manufacture of the sulphur dyes which have come so much to the front in these later years.

O. N. W.

INDANE v. INDENE.

INDANTHRENE. Within recent years, considerable advances have been made in the discovery and commercial production of certain compounds belonging to the class of the vat dyes. By the term 'vat dye' is understood an insoluble pigment which, when reduced by an alkaline reducing agent, passes into a hydro-derivative soluble in the alkaline reducing solution. The hydro-derivative is absorbed by fabrics steeped in this solution and is then reconverted into the pigment when the material is exposed to the oxidising action of the air. Indigo, the most important of all colouring matters, is a typical vat dye, and it is apparent that the process entailed by the use of these colours not only produces the shades fastest to light and washing, but is also one of the simplest with which the dyer has to deal.

For many years research on the formation of new vat dyes was confined to the indigo group, but in the year 1901 it was demonstrated by R. Bohn that certain derivatives of anthraquinone could be applied for this purpose. The vat dyes of this series possess, however, one important property which distinguishes them from all other members of the class, that is, the vat formed by the alkaline reduction of the pigment is always strongly coloured. The hydro-derivatives are, therefore, themselves coloured substances, whereas the hydro-derivatives from other vat dyes, for example indigo-white, are colourless or at most faintly yellow.

The vat dyes of the indanthrene series may be conveniently divided into five groups:—

- (1) Indanthrene.
 - (2) Flavanthrene.
 - (3) Benzanthrone colours.
 - (4) Anthraquinoneimide colours.
 - (5) Acyl derivatives of aminoanthraquinone.
- Indanthrene: Preparation** (R. Bohn, D. R. P. 129845; *Zusätze*, 129846, 129847, 129848, 135407, 135408, 138167, 155415, 210223, and 216891; Scholl and Berblinger, Ber. 1903, 36, 3427).

nor 1-hydroxy-2-aminoanthraquinone yields indanthrene when fused with potash.

Properties of indanthrene.—When indanthrene in dilute alkaline solution is heated at 40°–50° with sodium hydrosulphite, it passes into a blue hydro-derivative, dihydroindanthrene. This substance possesses the property of dyeing unmordanted cotton blue, and when the fibre so dyed is exposed to the oxidising action of the air the hydro-derivative is reconverted into indanthrene. When indanthrene is reduced by zinc dust, a brown hydro-derivative is formed; this hydro-derivative is also converted into indanthrene on exposure to the air. Scholl, Steinkopf, and Kabacznik (Ber. 1907, 40, 390) have shown that the blue substance is *N*-dihydro-1 : 2 : 2' : 1'-anthraquinone-anthrahydroquinoneazine (1), and that the brown solution contains *N*-dihydro-1 : 2 : 2' : 1'-anthrahydroquinoneazine (2).

(1) Blue hydro-derivative. (2) Brown hydro-derivative.

The compound commercially known as indanthrene S is the disodium salt of formula 2, and this is the substance which is always formed in the indanthrene vat.

When indanthrene is oxidised by nitric acid (sp.gr. 1.24), it is converted into the yellow 1 : 2 : 2' : 1'-anthraquinoneazine (Scholl and Berblinger, Ber. 1903, 36, 3427; *cp.* Scholl, Berblinger, and Mansfield, *ibid.* 1907, 40, 321).

This substance is reconverted into indanthrene on reduction, a reaction which may be effected by means of direct sunlight.

Indanthrene is one of the most stable substances known; sodium hypochlorite, which destroys most colouring matters such as the alizarins, indigos, &c., merely converts indanthrene into the above yellow azine, which can be readily reconverted into indanthrene by means of sodium hydrosulphite.

When halogen atoms enter the molecule of indanthrene, the shade becomes greener. Indanthrene blue GC (D. R. P. 131167) is a brom-indanthrene; indanthrene blue GCD and CE are chloro-derivatives (D. R. P. 155415). Monochlorindanthrene is prepared by the action of boiling concentrated hydrochloric acid on

anthraquinoneazine whereby chlorination and reduction take place simultaneously—

The reaction is analogous to the formation of chlorhydroquinone from quinone and hydrochloric acid. Owing to the alkali required in the preparation of the indanthrene vat, this substance cannot be used for the dyeing of wool. The sulphonic acid (D. R. P. 216891) can be employed, however, for this purpose. The blue produced on cotton by the aid of indanthrene is one of the fastest known. (For the method of dyeing *cp.* D. R. P. 139834; for printing, *cp.* D. R. PP. 132402, 140573.)

Flavanthrene (indanthrene yellow, chloranthrene yellow). As already mentioned, flavanthrene was discovered by R. Bohn (D. R. P. 138119), in the products formed by the fusion of β -aminoanthraquinone with potash. At the present time it is prepared by treating β -aminoanthraquinone with antimony pentachloride in boiling nitrobenzene. (V. art. FLAVANTHRENE.)

When reduced by alkaline hydrosulphite, flavanthrene yields a violet-blue vat in which cotton is dyed a deep blue; when exposed to the oxidising action of the air the colour changes, in the course of a few minutes, to the light yellow of flavanthrene.

Preparation.—Ten grams of β -aminoanthraquinone are gradually added to a solution of 35 grams anhydrous antimony pentachloride in 100 grams nitrobenzene, heated at 60°–80°. The mixture is then heated to the boiling-point and maintained at this temperature for one hour, the containing flask being without a condenser. The yellow-brown solution deposits, on cooling, chemically pure flavanthrene as brownish-yellow needles.

The constitution of flavanthrene has been determined by Scholl (Ber. 1907, 40, 1691). The molecular formula is $C_{23}H_{12}O_2N_2$, and it must therefore be formed from β -aminoanthraquinone in accordance with the equation

The two molecules of water formed in the reaction at once suggest the interaction of the hydrogen atoms of the amino-groups with the carbonyl oxygens, an assumption which leads to the following formula:—

The ring then closes thus :

The hydrogen thus formed is not eliminated in the free condition, but reduces the colour to the dihydro-base, the state in which it always occurs in the melt.

This view of the constitution of flavanthrene has been confirmed by Scholl by the actual synthesis of this substance in the following way : 2-methyl-1-aminoanthraquinone (1) is converted into 2:2'-dimethyl-1:1'-dianthraquinonyl (2) either by heating the corresponding iodide with copper powder or by the action of copper powder and acetic anhydride on the diazonium sulphate :

This substance is then oxidised to the dicarboxylic acid which is converted, through the acid chloride, into the acid amide (3). An attempt to prepare the amino-compound from this by the action of bromine and potash led to the formation of flavanthrene :

Pyranthrene (indanthrene golden orange) (D. R. P. 175067; Ber. 1910, 43, 346; 1911, 44, 1448; R. Scholl). This substance is a valuable orange vat dye which is formed by the elimination of two molecules of water from 2:2'-dimethyl-1:1'-dianthraquinonyl (formula (2) above). It differs from flavanthrene in having two methin groups in place of the azine nitrogen atoms :

The condensation proceeds readily in the presence of a dehydrating agent such as zinc chloride or by merely heating alone at 350°-380°. Pyranthrene forms a magenta red vat with alkaline hydrosulphite in which cotton is dyed a deep red; on exposure to the air this oxidises to a fast orange.

The entrance of halogen atoms into the molecule of pyranthrene reddens the shade and of these derivatives dibromopyranthrene (D. R. P. 218162) is the most red.

The benzanthrone colours. The vat colours of this class were discovered by O. Bally (Ber. 1905, 398, 14; D. R. P. 176018), who found that when the Skraup quinoline synthesis was applied to 2-aminoanthraquinone, two glycerol residues entered into the molecule, forming benzanthrone-quinoline (1) :

When this reaction was applied to anthraquinone, benzanthrone (2) was formed.

Blue vat dyes are formed from these substances on fusion with potash, two molecules condensing with loss of four atoms of hydrogen. To this group belong indanthrene dark blue (D. R. P. 185221), which is a mixture of indanthrene blue BO and indanthrene violet RT (Chem. Zeit. 1917, 41, 713), as well as its isomeride and chlorine substitution product, indanthrene violet (D. R. PP. 177574, 194252, 217570); indanthrene green (D. R. P. 185222) is an amino-derivative of indanthrene dark blue; if the last-named colour is strongly chlorinated a deep, very fast black is formed. Cyananthrene and violanthrene (Annalen, 1913, 398, 82) also belong to this group.

Colours derived from anthraquinoneimide. These colours consist of several anthraquinone residues joined together in much the same manner as in flavanthrene. They are, for the most part, trianthraquinonedimides and their substitution products which are formed by the condensation of aminoanthraquinones and halogenanthraquinones. Indanthrene Bordeaux (D. R. PP. 184905 and 206177) and indanthrene red (D. R. P. 197554) belong to this group.

Acyl derivatives of aminoanthraquinone. Colours of this group are derived from anthraquinonepyridone :

by the replacement of the hydrogen atom in the para-position to the imino-group by arylamino residues. Thus algol red is formed when 1-bromanthraquinone (1) is converted into methyl-1-aminoanthraquinone (2) by means of

methylamine. This is acetylated and condensed to *N*-methylantraquinonepyridine (3), which is then brominated, yielding 4-brom-*N*-methylantraquinonepyridine (4), and this, on condensation with 2-aminoanthraquinone, yields algol red (5) :

Other members of this class are algol yellow, algol rose, algol scarlet, algol green, algol blue, and algol brown. They all yield coloured vats with sodium hydrosulphite in which cotton is dyed the colour of the dihydro-derivative; on exposure to the air the colour on the fibre is quickly oxidised to the algol dye.

The following indanthrene colours are formed from anthraquinone derivatives by the aid of various reactions, but have not as yet had a definite constitution assigned to them. Indanthrene maroon (D. R. P. 160184) and indanthrene grey (D. R. P. 157685) are derived from diaminoanthraquinones. Indanthrene orange and indanthrene copper (D. R. P. 198048) are prepared from the acetyl derivatives of aminoanthraquinone by means of phosphorus oxychloride. Cibanon yellow, cibanon orange, and cibanon brown, are derived from methylantraquinone and its derivatives.

Indanthrene yellow GN and indanthrene gold orange GN (U.S. Pats. 1044673, 1044674, 1044675) have the formulæ :

respectively.

Hydron yellow G, prepared by condensing

N-ethylcarbazole with phthalic anhydride (Eng. Pat. 2887411) has the formula :

J. F. T.

INDAZINE v. AZINES.

INDENE. The compounds of the indene group are derived from the hydrocarbons indene and hydrindene

by the replacement of the hydrogen atoms either in the five-membered ring or in the aromatic nucleus. They therefore yield two classes of derivatives: (1) Those of aromatic character which are formed when the hydrogen atoms of the benzene ring are substituted. (2) Those of aliphatic character which are produced by the replacement of the hydrogen atoms attached to the five-membered ring.

Constitution.—The constitution of indene follows from its conversion into homophthalic acid by oxidation with permanganate :

and the structure of hydrindene is shown by the production of this substance from indene by reduction with sodium and alcohol.

Occurrence and preparation of indene and indene derivatives. Indene was isolated from coal-tar by Krämer and Spilker (Ber. 1890, 23, 3276), who obtained it from the higher boiling fraction of the light oil in which it occurs to the extent of about 30 p.c. It is formed, accompanied by hydrindene, in the dry distillation of paraindene (C_9H_8)_x, a white substance which is formed when benzene containing indene is treated with concentrated sulphuric acid (Ber. 1900, 33, 2261). It has, moreover, been prepared synthetically by Perkin and Revay (Chem. Soc. Trans. 1894, 65, 228; *cp.* Kipping and Hall, *ibid.* 1900, 77, 469), by the distillation of barium hydrindenecarboxylate, a substance which can be prepared from *o*-xylene dibromide by the following series of reactions.

Owing to the ease with which the five-membered ring is usually formed, derivatives of indene and of hydrindene are readily produced from the corresponding benzene derivatives, having a side chain containing the requisite number of carbon atoms. The benzene derivatives which lend themselves to this change may therefore be divided into two classes: (1) those having one side chain of three carbon atoms; (2) those having two side chains, attached in the ortho-position to the benzene nucleus, one of these side chains being composed of one carbon atom, the other of two carbon atoms.

The derivatives of hydrocinnamic acid fall within the first class and a large number of indene compounds have been prepared from this substance and its derivatives (*v.* Miller and Rohde, Ber. 1902, 35, 1762).

The general character of this reaction may be expressed by the scheme

(X=halogen).

As an illustration of the formation of hydrindene derivatives by the method indicated under class (2), the formation of 1:3-diketohydrindene can be given. The ethyl salt of the carboxylic acid of this substance is formed when ethyl phthalate is condensed with ethyl acetate in the presence of sodium or sodium ethoxide (W. Wislicenus, Ber. 1887, 20, 593).

A curious molecular rearrangement, leading to the formation of hydrindene derivatives, has been discovered by Gabriel and Neumann (Ber. 1893, 26, 951). The condensation of phthalic anhydride and sodium acetate in the presence of acetic anhydride leads to the formation of phthalylacetic acid:

and this substance, when treated with sodium methoxide, passes into a derivative of 1:3-diketohydrindene. The reaction may be explained as follows:—

It can be applied to the preparation of numerous derivatives of 1:3-diketohydrindene.

The formation of indene derivatives from compounds containing the naphthalene nucleus

in which the stability of the ring is weakened by the presence of strongly negative groups has been investigated by Zincke and his pupils (Ber. 1886, 19, 2500; 1887, 20, 1265, 2394, 3216; 1888, 21, 491, 2381, 2379; 1894, 27, 744; Annalen, 1892, 267, 319; 1894, 283, 341; 1898, 300, 197). This type of reaction may be illustrated by the transformation of dichloro- β -naphthaquinone into dichlorohydroxyindene carboxylic acid by the action of caustic alkali.

Derivatives of hydrindene can also be formed from ortho-benzenoid dinitriles. Thus *o*-phenylenediacetonitrile passes into β -imino- α -cyano-hydrindene when its solution in alcohol, containing a trace of sodium ethoxide, is warmed (Moore and Thorpe, Chem. Soc. Trans. 1908, 93, 165).

Preparation of indene from coal-tar. The fraction boiling at 176°–182° obtained from crude benzene is first titrated with bromine and the amount of unsaturated material present determined. A sufficient quantity of picric acid is then added to the hot liquid and the crystalline material which separates is isolated by filtration. The impure picrate is then distilled with steam, under which conditions the naphthalene picrate contained in it is only slowly decomposed, whereas the indene picrate is readily transformed into indene which passes over with the steam. The crude hydrocarbon is then again converted into the picrate and the operation repeated until pure indene is obtained. Indene picrate forms golden yellow needles which melt at 98°.

Indene is a clear mobile liquid boiling at 179.5°–180.5° (corr.).

It is obtained pure only with great difficulty, as it rapidly absorbs oxygen from the air and when kept in a sealed vessel polymerises to a resin. The most convenient synthetic method for the preparation of indene is from α -hydrindone, the oxime of which passes on reduction into 1-aminohydrindene, and when the hydrochloride of this base is distilled, ammonium chloride and indene are formed, thus—

Reactions of indene. Indene readily combines with bromine, forming 1 : 2-dibromohydrin-

first into hydrindene glycol and then into homophthalic acid

The hydrogen atoms of the methylene group present in indene are reactive; thus, when the hydrocarbon is condensed with benzaldehyde, benzylidene indene is formed :

In fact, this grouping behaves in much the same manner as the corresponding complex in ethyl malonate and analogous compounds; thus, when indene is treated with methyl iodide and powdered alkali, methylindene is formed (Marckwald, Ber. 1900, 33, 1504) :

Hydrindene (Indane) $\text{C}_6\text{H}_4 \begin{array}{c} \text{CH}_2 \\ \diagup \quad \diagdown \\ \text{CH}_2 \end{array} \text{CH}_2$.

This hydrocarbon can be prepared by dissolving 1 part of indene in 10 parts of 90 p.c. alcohol and adding metallic sodium in small proportions until the product is no longer converted into a resin by concentrated sulphuric acid. It is a mobile oil boiling at 176°-176.5° (corr.).

The ketones derived from hydrindene. The ketones derived from this substance may be classified as follows : (1) The mono-ketones (hydrindones), which comprise :

α -Hydrindone.

β -Hydrindone.

(2) **The di-ketones** (di-ketohydrindenes), which are

1 : 3-Diketohydrindene. 1 : 2-Diketohydrindene.¹

(3) The tri-ketone is

1 : 2 : 3-Triketohydrindene.

α -Hydrindone $\text{C}_6\text{H}_4 \begin{array}{c} \text{CH}_2 \\ \diagup \quad \diagdown \\ \text{CO} \end{array} \text{CH}_2$. This substance is best prepared by the action of aluminium

¹ This substance has been prepared by Perkin, Roberts and Robinson (Chem. Soc. Trans. 1912, 101, 232) from isonitroso- α -hydrindone (Kipping, *ibid.* 1894, 65, 492). It crystallises from benzene as golden-yellow plates, m.p. 95°-115°, and gives a semicarbazone (m.p. 230°-233° with decomposition), an osazone (m.p. 230°-235°), and an indenquinoxaline (m.p. 164°-165°).

chloride on the chloride of hydrocinnamic acid in accordance with the following equation :—

It forms rhombic plates from dilute alcohol, melts at 40° and boils at 243°-245°. The oxime melts at 146° and the phenyl hydrazone at 130°-131°. The methylene group adjacent to the carbonyl group in α -hydrindone is reactive and derivatives of the ketone can be formed by the usual reagents. Thus amyl nitrite gives the oxime of 1 : 2-diketohydrindene

and the action of benzaldehyde leads to the formation of the benzylidene derivative

β -Hydrindone $\text{C}_6\text{H}_4 \begin{array}{c} \text{CH}_2 \\ \diagup \quad \diagdown \\ \text{CH}_2 \end{array} \text{CO}$. This ketone

is best prepared from β -imino- α -cyanohydrindene by distilling with dilute sulphuric acid (Moore and Thorpe, Chem. Soc. Trans. 1908, 93; cf. also Chem. Soc. Proc. 1911, 27, 128).

It can also be prepared from the indene of coal-tar (Heusler and Schieffer, Ber. 1899, 32, 28). The method most convenient for this purpose is to convert indene into the *chlorohydrin* by the method of Krämer and Spilker (Ber. 1890, 23, 3280) and then to transform this into the methoxy-derivative which, with dilute sulphuric acid, yields β -hydrindone :

It can also be formed by distilling the calcium salt of *o*-phenylenediacetic acid (Benedikt, Annalen, 1893, 275, 353; Schad, Ber. 1893, 26, 222) :

β -Hydrindone crystallises from dilute alcohol as long needles, melts at 61° and boils with partial decomposition at 220°-225°. The oxime melts at 155°, the phenylhydrazone at 120° and the semi-carbazone at 210°.

1 : 3-Diketohydrindene $\text{C}_6\text{H}_4 \begin{array}{c} \text{CO} \\ \diagup \quad \diagdown \\ \text{CO} \end{array} \text{CH}_2$, is probably the best known derivative of indene and is formed by the method of W. Wislicenus already described. It may be isolated (Kaufmann, Ber. 1897, 30, 385) by dissolving the sodium compound of ethyl diketohydrindene-carboxylate, prepared from ethyl phthalate and ethyl acetate, in as little boiling water as possible, cooling to 70°-75° and adding dilute sulphuric acid. A vigorous evolution of carbon dioxide then ensues and the diketone separates in the

crystalline form. 1 : 3-Diketohydrindene melts and decomposes at 129°–131°.

As is to be expected, the methylene group between the two carbonyl complexes of 1 : 3-diketohydrindene is exceedingly reactive and this substance shows all the reactions of the β -diketones. When oxidised by hydrogen peroxide or potassium persulphate, it is converted into the oxygen analogue of indigo, having the formula

This substance crystallises from aniline as glistening red needles.

1 : 2 : 3-Triketohydrindene $\text{C}_6\text{H}_4 \begin{array}{c} \text{CO} \\ \diagup \quad \diagdown \\ \text{C} < \text{CO} > \text{CO} \end{array}$

A substance of this formula was prepared in small quantity by Kaufmann (Ber. 1897, 30, 387) by the oxidation of 1 : 3-diketohydrindene with hydrogen peroxide. The compound prepared in this way crystallised from glacial acetic acid as brown leaflets which melted and decomposed at 190°–206°. It is probable that the substance obtained by Kaufmann possesses another structure, and that the true triketohydrindene is the compound prepared by Ruhemann, in the form of a hydrate, by the action of dilute sulphuric acid on the compound formed by the condensation of α -hydrindone with p -nitrosodimethylaniline

This reaction can also be applied to 1 : 3-diketohydrindene and to β -hydrindone (Chem. Soc. Trans. 1910, 97, 1438, 2025; 1911, 99, 792).

Triketohydrindene hydrate forms prisms from water which redden at 125°, give off gas at 139° and melt with decomposition at 239°–240°. The hydrate colours the skin red and reduces Fehling's solution. The diphenylhydrazone melts at 207°–208°, and the disemicarbazone darkens at 175° and melts with evolution of gas at 108°.

Triketohydrindene hydrate may be used as a reagent for proteins and their hydrolytic products (*cp.* Chem. Soc. Trans. 1911, 99, 798).

J. F. T.

INDIAN FIRE is a light used in pyrotechnical displays and for purposes of signalling. It is usually composed of 7 parts of sulphur, 2 of realgar, and 24 of nitre.

INDIAN GUM, or **GHATTI GUM**, is a gummy exudation from the stem of *Anogeissus latifolia* (Watt), occurring in vermiform or rounded tears, colourless pale yellow, and of a vitreous lustre; soluble in water forming a viscous adhesive mucilage; *v.* GUMS.

INDIAN HEMP RESIN *v.* RESINS.

INDIAN INK or **CHINESE INK**. This substance, used for writing or drawing, consists of lamp-black held together with animal or fish glue and dried in the form of cakes or sticks of paint. According to Chinese writers, the invention of ink is due to one Tien-Tehen who lived between 2697 and 2597 B.C. It is said by them that at that time the ink used was a kind of lacquer; later some kind of black stone rubbed in water came into use; lastly,

about 250 years B.C., balls of lamp-black from the burning of lacquer and firewood, afterwards mixed with size, became the customary material. It is probable, however, that the Chinese became acquainted with the substance from the Koreans, to whom they are indebted for other useful arts. The material used for producing the lamp-black is in most instances fir timber, although many other media, such as rice treated with a decoction of *Hibiscus mutabilis* (Linn.), the bark of the pomegranate tree infused with vinegar, sesamé, rape seed, wood-oil, and rock-oil are employed, to which are added varnish and pork fat. The glue or size appears at the present day to be always obtained either from oxen or fish; the points of difference between various makers being (1) the mode of preparation; (2) the method of incorporation; and (3) the quantity relative to the amount of soot. Sometimes perfumed essences, as of musk or camphor, are added, especially in the choicest qualities. The paste is pressed into carved wooden moulds and, after baking, the sticks or other moulded forms are laid in a cool, dry place, and are said to improve with long keeping. The best ink is made from wood-oil lamp-black, and comes from the Anhui province.

The manufacture of Indian ink is also carried on in Japan, the following description, from a native source, indicating the method followed in that country: 'The body of the ink is soot obtained from pine-wood or resin, and lamp-black from sesamé oil for the finest sort. This is mixed with liquid glue made of ox-skin. This operation is effected in a large, round, copper bowl formed of two spherical calottes placed 1 inch apart, so that the space between can be filled up with hot water to prevent the glue from hardening during the time it is being mixed by hand with the lamp-black. The cakes are formed in wooden moulds, and dried between paper and ashes. Camphor, or a peculiar mixture of scents which come from China, and a small quantity of carthamine (the red colouring substance of safflower) are added to the best kinds for improving the colour as well as for scenting the ink.'

M. Merimée (De la Peinture à l'Huile) asserted that the Chinese do not use an animal but a vegetable size; but apparently without warrant. For a curious monograph compiled from native Chinese sources *v.* L'Encre de Chine, son Histoire et sa Fabrication d'après documents chinois traduits, par Maurice Jametel, Paris, 1882.

INDIAN PODOPHYLLUM RESIN *v.* RESINS.

INDIAN RED. A mineral pigment from the Persian Gulf. In appearance it is a coarse powder of a purplish-red colour.

Howe's analysis of (1) the entire mineral, and of (2) that portion soluble in hydrochloric acid, gave

$\text{SiO}_2, \text{Fe}_2\text{O}_3, \text{Al}_2\text{O}_3, \text{CaO}, \text{MgO}, \text{SO}_3, \text{CO}_2, \text{H}_2\text{O}$
 (1) 30.17 56.59 3.79 2.65 1.43 2.28 1.73 1.62 = 100.26
 (2) — 3.19 2.22 2.65 0.87 2.28 1.73 — = 12.94
 (Edin. New Phil. Jour. New Series, 2, 306.)

The portion insoluble in hydrochloric acid is a ferric silicate $\text{Fe}_2\text{O}_3 \cdot \text{SiO}_2$. A pseudo-Indian red is composed principally of sesquioxide of iron.

INDIAN VALERIAN RHIZOME. The dried rhizome of *Valeriana Wallichii*.

INDIAN YELLOW, PIURI, PURREE, or PIOUSRY, is a pigment mainly used in India for colouring walls, doors, and lattice-work, and by artists for water-colour work. On account of its disagreeable smell it is but rarely employed as a dyestuff. It is, or was, made almost exclusively at Monghyr in Bengal, and is obtained from the urine of cows which have been fed upon mango leaves. On heating the urine, usually in an earthen pot, the colouring matter separates out; this is pressed into a ball and dried partly over a charcoal fire and finally in the sun. It sold on the spot at about 1 rupee per lb. and is, or was, mainly sent to Calcutta and Patna. One cow produces, on the average, 3·4 litres of urine per diem, yielding 2 ozs. (56 grams) of piuri. The yearly production is stated to have been from 100 to 150 cwts., which was probably over-estimated (*v. Journ. Soc. Arts*, 1883, [v.] 32, 16, and *Annalen*, 254, 268).

Piuri occurs in commerce in the form of round balls, which internally are of brilliant yellow colour, whereas the outer layers are either brown or of a dirty-green colour. The substance has a characteristic urinous smell. The undecomposed part consists only of *euxanthic acid* ($C_{19}H_{18}O_{11}$) in the form of a magnesium or calcium salt; the outer and decomposed portion contains in addition *euxanthone*, both free and combined. The composition of piuri seems to be variable; a fine sample, according to Graebe, contained

Euxanthic acid	51·0
Silicic acid and alumina	1·5
Magnesium	4·2
Calcium	3·4
Water and volatile matter	39·0
	99·1

Euxanthic acid is easily obtained by digesting piuri of good quality with dilute hydrochloric acid and treating the residue with a solution of ammonium carbonate. On the addition of hydrochloric acid to the filtered solution *euxanthic acid* crystallises out with $1H_2O$ in glistening straw-yellow needles, melting at 162° . *Euxanthic acid* is, according to Spiegel, decomposed by hydrochloric acid into glycuronic acid and *euxanthone*: $C_{19}H_{18}O_{11} = C_{18}H_8O_4 + C_6H_{10}O_7$. Külz, in order to prove the animal origin of *euxanthic acid*, gave *euxanthone* to rabbits and dogs, and was able to detect *euxanthic acid* in the urine. Külz's experiments did not corroborate Schmid's statement that mangostin (obtained from *Garcinia mangostana*, Linn.) is similarly converted into *euxanthic acid* by animals (*E. Külz, Zeitsch. Biol.* 33, 475; *J. Soc. Chem. Ind.* 6, 507).

Although the potassium and sodium salts of *euxanthic acid* are of the type $C_{19}H_{17}O_{11}M$, the silver salt obtained from the potassium salt by silver nitrate has the composition $C_{19}H_{16}O_{10}Ag$, and is derived from an anhydride of the acid (*Anhydroeuxanthic acid*); the methyl and ethyl esters prepared from the silver salt are of the same type (Graebe, *Ber.* 1900, 53, 3360).

Potassium euxanthate $C_{19}H_{17}O_{11}K.H_2O$ crystallises readily from water, and is prepared by neutralising *euxanthic acid* with potassium carbonate.

Magnesium euxanthate $C_{19}H_{16}O_{11}Mg.5H_2O$ is the main constituent of Indian yellow (Graebe, *Annalen*, 254, 268).

Barium euxanthate $Ba(C_{19}H_{17}O_{11})_2.9H_2O$ is soluble in boiling water, and on cooling separates in the gelatinous condition.

Silver anhydroeuxanthate $C_{19}H_{15}O_{10}Ag$ behaves similarly.

Ethylanhydroeuxanthate $C_{19}H_{15}O_{10}C_2H_5$, yellow-coloured needles, melts at 198° .

Tetra-acetyletethylanhydroeuxanthate

colourless needles, melts at 216° .

Methyl anhydroeuxanthate $C_{19}H_{15}O_{10}CH_3$, melts at 218° , and closely resembles the ethyl derivative.

Benzoyl-anhydroeuxanthate

melts at 194° , but has not yet been crystallised.

The constitution of *euxanthic acid* is expressed by Graebe (*Annalen*, 254, 267) as

whereas for that of *anhydroeuxanthic acid* one of the following two formulæ is suggested:—

Euxanthone, *Purrenone*, *Purrone* $C_{18}H_8O_4$ was first obtained by Stenhouse (*Annalen*, 51, 425), and soon afterwards by Erdmann (*ibid.* 52, 365), from *euxanthic acid*. It crystallises in pale yellow needles or laminae, melting at 240° (corr.), which sublime with little decomposition on gentle heating.

Diacetyl-euxanthone, pale yellow prisms (Salzmann and Wichelhaus, *Ber.* 1877, 10 1397), melts at 185° .

By distillation with zinc-dust (Salzmann and Wichelhaus; Graebe and Ebrard, *Ber.* 16, 75) *euxanthone* gives *methylenediphenylene oxide* (I.), which by oxidation is converted into *xanthone* (II.), indicating that *euxanthone* possesses the

constitution of a *dihydroxyxanthone* (S. and W.).

When fused with alkali *euxanthone* yields *euxanthonic acid*,

hydroquinone (*v. Baeyer, Annalen*, 155, 257), and resorcinol (Graebe, *ibid.* 254, 265).

The first synthesis of euxanthone is due to Graebe (*l.c.*) who accomplished this by distilling a mixture of β -resorcylic acid and hydroquinone carboxylic acid, and it was shown later by v. Kostanecki and Nessler (Ber. 1891, 24, 3983), that if in this reaction the β -resorcylic acid is replaced by resorcinol the same product is obtained. As the result of these syntheses two constitutional formulæ for euxanthone were possible:

When methylated by means of methyl iodide in the usual manner (v. Kostanecki, Ber. 1894, 27, 1992), euxanthone yields only a *monomethyl ether* $C_{13}H_{10}O_3(OCH_3)$ (yellow plates, m.p. 129°), and this on treatment with strong sodium hydroxide solution gives an insoluble yellow sodium salt. The latter, by washing with water, is decomposed with regeneration of the free monomethyl ether. These reactions indicate that euxanthone contains an hydroxyl in the ortho-position to a carboxyl group (*cf.* also Herzig, Monatsh. 12, 161), and that, therefore, its constitution is represented by formula II. The final proof of this formula is afforded by a later synthesis of euxanthone (Ullmann and Panchaud, Annalen, 350, 108).

2-Chloro-6-methoxybenzoic acid is condensed with the potassium derivative of hydroquinone monomethyl ether, employing copper powder as a catalyst:

The resulting 4-methoxy-2-phenoxy-6-methoxybenzoic acid when treated with concentrated sulphuric acid is converted into euxanthone dimethyl ether

and this by treatment with aluminium chloride in the presence of benzene gives euxanthone.

According to Neirenstein (Ber. 1913, 46, 649) by oxidising euxanthone with chromic acid the quinone

is produced. This consists of dark-red needles soluble in alkali with a blue coloration, and on

reduction is converted into 2:5:8 trihydroxy-xanthone, pale yellow needles, m.p. 328° – 330° .

The triacetyl derivative melts at 226° – 230° .

Disazobenzene-euxanthone $C_{13}H_8O_4(C_6H_5N_2)_2$ (Perkin, Chem. Soc. Trans. 73, 666), red needles, m.p. 249° – 250° (decomp.), is readily prepared by adding diazobenzene sulphate to a weak alkaline solution of euxanthone.

Acetyl disazobenzene-euxanthone, ochre-yellow needles, melts at 197° – 199° .

Euxanthone possesses only feeble tinctorial properties; the respective shades obtained with woollen cloth mordanted with chromium, aluminium, and tin being dull brown-yellow, pale bright yellow, and very pale bright yellow (Perkin and Hummel, Chem. Soc. Trans. 1896, 69, 1290).

A. G. P.

INDIRUBBER or CAOUTCHOUC v. RUBBER.

INDICAN v. GLUCOSIDES; **INDIGO**, NATURAL.

INDICANURIA v. INDOXYL COMPOUNDS.

INDICATORS v. ACIDIMETRY AND ALKALIMETRY; also art. ANALYSIS.

INDIGO, NATURAL. Indigo has been known in Asia from a remote period of antiquity, and there exist very ancient records in Sanskrit describing its methods of preparation. The Romans appear to have recognised it only as a pigment (*indicum*), but evidence as to its use as a dye by the ancient Egyptians has been abundantly proved from the examination of mummy cloths. Its employment in Europe was very limited until in 1516 when it began to be imported from India by way of the Cape of Good Hope, but its introduction in large quantity did not occur until about 1602. Owing chiefly to the opposition of the growers of woad, its European rival, as a dyeware it met with much opposition, and various laws were enacted both on the Continent and in England prohibiting its use. It was called a 'devilish drug,' and was said to be injurious to fabrics. In 1737 its employment was legally permitted in France, and from this period its valuable properties appear to have become gradually recognised throughout Europe.

The most important plants which yield indigo are those of the genus *Indigofera* belonging to the natural order of the *Leguminosæ*; these have been cultivated in India, China, Egypt, the Philippines, Caracas, and Brazil.

For the purpose of indigo manufacture the *Indigofera tinctoria* (Linn.), *I. sumatrana* (Gartrn.) (the Indian plant), *I. disperma* (Linn.), *I. argentea* (Linn.), and *I. arrecta* (Hochst.) (the Natal plant), the *I. paucifolia* (Delile) (Madagascar plant), and *I. secundiflora* (Poir.) (Guatemala plant), have been mainly used, though certain less valuable varieties, viz. the *I. pseudotinctoria* (R. Br.), *I. angustifolia* (Linn.), *I. arcuata* (Willd.), *I. caroliniana* (Walt.), *I. cinerea* (Willd.), *I. longeracemosa* (Boiv.), *I. cærulea* (Roxb.), *I. endecaphylla* (Jacq.), *I. glabra* (Linn.), *I. hirsuta* (Linn.), *I. indica* (Lam.), *I. mexicana* (Benth.), *I. leptostachya* (DC.), have been employed. In Japan, China, and Russia the plant usually cultivated has been

the *Polygonum tinctorium* (Ait.), but the *Isatis tinctoria* (Linn.), or woad plant, at one time very largely grown in Europe, is now only used in very limited quantity as an adjunct in the dyeing of indigo (woad vat). The native source of indigo in Western Africa appears to consist almost entirely of the *Lonchocarpus cyanescens* (Benth.) (Perkin, J. Soc. Chem. Ind. 1907, 26).

Other indigo-yielding plants are the *Nerium tinctorium*, *Gymnema tingens* (Spreng.), *Eupatorium laeve* (DC.), *Tephrosia tinctoria* (Pers.), *Marsdenia tinctoria* (R. Br.), and certain species of orchids such as the *Phaius grandifolius* (Reich.), and *Calanthe veratrifolia* (R. Br.).

In addition to these, various plants, of which the *Mercurialis perennis* (Linn.), *Fagopyrum esculentum* (Moench.), *Fraxinus excelsior* (Linn.), *Baptisia tinctoria* (R. Br.), and *Rhamnus alaternus* (Linn.) (Georgievics, Der Indigo, 1892) may be given as examples, are stated to yield indigo, or a very similar colouring matter, but this requires confirmation.

The production of indigo from the indigo plant is of a simple character and consists mainly of two processes, viz. a steeping of the plant with water (fermentation), followed by the oxidation of the solution with air in a separate vessel. Until very recently but little modification appears to have been introduced into this ancient process, and there is also but little variation to be found in the main features as described by Bancroft (Philosophy of Permanent Colours, 1813), Crookes (Manual of Dyeing and Calico Printing, 1874), Bridges-Lee (Indigo Manufacture, 1892), Georgievics (l.c. 1892), and Rawson (The Cultivation and Manufacture of Indigo, J. Soc. Dyers, 1899).

Directly the plants are cut down they are tied in bundles and brought to the factory without delay, because it is necessary that the material should be operated on at once.¹ The tanks for the extraction (steeping vats) and precipitation of the indigo by oxidation (beating vats) are sometimes of stone, but more usually of brick-work lined inside with cement, and are respectively ranged in two rows one above the other, so that the former can be drained into the latter. The steeping vats may have a capacity of about 1000 cub. ft., and are usually of much smaller dimensions than the beating vats, of which less are consequently required. According to Rawson (l.c.), who describes a small indigo

factory, each range of beating vats runs the whole length of six steeping vats, and has a width of 13 feet 6 inches.

Into each of the upper tanks the bundles of the plant are tightly packed (preferably in a horizontal position, Bridges-Lee, l.c.), on the top of this is laid a horizontal trellis of bamboo, and the whole is wedged down into the tanks by means of timber, so that the material is unable to float during the fermentation process. Water is then run in, in such quantity that the bundles are entirely submerged. After about two hours an active fermentation is observed, and the surface of the liquid becomes covered with froth owing to the evolution of a mixture of carbon dioxide, oxygen, and nitrogen (Georgievics, l.c.); in the later stages (Rawson, l.c.) either marsh gas or hydrogen or a mixture of the two is freely produced. After 10-15 hours, according to the prevailing temperature of the water, the straw-yellow, orange, or olive-green coloured liquid is drawn off into the tanks below, and submitted to oxidation with air.

This may be accomplished by 'hand beating,' by machinery (the beating wheel), by blowing air through the liquid, or by the shower-bath method. During this operation the colour of the liquid gradually changes, becoming first dark green and then blue, and considerable frothing is produced. When it is observed that the indigo precipitate or 'fecula' readily settles, the beating is discontinued and the mixture allowed to rest for some two hours. The supernatant liquid, or 'seeth water,' having been drained off as completely as possible, the indigo sludge or 'mal' is led into a reservoir inside the factory, from which it is subsequently elevated by means of a hand pump or steam injector into a large cauldron known as the 'mal boiler.' It is here heated by direct fire or by the admission of steam, and this has for its object the prevention of a further fermentation, the solution of certain brown impurities, and a more complete granulation of the 'mal.'

The product is then run on to a filter known as a 'table,' consisting of stout cotton or linen cloth stretched over a shallow rectangular basin of stone or cement, with a drainage opening at one corner, and allowed to remain until it has the consistency of a stiff paste. In order to remove excess of moisture the indigo is transferred to perforated wooden boxes lined with sail cloth and cautiously pressed. Finally, the resulting slab is cut into cakes by means of a guillotine or metal wires and allowed to dry at the ordinary temperature on trellis-work shelves in a specially constructed drying house.

THE PLANT.

Until the last few years the *I. sumatrana* appears to have been exclusively employed in the best-conducted factories in India. According to Leake (Report of the Dalsingh Serai Research Station, 1903-1904) this is a mixture of several sub-varieties of different values. In this, as in apparently all other indigo plants, the indican exists exclusively in the leaf, though Bloxam and Leake (l.c.) point out that the midrib or rachis also contains the glucoside. For the manufacture of indigo the main points in connection with the plant are the weight yielded per acre, the percentage of leaf present, and the

¹ It has long been known that the percentage of indican rapidly disappears from the leaf in the freshly plucked moist condition, and on this account it is advisable that the plant when cut down should be dealt with at once. On the other hand, it has been the practice to a small extent in certain districts to air-dry the leaf before proceeding with the manufacture of indigo. In order to determine if when air-dried under ideal conditions, the leaf in these circumstances loses a material amount of indican, experiments were made by Watson (Jour. Chem. Soc. Ind. 1918, 37, 81) with indigo plant specially grown for the purpose. The leaf when gathered was divided into two portions, one of which was analysed at once, and the second dried by spreading in a thin layer upon filter paper in a north verandah for three or four days until constant in weight.

The analyses were carried out by the isatin method (l.c.) with 10 grammes of leaf weighed in each case in the fresh condition, and the results expressed as indirubin indicate that a serious loss of colouring principle does occur in these circumstances:—

	Fresh Leaf.	Air-dried Leaf.
(a)	0.1008	0.0568
(b)	0.0825	0.0610
(c)	0.1057	0.0763

indigotin-producing value of the latter. According to Rawson (Cultivation and Manufacture of Indigo, *l.c.*) the good plant contains 40 p.c. of leaf, though occasionally, but not often, the proportion of leaf rises to as much as 60 p.c. Bloxam and Leake found, however, much higher values, 51.7–61.6 on ordinary Indian plant, and 65 p.c. given by twelve experimental plots, figures which include the rachis. Bergthell (Report of the Indigo Research Station, Sirsiyah, 1906, 8) found the percentage of leaf to be 40 p.c., and never higher than 45 p.c.; but, on the other hand, in a redetermination, Leake (*J. Soc. Chem. Ind.* 1907, 26, 1174) records the value as 62.2 p.c. Rawson, who conducted numerous analyses of the leaf by his persulphate process (*l.c.*), shows that the indican content as expressed by indigo-yielding capacity varies at different periods of the year. Thus, whereas in one instance on May 28 the figure was 0.20 p.c., on August 25 this had risen to 0.76 p.c. of indigotin. Though the leaf on a young plant gives but a small percentage of colouring matter, yet as the plant grows the new leaf contains more colouring principle than the old on the same plant. As an example, on one occasion the percentages of indigotin recorded with new and old leaf were respectively 0.71 and 0.35 p.c. Finally, there is a gradual increase in colouring matter given by leaves from the bottom of the plant upwards as represented by the figures 0.30, 0.44, and 0.62 p.c. respectively. According to Bergthell (Report of the Indigo Research Station, 1907, 3) the 'indigotin content' of the plant is rarely so high as 0.3 p.c. Though the leaf, as a rule, contains a maximum of colouring matter from about the middle to the end of August, it does not necessarily follow that this is the best period for manufacture, as by this time the plant will usually have lost a considerable portion of leaf (Rawson). The manufacture, indeed, usually commences about the middle of June. Gaunt, Thomas, and Bloxam (*J. Soc. Chem. Ind.* 1907, 26, 1174) refer to a sample of the air-dried leaves of the *I. sumatrana*, which, in comparison with other dry samples of the same variety (0.6 approx.) and of the Java plant, *I. arrecta* (1.81 p.c.), yielded indigotin to the value of 3.53 p.c., and consider that this indicates that by selection and suitable methods of cultivation it should be possible to obtain an average plant of greater indigo-producing power than has hitherto been the case.

The plant formerly employed by the Java planters was the *I. secundiflora*, 'Guatemala plant,' but for several years past this has been replaced by the *I. arrecta* or 'Natal plant.' The latter, it is stated, contains not only more leaf than the ordinary Indian plant, but, as a rule, the leaf yields also a considerably larger percentage of indigo. More recently the Indian planters have recognised the value of the *I. arrecta*, and accounts are given by Coventry (Indigo Improvements Syndicate Report, 1901) of experiments in connection with its introduction. Leake (Dalsingh Serai Report, 1905) discusses the difficulties of the germination of the seed of the Natal-Java plant, which is due to the impermeable character of the seed coat. This defect, it is pointed out, can be overcome by a process of scratching, and a practical method for this purpose is described. Bergthell (*l.c.*), in

conjunction with D. L. Day, treats the seed with strong sulphuric acid, which leads either to a swelling of the seed coat and its eventual rupture or converts it into a body akin to cellulose and permeable to water. Analyses of the indigo-yielding power of this leaf by Rawson (*l.c.*) gave figures up to 0.96 p.c., whereas Bergthell (*l.c.* 1906) finds in comparison to the *I. sumatrana* (0.585) that the *I. arrecta* produced 1.05 p.c. of colouring matter. The percentage of leaf given by the latter averages 52.2 p.c. Again, in 1909 the yield from 100 maunds of the *I. arrecta* was 15 seers 10 chittacks, as against 11 seers 14 chittacks from the same quantity of the *I. sumatrana*. The Natal plant is now established in India, and its value appears to be fully recognised. According to Bergthell (1907) the indigo made from the Java plant has generally been of a high indigotin content, and (1906) that whereas the yield of indigo per acre was 12.6 'seers,' that given by the *I. sumatrana* was by comparison only 8 seers.

An account of recent work on the indigo plant by W. A. Davis is given in the Indigo Publications (1918–21) of The Agricultural Research Institute, Pusa. Davis attributes (Publ. Nos. 1 & 2) the progressive deterioration of the indigo crops during the last twenty years chiefly to the fact that the soils are exhausted as regards phosphate. The good effects of phosphate manuring is confirmed by experiment (*cf.* also Publ. No. 6), and there can thus be no doubt that the continuous and systematic treatment of the soil with superphosphate is essential for the proper cultivation of the indigo plant. Dealing particularly with the Java indigo plant (Publ. No. 7), it is stated (see p. 32) that:—

"High quality plant rich in indigotin is obtained when the soil is poor in nitrogen, so that the plant is forced to grow on nitrogen taken up from the air by the nodule bacteria. It seems probable that the activity of these organisms determines high indigotin content, and that the production of indican is due to the plant removing from the nodules nitrogen compounds which would be prejudicial to their continuous action."

The factors which make for development of the nodules are: (1) low nitrogen in soil; (2) good supply of soluble phosphate; (3) good supply of organic matter (yielding carbohydrates).

Care must be taken in supplying humus not to supply nitrogen. Thus a manure such as seet, whilst giving high yields of plant per acre, gives leaf poor in indican content. The use of cover crops (*e.g.* wheat or mustard) grown with indigo, which remove nitrogen from the soil, is advantageous.

THE CHEMISTRY OF NATURAL INDIGO MANUFACTURE.

According to the early researches of Chevreul (*Ann. Chim. Phys.* 1808, 66, 8, and 1808, 68, 284) and of Geradin and Preissner (*J. Pharm. Chim.* 1840, 26, 344) the colouring principle of indigotin present in indigo-yielding plants was considered to consist of indigo white, and this theory remained uncontradicted until Schunck (*Phil. Mag.* 1855, [iv.] 17, 74, and 1858, 15, 127) isolated from the *Isatis tinctoria* (woad), *Polygonum tinctorium*, and *Indigofera tinctoria*

(Schunck and Roemer, Ber. 1879, 12, 2311) a glucoside, which was named indican.

To prepare this substance from woad the leaves were extracted with cold alcohol, the solution treated with a little water, and concentrated at the ordinary temperature by blowing air over it. The waxy matter which thus separated was removed by filtration, and the filtrate shaken up with freshly precipitated cupric hydroxide. The mixture was filtered, the liquid freed from dissolved copper by means of sulphuretted hydrogen, and then evaporated at the ordinary temperature. The residue was extracted with cold alcohol, the extract treated with ether to precipitate certain impurities, and the solution evaporated.

Thus obtained it consisted of a yellow or yellowish-brown syrup, which was of an exceedingly unstable nature, and could not be dried without decomposition. With alcoholic lead acetate it gave a yellow precipitate, whereas in aqueous solution it could only be precipitated by means of basic lead acetate. Analyses of the lead compound indicated that indican possessed the formula $C_{20}H_{31}NO_{17}$. Schunck found that this compound was a glucoside, and that by the action of dilute acids, alkalis and of a ferment present in the plant, it was readily hydrolysed with the formation of indigotin, and a sugar *indiglucin* :

For the production of indigotin the presence of air or other suitable oxidising agent was however necessary, and it appeared, therefore, that during the reaction the indigotin at first formed was reduced to indigo white.

Later, however, Schunck and Roemer showed (*loc.*) that indican, when hydrolysed in the absence of air, gave a product which, on subsequent treatment with oxidising agents, did not yield indigotin. Schunck further obtained by the action of cold dilute acids on his indican a brown powder, from which he isolated six distinct substances, viz. *indihumin*, *indifuscin*, and *indiretin*, soluble in warm sodium hydroxide solution, and α - and β -*indifulvins* and *indirubin*, insoluble in alkalis.

When aqueous solutions of the indican were boiled or heated for some time a decomposition ensued, and the product, on treatment with acid, gave indiglucin, but no indigotin, this being replaced by *indiretin* and *indihumin*, brown amorphous substances. The latter closely resembled, and was probably identical with, indigo brown. By the action of alkalis or alkaline earths at the ordinary temperature, indican was converted into a new glucoside, *indicavin* $C_{20}H_{23}NO_{12}$, which on treatment with acid gave indiglucin and indirubin.

Oxyindicanin, a brown gummy substance, insoluble in alcohol, was isolated during the preparation of indican, and yielded, under the influence of acids, indiglucin and a brown substance similar to indifuscin.

In 1896 Surg. Lt.-Col. G. S. A. Ranking (Jour. Asiatic Society of Bengal, lxx. ii. No. 1), as the result of a careful examination of the fermented leaf extract, pointed out for the first time that the soluble compound present and which by air oxidation gives indigotin, cannot be indigo white, but is evidently *indoxyl*. He also

suggested that as CO_2 is largely evolved during the leaf fermentation it is not improbable that *indoxyl* acid,

may also be present.

Marchlewski and Radcliffe (J. Soc. Chem. Ind. 1898, 17, 434), evidently unaware of Ranking's paper, and indeed this seems to have been lost sight of by later workers, in a theoretical discussion of the subject, suggested that indican $C_{14}H_{17}O_6N$ was a glucoside of indoxyl, the hydrolysis of which could be represented by the following equation :—

As a result of the communication of Marchlewski and Radcliffe, Hazewinkel, the director of the experimental station for indigo, Klaten, Java (Proc. K. Akad. Wetensch. Amsterdam, 1900, 2, 512), gave an account of a research, concluded in 1898, which he had hitherto considered to be to the interest of the Java planters to keep secret. In this important paper he shows that indican is an indoxyl glucoside, and that the sugar obtained from it is dextrose.

The elaborate researches of Beyerinck, van Romburgh, and other Dutch chemists proved that the indican present in the various *Indigofera* and in the *Polygonum tinctorium* was far more stable than Schunck supposed, and the experiments of these authors eventually led to the isolation of this glucoside, in a crystalline condition from the *Indigofera leptostachya* and *Polygonum tinctorium* by Hoogewerff and ter Meulen (Proc. K. Akad. Wetensch. Amsterdam, 1900, 2, 520).

The leaves were immersed in two and a half times their weight of boiling water, boiled for a few minutes, and further systematically exhausted. Without any sensible decomposition the decoction could be evaporated *in vacuo* if care was taken to keep the reaction alkaline. The dry residue was extracted with methyl alcohol, and to the solution ether was added as long as a precipitate was formed. This was removed, the clear liquid evaporated, the residue completely dried *in vacuo*, and then dissolved in water. The filtered and concentrated solution deposited on cooling well-defined crystals of indican. This process may be modified by treating the decoction of the leaves with baryta water before concentration, by which means a large proportion of the impurities are precipitated. Seventeen kilos. of the leaves of *Polygonum tinctorium* yielded 5 grams of pure indican.

Thus obtained indican $C_{14}H_{17}O_6N$ crystallises from water in spear-shaped crystals, which contain 3 molecules of water of crystallisation. Heated in a test tube, or on platinum foil, purple-coloured fumes are given off, but this does not take place in an atmosphere of carbon dioxide. By passing a current of air through a hot solution of indican in dilute hydrochloric acid containing a little ferric chloride, 91 p.c. of the indican was converted into indigotin according to the equation

There was no difference between the indican prepared from the *I. leptostachya* and that obtained from the *P. tinctorium*.

In a paper by Beyerinck (Proc. K. Akad. Wetensch. Amsterdam, 1900, 3, 102), 'On the Formation of Indigo from Woad,' this chemist discusses Schunck's well-known work on the same subject, and points out that the indigo-yielding substance contained in this plant is not, as Schunck regarded it, identical with the indican present in the *Polygonum tinctorium*. The colouring principle of woad Beyerinck names *isatan*, and shows that this compound, unlike indican, is decomposed in feebly alkaline solutions, whereas indican is stable even in concentrated alkaline liquids. In presence of acids both isatan and indican are hydrolysed, but indican with greater difficulty. *Isatase*, the specific enzyme of woad, does not act on indican, and isatan, on the other hand, is unaffected both by the indigo enzyme or by common bacteria.

Schunck (Chem. News, 1900, 82, 176) considered that the crystalline indican of Hoogewerff and ter Meulen was not the substance obtained by him, and should not be considered as a pure variety of it, but was rather derived from it, by extracting the plant with a hot solvent and the use of chemicals. He preferred to name his compound *a*-indican and theirs *b*-indican.

Bergthel (Chem. Soc. Trans. 1904, 85, 877), who experimented with the *I. sumatrana* and *I. arrecta*, did not find it possible to prepare indican from the leaves of these plants in the manner described by Hoogewerff and ter Meulen.

It was, however, shown by Perkin and Bloxam (Chem. Soc. Trans. 1907, 91, 1715) that crystalline indican can be isolated from both of these plants by such a method, and is in reality the source of the natural indigo which is derived from them.

In a further communication ter Meulen (Rec. trav. chim. 1905, 29, 444) describes a modification of the method previously given for the isolation of indican from the *Polygonum tinctorium*, which consists in treating a cold solution of the partially purified substance with sulphuric acid, by which means certain impurities are precipitated. The acid is then removed with barium carbonate. The main object of the investigation was, however, the determination of the sugar that this glucoside yields when hydrolysed by its specific enzyme, and this proved to be dextrose, as already indicated by Hazewinkel (*l.c.*).

As a result of the study of the behaviour of indican with solvents, Perkin and Bloxam (*l.c.*) devised a very simple process for the isolation of this glucoside, by the aid of which large quantities of the pure substance could be readily prepared.

The leaves and stems of the *I. sumatrana* (1000 grams) were treated with 4 litres of cold acetone, the mixture being occasionally shaken during 7 days, and the green-coloured extract was evaporated on the steam-bath to a very small bulk. To the residue light petroleum was added, causing the deposition of a brown viscous precipitate of crude indican, and this was repeatedly agitated with small quantities of light petroleum. The product on treatment with water gave a pale yellow liquid, containing resinous matter in suspension, and the latter was removed by shaking with ether. The clear aqueous solution, treated with 10 c.c. $N/2$

sodium carbonate, on gradual evaporation *in vacuo* deposited crystals, and eventually a semi-solid mass was obtained. It was collected, drained, and allowed to dry at the ordinary temperature. When exhaustively extracted, 1000 grams of leaf gave 31.66 grams of indican, and by a continuous system of working more than 500 grams of crystalline indican were prepared. The preparation of this glucoside from the leaves of *I. arrecta* is more troublesome, owing partly to the presence of kaempferitrin (*l.c.*), but more especially of a colourless sugar-like compound $C_6H_{12}O_5$; m.p. $186^\circ-187^\circ$; possibly a modification of quercitol. The fact that indican can be so readily isolated without the aid of heat, and merely with the use of acetone, light petroleum and ether, is not in harmony with the contention of Schunck (*l.c.*) that the crystalline glucoside is an alteration product of his amorphous substance, and consequently the terms α - and β -indican suggested by him should disappear.

Indican crystallised from water

melts at $57^\circ-58^\circ$, but in the anhydrous condition as obtained by the addition of boiling benzene to its hot alcoholic solution, at $176^\circ-178^\circ$. Owing to its somewhat ready solubility in water it can be more economically purified by the latter process, and, according to Perkin and Thomas (Chem. Soc. Trans. 1909, 95, 793), crystallisation from absolute alcohol gives excellent results.

A newer method of preparing indican from indigo-yielding plants, in which acetone is also employed, has been devised by B. M. Amin (Agr. Res. Inst., Pusa, Indigo Publ. No. 5). The fresh leaf is extracted with hot water, and freshly slaked lime added to precipitate impurities. These are removed, the filtrate evaporated and extracted with acetone. By evaporation and cooling in ice indican hydrate separates from the aqueous solution. Dissolved in absolute alcohol, and by precipitation with benzene (*cf.* Perkin and Bloxam) pure anhydrous indican crystallises (yield 70-80 p.c.). This method is specially suitable for preparing pure indican in large quantities from the Java indigo plant (*I. arrecta*) for which Perkin and Bloxam's method is hardly serviceable. The advantages claimed by this method are its rapidity, its general application and the small amount of organic solvent required.

It has been shown by Baeyer (Ber. 1881, 14, 1745) that indoxyl readily condenses with aldehydes and ketones to form the so-called *indogenides*, and Hazewinkel (*l.c.*) partly identified this substance by means of its condensation products with isatin, benzaldehyde, and pyruvic acid, relying, however, on their qualitative reactions, as he did not prepare these compounds in a pure enough condition for analysis. Almost simultaneously Beyerinck (Proc. K. Akad. Wetensch. Amsterdam, 1899, 2, 120) prepared indirubin by hydrolysing crude indican in the presence of isatin.

Perkin and Bloxam (*l.c.*) and Gaunt, Thomas, and Bloxam (J. Soc. Chem. Ind. 1907, 26, 1174), who experimented with the pure substance, found that when indican dissolved in water is added to a boiling solution of isatin, acidified with a little hydrochloric acid, and the operation

is carried out in an atmosphere of hydrogen or carbon dioxide, the yield of indirubin is quantitative according to the following equations:—

This 'isatin' method, for details of which see later, affords a ready means, not only for the analysis of the crystalline glucoside, but also for the estimation of the amount which is present in aqueous infusions of the leaf (*v. infra*).

More recently Perkin and Thomas (Chem. Soc. Trans. 1909, 95, 795), who studied in a similar way the condensation of indoxyl derived from indican with *p*-nitrobenzaldehyde, found that the *p*-nitrobenzaldehydeindogenide is deposited in quantitative amount, and that this reaction could also be employed for the analysis, both of crystalline indican and of that present in the leaf extract. The reaction takes place with extreme readiness, for with indican solution at a dilution of 1 in 1000, the above compound quickly separates, and even at 1 in 10,000 the condensation can be observed to take place. Piperonal and indican in the presence of dilute acid yield the analogous compound $\text{C}_{18}\text{H}_{11}\text{O}_3\text{N}$, orange-coloured needles, m.p. 223°–224°; but this process, under analytical conditions, gave only approximately satisfactory results. As a side issue, *p*-hydroxybenzaldehydeindogenide $\text{C}_{15}\text{H}_{11}\text{O}_2\text{N}$, orange-red needles, m.p. 267°–269°, and dihydroxybenzaldehydeindogenide

orange-red needles, m.p. 264°–265°, were prepared from indican. The latter compound derived from protocatechuic aldehyde dissolves in concentrated sodium hydroxide, with a bluish-violet coloration, and dyes with mordanted woollen cloth well-defined shades.

On the other hand, when indican is hydrolysed with acid in the presence of an oxidising agent it does not appear possible to obtain a quantitative yield of indigotin. Hazewinkel (*l.c.*) states, in regard to this point, that acid oxidising agents convert indican into indigo, and this in turn is oxidised by an excess of the reagent. By the use of ferric chloride and hydrochloric acid, Hoogewerf and ter Meulen obtained from the pure glucoside only 91 p.c. of the theoretical quantity of colouring matter, which appeared to contain indirubin, and was of doubtful purity. Gaunt, Thomas, and Bloxam (*l.c.*), who examined the behaviour of ammonium persulphate, a reagent suggested by Rawson for the analysis of the plant extract (Report on the Cultivation and Manufacture of Indigo, Mozufferpore, 1904; *cf.* also Bloxam and Leake, Dalsingh Serai Report, 1904), found that the process was far from quantitative with pure indican, and that the yield of colouring matter averaged but 82 p.c. of the theoretical. Perkin and Thomas (*l.c.*) studied the effect of the hydrolysis of solutions of indican with acid during the aspiration of air through the liquid, under varying conditions of temperature and concentration. The most satisfactory yield of pure colouring matter (93.5 p.c.) was produced when air was passed during eight hours through a solution of 0.5 gram of the glucoside in 850 c.c. of water acidified with 15 c.c. of 33 p.c. hydro-

chloric acid, and the temperature maintained at 60°.

When, however, the operation was carried out at 70° less colouring matter was obtained (87.6 p.c.), and, curiously enough, replacement of the hydrochloric acid by an equivalent amount of sulphuric acid gave, under similar conditions, a much lower result. The deficiency in the yields given by these air-oxidation processes was due to the fact that a portion of the indoxyl had been converted into substances other than indigotin, and it was observed that whereas in the case of hydrochloric acid the filtrate possessed a pale yellow colour, that containing sulphuric acid had a browner and darker tint. Indirubin was also present in these indigo preparations.

Whereas Schunck (*l.c.*) had described the production of various brown substances by the action of dilute acids on his indican, and Schunck and Roemer (*l.c.*) had obtained a brown-yellow compound by means of hydrochloric acid in absence of air, the behaviour of the pure crystalline glucoside in this respect was studied by Perkin and Bloxam. When 100 c.c. of a 4 p.c. solution of indican was treated with 3 c.c. of sulphuric acid, and digested at a boiling temperature, the liquid, at first yellow, became brown, a brown resinous substance, together with a little indigotin, quickly separated, and the presence of indole was observed. The product of the reaction was almost identical in weight with that required by the amount of indoxyl which the glucoside would yield on hydrolysis, and consisted chiefly of a dark reddish-brown powder (*a*), sparingly soluble in alcohol, together with a small quantity of a similar, though more readily soluble substance (*b*).¹ Analyses of (*a*), which is termed *indoxyl brown*, gave C=68.10; H=4.10; N=9.34, figures almost identical with those found by the same authors for the main constituent of indigo brown, and though these two products differed from one another in certain minor respects, there could be no doubt that they were closely allied. The more readily soluble substance (*b*) also closely resembled the indoxyl brown, and gave on analysis N=9.65 p.c. Indicn, when treated with cold hydrochloric acid in the absence of air for 90 hours, gave indoxyl brown and a soluble brown substance similar to that described above (Perkin and Thomas). The acid filtrates from the indoxyl brown preparations contained dextrose, and this was identified by means of its osazone, and also by the preparation of its acetyl derivative.

The indigo enzyme discovered by Schunck (*l.c.*) has been elaborately investigated by the Dutch chemists. Beyerinck (Proc. K. Akad. Wetensch. Amsterdam, 1899, 1, 120) extracts the finely divided leaves of the plant, first with cold 96 p.c. alcohol, and subsequently with more dilute alcohol, which removes chlorophyll, indican, wax, &c., and leaves a snow-white highly active powder. From such preparations the enzyme itself could only be imperfectly removed, for in water it is almost insoluble, very sparingly so in glycerol, and rather more readily in 10 p.c. solutions of sodium and calcium

¹ According to Perkin (Chem. Soc. Trans. 1916, 109, 211) this operation can be so conducted that the total amount of nitrogen present in this product is approximately equivalent to that possessed by the indican originally employed.

chlorides respectively. The residue which remains after extraction in this way is not perceptibly less active than before treatment. A minute study of these leaf preparations was carried out by Beyerinck in regard to their behaviour with partly purified indican solutions, and he indicates the effect of temperature on the intensity of the hydrolysis by means of curves. Among numerous points of interest it was observed that ammonia quickly destroys the enzyme, and also that emulsin slowly hydrolyses indican, although the intensity of its action was only one-twentieth of that of *Indigofera* enzyme preparations.

Hazewinkel (*ibid.* 1900, 2, 513), who also investigated the subject in 1898, arrived independently at Beyerinck's conclusions. Finding that emulsin acted on indican solutions he called the indican enzyme *indimulsin*, and considered that a 10 p.c. solution of sodium chloride is the best medium for dissolving it. A very interesting point which he mentions is that during fermentation no indican passes from the leaf into the surrounding liquid.

In the paper of van Romburgh (*ibid.* 1899, 2, 344) allusion again is made to the insoluble character of the enzyme, and to the activity of emulsin with solutions of indican. Finally, Beyerinck (*ibid.* 1900, 3, 101) demonstrated that the ferment present in woad, *Isatis tinctoria*, is not capable of hydrolysing indican, though it reacts with isatan, the peculiar indigotin yielding principle of this plant. Bergthell (Chem. Soc. Trans. 1904, 85, 877), whose paper covers ground already traversed by Hazewinkel, Beyerinck, and van Romburgh, considers that the difficulty which occurs in extracting the enzyme is due to the presence of tannin in the leaves (*cf.* Brown and Morris, Chem. Soc. Trans. 1893, 63, 604). By pounding the leaves with hide powder the tannin becomes fixed, and a very active solution of the enzyme can be obtained.

Ter Meulen (Rec. trav. chim. 1905, 24, 444) is, however, in agreement with the other Dutch work referred to above, as is evident from his statement 'L'enzyme de l'indigo est insoluble dans l'eau.' According to Gaunt, Thomas, and Bloxam (*l.c.*), Bergthell's product is not a true solution, as the enzyme is entirely removed from it by means of a Berkfeld filter. Thomas, Perkin, and Bloxam (Chem. Soc. Trans. 1909, 95, 829), again, point out that there is no certainty of the presence of tannin in the leaves of the *I. sumatrana* and *I. arrecta*, and that any tannin matter if originally present would be eliminated during the repeated extraction of the material with alcohol. As the result of their experiments the insolubility of the enzyme was confirmed.

A study of the hydrolysis of pure indican by means of the enzyme and subsequent oxidation of the indoxyl solution with air under varied conditions has been made by Thomas, Perkin, and Bloxam (*l.c.*). The fermentation was carried out in an atmosphere of purified hydrogen, and the temperature and dilution of the solution in both this and the subsequent oxidation process were so arranged as to fairly approximate the ordinary factory routine. For full details of apparatus and the analytical precautions adopted the original paper must be consulted.

The results of this investigation show that the hydrolytic action of the enzyme proceeds

somewhat rapidly, and that by employing 2 grams of the enzyme and 1 gram of indican under the conditions of dilution stated, the reaction was complete after 2 hours' digestion at 50°. The solution, though free from indican, contains, however, less than the theoretical amount of indoxyl (93 p.c.). This is due to the fact that some quantity of the indoxyl (4 p.c.) is occluded by the enzyme powder, and it was found that by increasing the quantity of this latter a correspondingly greater loss occurs. The residual deficiency (3 p.c. approx.) arises from the instability of indoxyl itself, which even in an atmosphere of hydrogen at 50° is slowly converted into a product which is incapable of giving indigotin on oxidation. This property, which is referred to as the 'decay' of indoxyl, is much more evident when the digestion with the ferment is prolonged for several hours, and the experiments of these authors indicate that by such a treatment for 30 hours, at least 20 p.c. of the indoxyl undergoes this transformation. On the other hand, at 15°, in an atmosphere of hydrogen, the indoxyl solution is comparatively stable, and on standing for 24 hours, experienced a loss of only 3 p.c.

According to Beyerinck (*l.c.*) great attention should be paid to the degree of the acidity of indican solutions which are undergoing fermentation, and this is corroborated by Thomas, Perkin, and Bloxam. Thus, by the presence of a trace of sulphuric acid, during the fermentation, the decay of the indoxyl is practically inhibited, and, moreover, by the addition of a further quantity of the acid at the close of the operation, the occlusion of the indoxyl by the enzyme powder is also prevented. As a result of this procedure the solution contained 99.5 p.c. of the theoretical quantity of indoxyl.

When a dilute aqueous solution of indoxyl is oxidised by air the reaction is more complex than has usually been considered the case, and a quantitative yield of indigotin is not produced. Thomas, Perkin, and Bloxam have, for instance, found that the indoxyl solutions produced by the enzyme hydrolysis of indican, when treated with air at 60°, gave only 88 p.c. of the theoretical quantity of indigotin, admixed with a little indirubin. It thus appears evident that in addition to the oxidation of indoxyl to indigotin some secondary reaction occurs, but of the chemical nature of this change there is as yet no certain evidence. The isolation from the indigo thus produced of traces of substances resembling indoxyl brown or indigo brown indicates the effect, at least in part, of a condensation similar in character to that which is involved in the production of the former product. Moreover, the filtrate from the indigo, which is prepared in this manner, was invariably of a dull yellow colour, and yielded, by extraction with ether, a small quantity of a yellowish-brown resin.

This secondary change of indoxyl is facilitated by the presence of potassium acetate in the liquid during the oxidation, for by this means the yield of indigotin was decreased to 81 p.c., and the filtrate obtained from it possessed a rich dichromate colour. It has long been known that the oxidation of indoxyl solutions, in so far as the crude fermented factory liquid is concerned, is facilitated by the presence of ammonia or lime

water, and the subject has been discussed by Rawson and by Beyerinck (*l.c.*). According to Thomas, Perkin, and Bloxam, the employment of a small quantity of either of these reagents during the oxidation of the indoxyl derived from pure indican was beneficial, and an increase of about 5 p.c. in the yield of indigo thus took place. On the other hand, the addition of only a trace of these compounds is advisable, because should an excess be present the amount of indigo produced is rather decreased than increased thereby.

But whilst both ammonia and lime water in suitable amount partially inhibit the secondary change of the indoxyl referred to above, a third factor, well known to manufacturers, comes into play, which is represented by the production of notable amounts of indirubin. For the formation of this colouring matter isatin is necessary, and it is likely that, in the presence of a large amount of the above reagents, an excessive production of this substance occurs, and occasions the decreased yield of indigo which, under these circumstances, has been shown to take place. It has, in fact, been pointed out by Perkin (*Chem. Soc. Proc.* 1907, 23, 30) that traces of isatin exist in Java indigos, which are rich in indirubin.

Curiously enough the presence of a trace of hydrochloric acid during the oxidation acts in the same manner as ammonia, though to a less extent, in increasing the yield of colouring matter, but in this case the reaction proceeds much less rapidly. The employment of pure oxygen with neutral solutions of indoxyl gives 3-4 p.c. less colouring matter than is obtained when air alone is employed, whereas in presence of ammonia the yield is but little affected. The addition of Chile saltpetre to the fermentation vat has been a custom of Indian planters for some time, and Rawson (Report on the Cultivation and Manufacture of Indigo, 2nd ed., 1907) states that although no increase of colouring matter is thus produced in the oxidation vat, the precipitate settles better. The laboratory experiments of Thomas, Bloxam, and Perkin with pure indican corroborate this statement. Finally, there is but little difference in the yield of colouring matter experienced when the solution of indoxyl is oxidised by air at either 30° or 60°, although, if anything, the advantage is in the case of the higher temperature.

As a result, therefore, of the employment of acid during the enzyme hydrolysis of indican, and oxidation of the resulting indoxyl solution under feebly alkaline conditions, the best yields of colouring matter have been obtained. On the other hand, it has not been found possible either with synthetical indoxyl or indoxyl derived from indican to obtain a quantitative yield of pure indigotin or of an admixture of this colouring matter with indirubin. In regard to the bearing of this work on the commercial process, Thomas, Perkin, and Bloxam suggest that the effect of the addition of a small quantity of sulphuric or oxalic acid to the fermentation vat should be studied. They consider, however, that the most satisfactory laboratory results on the preparation of indigotin from the plant extract, or from pure indican, are given when the solution is hydrolysed by hydrochloric acid, with simultaneous oxidation by air. The cost of hot water extrac-

tion of the plant is, however, considered by Rawson to be prohibitive.

Bacterial fermentation. Though in the manufacture of indigo, hydrolysis of the indican is mainly due to the action of its specific enzyme indimulsin, it is well known that the bacteria which are present exert a similar although minor effect.

In 1887 Alvarez (*Compt. rend.* 115, 286) isolated from an extract of the indigo plant, an organism *Bacillus indigogenus*, which was capable of producing this fermentation. Beyerinck (*l.c.*), who studied the matter in considerable detail, points out that a similar effect is produced by infecting indigo plant infusions with garden soil, and that in this case the common gas-producing bacteria perform the chief part. Alvarez, he suggests, went too far in insisting on the existence of a specific bacterium in indigo fermentation. On the other hand, Bergthel (*l.c.*) considers that at least one organism capable of producing indigo fermentation is invariably found in large quantities in an infusion of the plant. This corresponds very closely with the description given by Alvarez of his *Bacillus indigogenus*, and is no doubt identical with it.

MANUFACTURE OF INDIGO.

Water. Pure water in large quantity is necessary for the manufacture of natural indigo (Crookes, Handbook of Dyeing and Calico Printing, 1874; Indigo Manufacture, Bridges-Lee, 1892; Rawson, Report on the Cultivation and Manufacture of Indigo, 1902). When such is not available, Bridges-Lee recommends its purification, if hard, by treatment with lime water, and should much organic matter be present by the use of permanganate. Rawson also lays stress on this point, and recommends a similar method of procedure. In special circumstances the employment of alumino-ferric is advisable (Bergthel, 1909). As the duration of the fermentation varies with the temperature of the water, Rawson recommends, in case this should be lower than 90°F., a preliminary heating in the reservoir.

Fermentation. The duration of this process is given by Crookes (*l.c.*) as 9-14 hours, according to the prevailing temperature of the water, whereas Georgievics (*Der Indigo*, 1892) suggests 18 hours when the external temperature is 35-6°C. In very hot weather the fermentation is completed in 6 hours. According to Rawson (*l.c.*) when the temperature of the fermentation vat is from 90° to 92°F. a 12 hours' steeping gives the best result in the case of the *I. sumatrana*; whereas Bergthel (Indigo Research Station, Sirsiab, 1906) is of opinion that a 10 hours' fermentation is sufficient. With the *I. arrecta* the steeping should vary from 13 to 15 hours at 90°, according to the indican content of the plant. In other respects, according to Rawson and Bergthel, there is practically no improvement necessary in the steeping operation as carried out in well-managed factories. The addition of such chemicals as mercuric chloride, sodium and potassium carbonates, lime, carboic acid, formaldehyde, and sugar are not of advantage, although sodium nitrate, which has been employed by planters for many years past, may facilitate the deposition of the indigo in the

oxidising vat. On the other hand, the work of Thomas, Bloxam, and Perkin indicates as beneficial the curtailment, as far as possible, of the steeping operation, and the addition of sulphuric or oxalic acid in small quantity to the vat as advantageous.

Hot-water extraction. The extraction of the indigo plant with hot water has been employed for many years, and in Bancroft's 'Philosophy of Permanent Colours' an account is given by Dr. Roxburgh, dated 1797, of such a method:— 'The hot-water process begins to be used over these provinces . . . with it they can make indigo when the weather is too cold for the usual process of fermentation, and it gives a more beautiful and lighter indigo. . . . A more complete and certain extraction of the basis of indigo is effected by subjecting the plant to the action of water heated to about 150°–160°F.' Bridges-Lee (*l.c.*) claims an advantage by the employment of hot water, and heats the contents of the steeping vat gradually, either by direct fire or steam pipes. It is also well known that the Java planters who have employed the *I. arrecta* for several years past have favoured a hot-water process, and although the exact details of their methods have not been disclosed, it is certain that sulphuric acid is also employed in the manufacture. Perkin (*Chem. Soc. Trans.* 1907, 91, 435) refers to samples of Java indigo prepared by three distinct methods, viz. 'the new process with hot water,' 'the new process with cold water,' and 'the old process in which no chemicals are used.' There can be no doubt that by these hot-water processes the indican is very rapidly hydrolysed by the ferment, and that the indigo eventually produced is of a superior quality. During this hot extraction it appears preferable, as far as possible, to exclude air from the vat by means of a cover, and the necessity in this case is easy to understand because the evolution of carbon dioxide and other gases which act as a protection to the indoxyl during the ordinary process of fermentation, is greatly decreased when operating in this manner (Roxburgh, *l.c.*). Rawson (*l.c.*), who refers to a patent No. 157, 1892, granted to A. Schulte in Hofe, for manufacturing indigo on these lines, and also to Henly's 'heating process of 1888,' carried out numerous experiments on this subject with the *I. sumatrana*. In order to economise fuel the indigo plant was, in the first instance, extracted by the accumulative method; but, contrary to expectation, this did not give such good results as a simple extraction in ordinary vats fitted with perforated steam pipes. He finally concludes, however, that except in wet or cold weather the hot-water system offers no advantage over ordinary steeping carried out under favourable conditions. The indigo made by this method was, however, of better quality (75–77 p.c.) than that made in the ordinary way (50–55 p.c.). In regard to extraction of the plant by means of boiling water, or extraction by steaming, Rawson considers that the cost would be prohibitive.

When the fermented liquid is run into the oxidising vat, the residual plant still contains a small quantity of indoxyl. The question of a second steeping in order to recover this is referred to by Roxburgh as early as about 1797; he considers that a considerable economy would

probably be effected thereby; but Rawson's (*l.c.*) experiments in this direction gave an unsuccessful result. Thomas, Perkin, and Bloxam (*l.c.*) suggest that the employment of a slightly acid water for this purpose should be advantageous, and that the amount of indoxyl retained by the plant residue is probably greater than the 5 p.c. (on the total colouring matter) believed by Rawson to be present. The extracted plant, known as 'seet,' is a valuable manure.

The oxidation vat. Although the oxidation of the fermented liquid was until very recently carried out to some extent by 'hand beating,' a method practised over a century ago, according to Bancroft (*l.c.*), this operation is commonly effected by machinery. The apparatus is identical with, or very similar to, the 'beating wheel,' a rimless wheel, the spokes of which are paddles, and which is now very generally employed in India. Geneste in 1888 patented the pumping in of air, and Bridges-Lee (*l.c.*) in 1891 a shower-bath arrangement, as improvements in the method of oxidation. Rawson, again (1902, *Eng. Pat.* 173), proposed to treat the liquid with acid and an alkaline persulphate; but although excellent results were obtained in the laboratory, these were not satisfactory on the manufacturing scale. As the outcome of an elaborate investigation, Rawson considers that the oxidation of the fermented liquid by blowers and compressors is superior to wheel beating, the yield being thereby increased about 20 p.c.

It has long been the custom to facilitate the deposition of the indigo by what were termed 'precipitants,' and experiments are recorded by Roxburgh, who employed for this purpose ammonia, stale urine, caustic lye, lime water, and potassium ferrocyanide. That such chemicals must be considered to have assisted in the more rapid oxidation of the indoxyl is certain, and their effect is not to be confused with the mere settlement of the indigo by the use of slaked lime, as adopted by the Chinese.

In 1894 Coventry patented a process which was based on the employment of lime under certain conditions. The invention consisted in the employment of a special vat intermediate between the steeping and oxidising vats, in which the fermented liquid was treated with lime. A copious precipitate of calcium and magnesium carbonates was thus produced, which on settling carried down various impurities. The supernatant liquid was then oxidised in the usual manner. The indigo thus produced is somewhat contaminated with lime, and the removal of this is subsequently effected by the addition of a certain amount of acid to the 'mal' in the boiler. Indigo prepared in this manner is of superior quality, and although not equal to the Java product resembles the latter in containing some quantity of indirubin. According to Rawson a substantially increased yield of colouring matter is given by this process.

Caustic soda added to indigo liquor before oxidising behaves very similarly to lime, and on the large scale gave an increase of 43 p.c. of dry indigo as weighed. Sodium peroxide also gave an average increase of 33 p.c., but on the whole was not so serviceable as caustic soda (Rawson).

The oxidation of the fermented plant extract in the presence of ammonia, first mentioned by Roxburgh (*l.c.*), was patented by Michea in 1876,

whereas Geneste in 1889 suggested the use of caustic soda and ammonium sulphate instead of liquid ammonia itself. The use of ammonia is mentioned as beneficial by Georgievics (*l.c.*), and there appears to be no doubt that it is superior to the other reagents which have been employed for this purpose. In its presence the indoxyl is rapidly oxidised to indigotin, and the precipitated colouring matter settles well. The more general employment of ammonia in India has resulted from the work of Rawson, and its use in conjunction with the steam injector blower constitutes the most important improvement which he has recommended to the notice of the indigo planters. The procedure adopted by Rawson consists briefly in connecting the outlet of an ammonia still (containing lime and ammonium sulphate) loosely with the steam blower, so that when in action, ammonia, air, and steam are injected into the vat by means of perforated pipes laid at the bottom of the receptacle. During the operation the temperature rises 10° – 15° F., and the oxidation is rapidly completed. The employment of ammonia gas and steam in connection with the beating wheel gives also satisfactory results. By these methods Rawson describes increases in the yields of dry indigo, varying from 37 to 63.3 p.c., and considers that the average increase of colouring matter is about 34 p.c. as compared with that given by the ordinary oxidising process.

On the other hand, Bergthel (Report of the Indigo Research Station, Sirsiah, 1906, 6) states that the ammonia process effects very little, if any, improvement over ordinary oxidising when this is carried out under optimum conditions of speed, weather, &c.

After the indigo has settled in the vat, the supernatant liquid, or 'seeth' water, is run off as completely as possible. This seeth water, as a rule, contains more or less colouring matter in suspension, and it is during this operation that a considerable loss of indigo occurs, which may reach as much as 20 p.c. (Rawson). This, as a rule, is much reduced by using an alkali in oxidising, on account of the readier settlement of the precipitate. Rawson found that filter pressing cannot be employed for recovering the indigo, but suggests treating the 'seeth' water with an alkali which causes the suspended indigo to more readily subside. On the other hand, Bergthel (1909) recommends the employment of alumino-ferrie as an aid to the deposition of the indigo precipitate in the oxidation vat.

Davis (Agric. Res. Inst. Pusa, Indigo Publ. No. 3) recommends the use of Dhak gum to aid settling and to give a product which can be easily filtered and pressed. Loss due to incomplete settling is often considerable, and whereas alumino-ferrie also precipitates impurities, Dhak gum has not this disadvantage. In certain cases Dhak gum, which is added five minutes before the beating is ended, gave an increase in yield of 70 p.c. for Sumatran working and of 35 p.c. with Java plant. No appreciable deterioration of quality is observed. Not only does the addition of the gum give an increase in yield when the conditions for settling are bad, but again when these are good it causes no harmful effects.

Final treatment of indigo. According to Bancroft (*l.c.*) it was the practice of some manu-

facturers in the East Indies to purify their indigo by boiling it with water and fossil alkali (soda), whereas Roxburgh, as well as de Cosigny, recommended also the action of a diluted sulphuric acid. The more general procedure, until very recently, in India has consisted in merely boiling the semi-fluid indigo paste in a large cauldron, but the addition of dilute sulphuric acid appears now to be generally adopted. According to Rawson the quality of the indigo may be in this way improved 5–10 p.c. At the close of the operation the indigo is allowed to settle, the acid liquid run off, and the precipitate treated with fresh water and again boiled.

The subsequent filtering, pressing, and drying operations call for no special comment. The slow drying of the product appears to be most advantageous, and in this way an indigo of slightly higher percentage than when the mass is dried artificially is obtained. This is accounted for by the fact that certain impurities of the indigo in the presence of moisture undergo gradual decomposition with evolution of ammonia and other gases.

Briggs (Pat. Spec. 292, 1906) devised an apparatus for drying the indigo paste, and simultaneously converting it into powder. An illustration of this machine, essentially a revolving drum, appears in Bergthel's Report, 1906, 12. Attempts, moreover, are being made to place natural indigo on the market in the paste form (*ibid.* 1910).

CONSTITUENTS OF NATURAL INDIGO.

In addition to indigotin, natural indigo contains varying proportions of indirubin, indigo brown, indigo gluten, and mineral matter. Indigo yellow or kaempferol is also present as a rule when the *I. arrecta* has been employed for the manufacture.

Indirubin. The identity of the natural indirubin or indigo red with the artificial product prepared according to Baeyer's method (*l.c.*), about which there was formerly some controversy, appears now to be fully established (Marchlewski and Radcliffe, *J. Soc. Chem. Ind.* 1898, 17, 434). Bloxam at one time (*Chem. Soc. Trans.* 1905, 87, 979) considered that a red substance other than indirubin was present in some quantity in natural indigo, whereas Bergthel (Report of the Indigo Research Station, Sirsiah, 1906) has stated that 'decisively there is more than one red body in most commercial indigos.' The investigation of numerous samples of the dyestuff by Perkin and Bloxam (*Chem. Soc. Trans.* 1907, 91, 279, and 1910, 97, 1461) indicate, however, that this is not the case. Whereas certain varieties of natural indigo, notably Java and Coventry process indigos, contain notable amounts of indirubin, it is probable that a trace occurs in all samples of the natural dyestuff. That the indirubin originates from the indican existing in the leaves of the various species of *Indigofera*, and is due to no second constituent of the plant, is now certain, and its production is to be explained in all cases as due to the condensation of isatin with indoxyl. Thus it has been shown by Thomas, Bloxam, and Perkin (*l.c.*) that indigo containing indirubin can be readily produced from indican by a repetition of the factory method, and again, isatin itself has been isolated from natural indigo rich in

indirubin (Perkin, Chem. Soc. Proc. 1907, 23, 30). The formation of the isatin is favoured by special circumstances such as the oxidation of the indoxyl by air in the presence of alkali or acid, and may also be affected to some extent by temperature. That indoxyl can be converted into isatin without an intermediate formation of indigotin has been shown by the Badische Anilin und Soda-Fabrik (D. R. P. 107719, 1898), and it has been found by Perkin (Chem. Soc. Trans. 1909, 85, 847) that indoxyllic acid, on long standing in the presence of moist air, is converted chiefly into indirubin, although some quantity of indigotin together with a substance, probably indigo brown, and traces of isatin are simultaneously produced. Again, it has been pointed out (Thomas, Bloxam, and Perkin) that the indican present in air-dried leaves of the indigo plant slowly disappears, and, according to Perkin (private communication), this is accompanied in most cases by a development in the leaf of considerable quantities of indirubin. It appears probable that this so-called 'secondary' oxidation of the indoxyl proceeds according to the following scheme:—

and may also be indirectly the cause of the production of indigo brown. The following are the results of analyses illustrating the percentages of indirubin and indigotin in certain indigos (Bloxam and Perkin):—

Java Indigo.—New process with hot water.

Sample	Total colouring matter	Indigotin	Indirubin
1.	75.20	67.76	7.43
2.	73.60	63.86	9.51
6.	62.91	57.35	5.01

Java indigo.—New process with cold water.

7.	72.88	69.23	3.06
8.	71.02	66.35	4.04
9.	58.30	55.61	2.15

Java indigo.—Old process without chemicals.

13.	74.96	72.89	1.74
15.	69.54	68.26	0.99

Coventry process indigo.

61.76	56.63	5.23
-------	-------	------

Finally, Bloxam and Perkin refer to an abnormal sample of laboratory indigo prepared from pure indican, which contained 88.9 p.c. of colouring matter, and of this 25.83 p.c. consisted of indirubin.

Though indirubin was at one time considered to be a valuable constituent of natural indigo (cf. Rawson and Knecht, J. Soc. Dyers, 1888, 4 Hummel, *ibid.*; and Bergtheil, Report Indigo Research Station, Sirsiah, 1907, 7), it is now known that such is not the case. Fasal (Mitt. K. Tech. Gew.-Mus. Wien, 1895, 11, 307) found that the shade of colour given by an indirubin vat became bluer from day to day, and that this was due to the formation of indoxyl by the further reduction of the leuco-indirubin. More recently Perkin (Chem. Soc. Proc. 1909, 25, 127) has shown that in addition to indoxyl, *oxindole* is simultaneously produced, and this is in

harmony with the formula assigned by Baeyer (*l.c.*) to this substance—

In vat dyeing, therefore, indirubin may thus produce not more than one-half its weight of indigotin. Matthews (J. Soc. Chem. Ind. 1902, 21, 22), again, points out that indirubin requires for reduction a much stronger reagent than indigotin, and as a result, in practice, the greater part of this dyestuff is not attacked, but settles to the bottom of the vat.

On the other hand, indirubin disulphonic acid is, according to Fasal (*l.c.*) and also to Rawson and Knecht (*l.c.*), a useful dyestuff, and gives colours much faster to light than indigotin disulphonic acid, which is present as sodium salt in the 'indigo extract' of commerce.

Indigo brown. An important impurity of natural indigo is the so-called indigo brown, a product isolated and cursorily examined by both Chevreul (Gmelin, Handbook of Chem. 1859, 13, 48) and Berzelius (*ibid.*). In order to isolate this substance, the latter chemist digested indigo with boiling dilute sulphuric acid to remove indigo gluten, and subsequently with potassium hydroxide to dissolve the brown. The alkaline liquid was neutralised with acetic acid, evaporated to dryness, the residue digested with alcohol, and the solution evaporated. Thus obtained the indigo brown consisted of a dark-coloured resin, soluble in alkaline solutions. According to Schunck (Phil. Mag. 1855, [iv.] 10, 74, and *ibid.* 1858, 15, 127) the indihumin $\text{C}_{10}\text{H}_9\text{O}_3\text{N}_3$, produced in conjunction with other brown amorphous products by the action of dilute acids on his indican, is perhaps identical with indigo brown.

Perkin and Bloxam (Chem. Soc. Trans. 1907, 91, 279) extracted Bengal indigo, which had been already digested with boiling dilute hydrochloric acid to remove the gluten, with boiling pyridine. In addition to a little indirubin the product contained three substances: (a) the main constituent $\text{C}_{16}\text{H}_{12}\text{O}_3\text{N}_2$ (?), insoluble in alcohol and acetic acid, (b) $\text{C}_{24}\text{H}_{22}\text{O}_3\text{N}_3$ (?), soluble in acetic acid, and (c) $\text{C}_{16}\text{H}_{14}\text{O}_4\text{N}_2$ (?), soluble in alcohol. These compounds, the molecular weight of which is uncertain, consist of brown amorphous powders, closely resembling one another in general property, and are readily reduced by zinc-dust in alkaline solution with formation of pale brown liquids. When digested with boiling 50 p.c. potassium hydroxide solution they give some quantity of *anthranilic acid*, a point which indicates that they are derived from indoxyl. At the same time a brown resinous substance is also produced, and this studied in the case of the main constituent (a) $\text{C}_{16}\text{H}_{12}\text{O}_3\text{N}_2$ contained C=71.39; H=4.05; N=7.94. Natural indigo further contains a small quantity of a brown substance, insoluble in pyridine, but soluble in boiling dilute alkali (Chem. Soc. Trans. 1910, 97, 1473), and is distinguished from the compounds above enumerated by the fact that it is not susceptible to sulphonation (with 96 p.c. sulphuric acid) or conversion by this means into a product soluble in water. In the analytical method described by Rawson (J. Soc. Chem. Ind. 1899, 18, 251) this brown material, at least in

part, consists of impurity which is carried down by a precipitation of barium sulphate in the liquid. There is now considerable evidence in favour of the view that the constituents of indigo brown are derived from indoxyl during the manufacture of indigo from the plant. The fact that indican itself, when boiled with dilute acids, produces the very similar indoxyl brown, and the isolation of brown substances, although in trifling amount, from indigo prepared by the hydrolysis of pure indican in the laboratory, harmonises with this suggestion.

Beyerinck (Proc. Roy. Akad. Scien. Amsterdam, 1899, 120) observed that the disappearance of indoxyl in a dyeing woad (*Isatis tinctoria*) leaf is accompanied by the appearance of brown substances. Again, he states that 'strong acids, just as alkalis . . . favour the formation of indigo from indoxyl, but then part of this substance constantly changes into a brownish-black matter.' It has also been noted by Thomas, Perkin, and Bloxam that the disappearance of indican in the leaves of the *I. sumatrana* on keeping is accompanied by the formation of brown extractive matter. Rawson, again (Report on the Cultivation and Manufacture of Indigo, Mozzufferpore, 1904), says, 'The blower . . . by quickly getting rid of CO_2 gas . . . prevents decomposition of a portion of the colouring matter into worthless brown substances, which takes place to a greater extent under other conditions.' All indigos, moreover, appear to contain indigo brown, so that this property is irrespective of their origin, which may have been 'due to such distinct plants as the *Indigofera*, the *Polygonum tinctorium*, or the *Lonchocarpus cyanescens* of West Africa. Finally, it has been shown by Perkin (*l.c.*) that among the decomposition products of commercial indoxyl acid which has been kept for a long time, a brown compound exists, which has a very similar percentage composition, and is probably identical with the main constituent of indigo brown. It is quite possible that indoxyl acid is produced during the fermentation process (Perkin) (*cf.* Ranking, *l.c.*), and may be concerned in the formation of this product. The percentage of indigo brown soluble in pyridine in natural indigos is very variable, and appears to depend upon the details of manufacture. Analyses made by Bloxam and Perkin (Chem. Soc. Trans. 1910, 97, 1472) gave the following result:—

<i>Java indigo</i> , new process, hot water.	<i>Java indigo</i> , new process, cold water.	<i>Java indigo</i> , ordinary process.	<i>Coventry</i> process. indigo.	<i>New</i> process. indigo.	<i>Bengal</i> indigo.
5.4	5.2	4.15	8.7	9.60	

Except in the case of the Coventry process indigo, these samples had all been derived from the *I. arrecta*. The average amount of crude indigo brown—containing, however, some mineral matter—in numerous samples of Bengal indigo prepared from the *I. sumatrana* was 14 p.c. (Chem. Soc. Trans. 1907, 297).

Indigo brown dissolved in alkaline hydro-sulphite solution does not colour cotton fabrics, though woollen material dyed with natural indigo and stripped by the method of Green, Gardner, Frank, and Lloyd (*l.c.*) frequently possesses a light brown tint which is probably due to the presence of this compound. The amount, however, remaining in this way on the fibre is not sufficient to materially strengthen the colour

effect, and the frequently asserted superiority of the natural over the artificial variety of indigo can hardly therefore be accounted for in this manner.

Indigo gluten. Indigo gluten was first isolated from crude indigo by Berzelius (Berz. Jahresb. 7, 26), who extracted it with dilute acid, neutralised the extract with chalk, evaporated to dryness and dissolved out the gluten with alcohol. It was subsequently prepared by Orchardson, Wood, and Bloxam (J. Soc. Chem. Ind. 1907, 26, 4), who describe it as a horny mass, which on grinding gives a light biscuit-coloured powder, and when heated evolves ammonia. In cake indigo it appears to exist in combination with mineral matter, possibly as a calcium compound, for though itself readily soluble in water, it can only be removed from the dyestuff by means of dilute mineral acid. A considerable quantity of this substance is frequently present in indigo, and Perkin and Bloxam (*l.c.*) found that when the crude Bengal variety containing approximately 62 p.c. of indigotin was digested with dilute hydrochloric acid, it lost 21.5 p.c. of its weight. This figure naturally includes some quantity of mineral matter simultaneously removed by the acid. It has been suggested that this compound plays an important rôle in the dyeing operation, and accounts in part for the alleged superiority of natural over artificial indigo. This point, however, has not been scientifically investigated.

Indigo yellow. The first application of the term 'indigo yellow' to a substance existing in natural indigos is due to Bolley and Crinsoz (Jahres. 1866, 573), who state that it is to be found in the Bengal variety, and can be isolated by sublimation. It is described as golden-yellow needles, subliming at 130° , and soluble in soda lye. Crude Bengal indigo, however, gives no sublimate of this character (Perkin, Chem. Soc. Proc. 1906, 22, 198), but by submitting refined indigo, or the commercial synthetical variety to sublimation with limited access of air, a trace of a yellow compound $\text{C}_{15}\text{H}_{13}\text{O}_2\text{N}_2$ is produced. This substance, however, is insoluble in alkaline solutions, and cannot, therefore, be the indigo yellow of Bolley and Crinsoz.

Rawson (J. Soc. Chem. Ind. 1899, 18, 251) detected in Java indigos a yellow compound, present usually to the extent of 2–3 p.c., although in one special sample as much as about 20 p.c. occurred. This substance was soluble in alkalis with a yellow colour; on heating it partially sublimed, and had the properties of an adjective yellow dyestuff. A more recent investigation (Perkin, Chem. Soc. Proc. 1904, 20, 172) has indicated that this in reality is *kaempferol*

a trihydroxyflavonol known to exist (Chem. Soc. Trans. 1902, 81, 587) in the flowers of the *Delphinium consolida* (Linn.) and other plants. Ultimately it was shown that the leaves of the *I. arrecta*, from which Java indigo is prepared, contain sometimes as much as 4 p.c. of a glucoside, *kaempferitrin* $\text{C}_{27}\text{H}_{30}\text{O}_{14}$, almost colourless

needles, m.p. 201°–203°, which when digested with acid gives kaempferol and rhamnose

This compound is not hydrolysed by the indigo enzyme, and no enzyme has as yet been isolated from the plant possessing such a property. It is likely (Chem. Soc. Trans. 1907, 91, 435) that the use of sulphuric acid, when manufacturing Java indigo, may result in the contamination of the dyestuff with kaempferol. When the wet indigo sludge or 'mal' is boiled in the 'mal' boiler with addition of a little of the acid, the kaempferitrin present in the adhering water will be hydrolysed, and the insoluble colouring matter remain with the indigo. Samples of Java indigo more recently obtained contained only a trace (0.2 p.c. approx.) of kaempferol, whereas in a sample of the new Bengal indigo manufactured from the *I. arrecta* approximately the same quantity was detected (Perkin, private communication). If indigo mixed with kaempferol is cautiously sublimed the sublimate then contains appreciable quantities of this yellow colouring matter, and it seems likely, therefore, that this is in reality the indigo yellow of Bolley and Crinsoz, but that the indigo experimented with by these authors did not, as they supposed, originate from Bengal. The leaves of the *I. sumatrana*, the Indian indigo plant, contain but the merest trace of a yellow dyestuff resembling kaempferol, but according to Henry (Gmelin's Handbook of Chem. 1846, 13, 50) the *Polygonum tinctorium*, or Chinese indigo plant, contains appreciable quantities of a yellow colouring matter.

SEETH WATER.

When 'seeth' water, the liquid from which the indigo precipitate settles out at the conclusion of the oxidation process, is evaporated to dryness, yellowish-brown to deep brown residues are obtained. These products are extremely hygroscopic and when ground emit an odour resembling that of decayed cheese. Three samples of this material were examined by Perkin (Chem. Soc. Trans. 1916, 109, 211), the first and most important of which, derived from water drawn from an oxidation vat in the Purtaphore factory in India, represented 0.75 p.c. of the original liquid. As in the process of manufacture 100 parts of *I. sumatrana* underwent fermentation in the presence of 540 parts of water, this residue corresponded to 4 p.c. of the original plant. Sample (b) consisted of evaporated drainings from the mahl table of the same factory and formed 0.77 p.c. of the original liquid, whereas the origin of sample (c) was doubtful.

The samples were neutral, in the main dissolved readily in water, and these liquids on acidification emitted a strong odour of volatile aliphatic acids. When incinerated, all yielded considerable amounts of mineral matter which consisted mainly of the oxides of calcium magnesium and potassium, traces of manganese oxide and alumina being also present.

When agitated with boiling water, a small amount of an insoluble brown precipitate separated which in appearance closely resembled indigo brown, and was found to consist of a mixture of compounds of variable nitrogen

content. The main constituent isolated as a dark brown amorphous powder, gave on analysis C=65.70; H=5.07; N=8.03 p.c., figures somewhat lower than those found for the main constituent of indigo brown (*l.c.*), whereas the more soluble fraction again contained still more oxygen C=64.7; H=5.0; N=4.6. From the neutral filtrate a small amount of succinic acid was isolated, the main bulk, approximately 20 p.c. of the 'seeth' water residue, consisting of a protein-like compound (N=8.22) which on heating evolved ammonia and in general property resembled the so-called 'indigo gluten' of crude indigo. It consisted of a friable mass, and to the presence of this substance the very hygroscopic nature of the dried 'seeth' residue was evidently due.

The following table illustrates the main results obtained by the analysis of the three samples of 'seeth' water residue:—

	(a) Per cent.	(b) Per cent.	(c) Per cent.
Nitrogen	2.25	2.77	2.72
Ash	27.30	25.90	26.87
Volatile acids	23.80	21.04	—
Succinic acid	2.21	2.18	—
Brown matter	5.58	12.03	11.18
Indigotin	0.18	0.10	0.082

THE ANALYSIS OF INDIGO.

The methods which have been proposed for the analysis of indigo are of a varied character, and the literature upon the subject is extremely voluminous.

These may be classified as follows: methods (a) involving the extraction of impurities with volatile solvents (Schützenberger, Die Farbstoffe, ii. 526); (b) the extraction of indigotin with coal-tar oil (Stein, Die Prüfung der Zeugfarben); with aniline (Hönig, Zeitsch. angew. Chem. 1899, 280); with phenol (Brandt, J. Soc. Dyers, 1898, 34); with naphthalene (Schneider, *ibid.* 1895, 194); with nitrobenzene (Gerland, J. Soc. Chem. Ind. 1897, 108); with acetosulphuric acid (Möhlau and Zimmermann, Zeitsch. farb. text. Chem. 1903, 10, 189); (c) the extraction of indigotin by sublimation (Lee, Chem. News, 1884); (d) the extraction of indigotin by processes of reduction, lime, and ferrous sulphate (Berzelius), stannous chloride and caustic soda (Dana, Jahres. f. prakt. Chem. 26, 398), zinc and caustic soda (Owen, Amer. Chem. J. 10, 178), grape sugar, alcohol and alkali (Fritzsche, Dingl. poly. J. 1842, 86, 306), and hydrosulphite and lime (Rawson, *l.c.*); (e) estimation of nitrogen (Voeller, Zeitsch. angew. Chem. 1891, 110).

More important, however, are the methods based upon the titration of a solution of the sulphonated indigo by oxidising agents (f) chlorine water (Berzelius), chloride of lime (Chevreul, Leçons d. chem. appliq. de la teinture, ii.), potassium chlorate and hydrochloric acid (Bolley, Dingl. poly. J. 119, 114), potassium dichromate and hydrochloric acid (J. pr. Chem. 1851, 18, and Schlumberger, Bull. de la Soc. Mullhouse, 1863, 210, 284), potassium dichromate and oxalic acid (Kinley, Chem. News, 1863, 210, 284), potassium ferricyanide (Ullgren,

Annalen, 136, 96), and potassium permanganate (Mohr, Dingl. poly. J. 132, 363); and by reducing agents (g) sodium hydrosulphite (Müller, Ber. 1880, 13, 2283), and titanous chloride (Knecht, J. Soc. Dyers, 1904, 97, and *ibid.* 1905, 292).

Finally (h) colorimetric methods (Dingl. poly. J. 27, 54, and 40, 448); (i) spectrum analysis (Wolff, Zeitsch. anal. Chem. 17, 65, and *ibid.* 23, 92); and (k) dye trial methods (Chevreul, *l.c.*, and Grossmann, J. Soc. Dyers, 1897, 124) have been proposed.

Of these methods of indigo analysis, modifications of Mohr's permanganate process are most generally employed, although others involving the reduction of sulphonated indigo with titanous chloride and sodium hydrosulphite are to some extent in use.

The permanganate methods. In order to eliminate the error due to the oxidising action of permanganate upon substances other than indigotin which are present in natural indigo, Rawson, who has been the pioneer in this respect, has devised two processes.

Salting-out method. 0.5 gram of finely powdered indigo mixed with its own weight of ground glass is sulphonated in a porcelain crucible by means of 20 c.c. of concentrated sulphuric acid at 70° for $\frac{1}{2}$ –1 hour; the product is diluted with water to 500 c.c. and the liquid filtered to remove insoluble impurities. 50 c.c. of this solution are mixed with 50 c.c. of water and 32 grams of common salt, and after standing for 1 hour the precipitated sodium indigotin sulphonate is collected and freed from certain soluble impurities by washing with about 50 c.c. of salt solution (sp.gr. 1.2). The precipitate is dissolved in hot water, treated with 1 c.c. of sulphuric acid, diluted to 300 c.c., and titrated with a solution of *N*/50 potassium permanganate. The liquid gradually takes a greenish tint, and the final disappearance of this constitutes the end point of the reaction. According to Rawson, 1 c.c. of the *N*/50 permanganate corresponds to 0.0015 of pure indigotin (J. Soc. Dyers, 1885, 74 and 201; A Manual of Dyeing, Knecht, Rawson, and Löwenthal, 1910, 817). Such a factor, however, according to Bloxam (*l.c.*) gives too high figures even with pure indigotin, and this has been corroborated by Frank and Lloyd (*ibid.* 1913, 226), who consider 0.00147 as more correct, and with this Rawson (*ibid.* 1914, 21) is now in agreement.

Barium chloride precipitation process. 0.5 gram of indigo is sulphonated as before, and after diluting with water, but before making up to 500 c.c., 10 c.c. of a 20 p.c. solution of barium chloride are added. The barium sulphate formed carries down with it the suspended impurities of the indigo, and the clear liquid can be pipetted off and titrated as before. The results are practically identical with those given by the 'salting-out' method (Rawson, J. Soc. Chem. Ind. 1899, 251).

Bloxam (*ibid.* 1906, 735) notes that the barium precipitate thus produced is always coloured blue, and this is confirmed by Bergtheil and Briggs (*ibid.* 1906, 729). The latter authors contend that the results given by this modification of Rawson are therefore too low, and consider that this defect is obviated by adding instead of barium chloride freshly precipitated barium sulphate to the indigo mixture.

Grossmann (*ibid.* 1905, 308) throws down the impurities from the indigo solution with calcium carbonate. Bergtheil and Briggs (*l.c.*) and also Bloxam (*l.c.*) find that some quantity of the colouring matter is also precipitated in this way. Knecht, however, recommends its successful use even in larger quantity (J. Soc. Dyers, 1904, 97, and 1905, 292) in connection with his titanous chloride method; but Bloxam (*l.c.*) points out that such being the case this can only be due to the observance of conditions which are not stated in Knecht's paper.

Hydrosulphite method. This process, devised by Müller (Ber. 1880, 13, 2283), depends upon the fact that sodium hydrosulphite ($\text{Na}_2\text{S}_2\text{O}_4$) quantitatively reduces pure indigotin sulphonic acids to their corresponding leuco compounds. The solution of the hydrosulphite contained in a stone bottle is covered with a layer of petroleum to prevent oxidation and connected with a supply of hydrogen gas. By means of a siphon, or other convenient arrangement, the liquid can be drawn into a burette. The solution should be equivalent to about 1 c.c. = 0.0025 gram of indigotin, and the titrations are performed in an atmosphere of hydrogen or coal gas.

Titanous chloride method. This reagent is much more stable than sodium hydrosulphite, and Knecht (J. Soc. Dyers, 1904, 97, and 1905, 292) was the first to recommend its use for the analysis of indigo. The apparatus employed is similar in character to that required for the hydrosulphite process, and the titration is carried out in an atmosphere of carbon dioxide. If the reduction of the indigotin is effected by the titanium chloride in the presence of mineral acid, no definite end-point can be observed (Knecht), but by the addition of salts of tartaric acid this end-point is rendered quite definite.

In working with natural indigo, Knecht (Manual of Dyeing; Knecht, Rawson, and Löwenthal, 822) sulphonates 1 gram of indigo with 5 c.c. of 100 p.c. sulphuric acid at 90° for 1 hour. The solution diluted to 300 c.c. is warmed and slowly treated with 12 grams of chalk, cooled, made up to 500 c.c., and 50 c.c. of the clear liquid, to which 25 c.c. of a 20 p.c. solution of Rochelle salt has been added, is titrated whilst boiling with titanium chloride.

On account of the sparing solubility of Rochelle salt, Bloxam (*l.c.*) recommends the use of sodium tartrate, but states that the presence of excess of this or of Rochelle salt (as advocated by Knecht) is to be avoided, or otherwise too high percentages of indigotin are indicated. In the case of pure indigotin (1 gram) sulphonated with 20 c.c. of 100 p.c. sulphuric acid, and made up to 500 c.c. with water, 25 c.c. of this liquid (containing 1 c.c. of acid) requires 4 grams of the sodium tartrate to give quantitative results when titrated with a solution of titanium chloride containing 1 c.c. of concentrated hydrochloric acid per 50 c.c. of solution.

Bloxam (Chem. Soc. Trans. 1905, 87, 975; J. Soc. Chem. Ind. 1906, 25, 735), Orchardson, Wood, and Bloxam (*ibid.* 1907, 26, 4), and Gaunt, Thomas, and Bloxam (*ibid.* 1907, 26, 1174) have critically investigated the subject of indigo analysis. Among the methods for preparation of pure indigotin, that involving the crystallisation of crude material from nitrobenzene was discarded as untrustworthy, but

the elaborate process of the B.A.S.F. Co. (Brochure, 1900) was found to give a pure substance. On the other hand, sublimation under reduced pressure in Jena flasks immersed in fusible metal at 370°–390°, gave, with synthetical indigo of 92 p.c. (approx.), a beautifully crystalline substance, which, after washing with boiling acetic acid, followed by boiling alcohol, was usually chemically pure. The permanganate factor resulting from experiments with these specially purified materials was 1 c.c. of permanganate solution 1/1000 = 0.00222 gram indigotin solution 1/5000, and is in agreement with that previously adopted by the B.A.S.F. Co. Wangerin and Vorlander (Zeitsch. Farben und Textilchemie, 1902, 1, 281) have stated that indigotin suffers loss of strength by oxidation, even when it is sulphonated by 94 p.c. sulphuric acid at 95°–100° for half an hour, whereas 8 p.c. fuming acid gives a deterioration of from 2 to 14.2 p.c., according to the time of heating. With the indigotin, however, purified as above, Bloxam showed that heating with 20 p.c. fuming acid for $\frac{1}{2}$ of an hour at 97° gave no loss, whereas with 30 p.c. acid for 20 minutes at 97°, a deterioration of only 1 p.c. could be observed. In both these cases indigotin tetrasulphonic acid was produced.

The tetrasulphonate method. As a result of these experiments a method for the analysis of indigo based on sulphonation with fuming acid was devised. 1 gram of the indigo, and 2–3 grams of purified sand (powdered glass contains iron, and should not be employed) is treated with 5 c.c. of 25 p.c. fuming sulphuric acid for half an hour in the water oven, and the solution is made up to 500 c.c. with water. 100 c.c. of this solution is treated with 100 c.c. of potassium acetate solution (450 grams per litre) which causes the precipitation of indigotin tetrasulphonate. The mixture is now warmed, and on cooling finally in ice-water,¹ the salt completely separates in a crystalline condition. This is collected by means of the pump on a Gooch crucible, and washed free from the brown supernatant liquid with a solution containing 90 grams of potassium acetate and 5 c.c. of acetic acid in 600 c.c. of water. The product is dissolved in 200 c.c. of water, and 20 c.c. of this solution, diluted with 80 c.c. of water, is treated with 0.5 c.c. of sulphuric acid, and titrated with permanganate (1/1000). In order to verify the accuracy of this method, Orchardson, Wood, and Bloxam studied the behaviour of indigo brown and indigo gluten, the main impurities of indigo, when submitted to the analytical process, as this subject had not been investigated by previous workers. Indigo brown when sulphonated with 96 p.c. acid gives, when dissolved in water, a dark-brown liquid, which is attacked by permanganate, though not perhaps so readily as the indigotin sulphonic acids, whereas indigo gluten gives similarly a light yellow solution, which is very rapidly oxidised by the reagent. On the other hand, kaempferol or indigotin yellow, treated in the same manner, gave a product which most readily absorbs permanganate, and, indeed, Rawson (J. Soc.

Chem. Ind. 1899, 251) had already pointed out its deleterious effect in indigo analyses. Finally, these authors prepared and submitted to analysis by Bloxam's process mixtures containing known quantities of indigotin and one or other of all of these impurities, with the result that the colouring matter was thus estimated with considerable exactness. Bloxam (Chem. Soc. Trans. 1910, 97, 1473), by an adaptation of the pyridine method for the estimation of indirubin (*l.c.*), in which the impurities are eliminated by a process of extraction, has analysed natural indigos, and obtained the same figures as those given by the tetrasulphonate method. Again, by Knecht's titanium chloride method, and employing the modifications above described, this process can also be effectively worked. It is only reasonable to suppose that an analysis based on the selective precipitation of the sulphonated colouring matter is more likely to be efficient than that which presumes the deposition of varied impurities of a diverse chemical character by one specific reagent, and the somewhat lower results given by the tetrasulphonate method, as distinguished from those yielded by the processes previously in use, are in reality due to the almost complete elimination of these impurities from the indigotin sulphonic acid during the analysis. Rawson (*l.c.*) is, however, of opinion that the effect of these impurities on the analytical results has been much overrated; but, on the other hand, no experimental evidence is given in support of this view (Manual of Dyeing, *l.c.*, 818).

The action of potassium permanganate on solutions of the indigotin sulphonic acids is of interest, because the amount of the reagent necessary for the decolorisation of the liquid varies to some extent with the concentration (Rawson, A Dictionary of Dyes, Mordants, &c., by Rawson, Gardner, and Laycock, 1901, 187). At the concentrations employed by the B.A.S.F. Co., and adopted by Bloxam (*l.c.*), 1 gram of indigotin as sulphonic acid requires 0.45 gram of permanganate for decolorisation, whereas the equation

implies that 0.4824 gram of the reagent is necessary. Again, for the oxidation under similar conditions of indirubin sulphonic acid considerably less permanganate is required, although the oxidation in this case is of a slower character. Bloxam and Perkin (Chem. Soc. Trans. 1910, 97, 1462) consider, therefore, that the oxidation is of a complex nature, and consists either (a) of two distinct stages in the formation of isatin sulphonic acid, or (b) of two distinct reactions involving the production of two separate substances. According to the first suggestion the isatin sulphonic acid formation would be preceded by that of an intermediate compound (I.), whereas by the latter, in addition to isatin sulphonic acid, a dehydroindigotin sulphonic acid (II.) may be produced—

In case the first product of the reaction consists entirely of dehydroindigotin sulphonic

¹ Prolonged heating should be here avoided, and it is preferable that the solution of the tetrasulphonate with its subsequent recrystallisation should be effected without unnecessary delay.

acid, this must, prior to further oxidation to isatin sulphonic acid, take up two molecules of water with formation of the sulphonic acid of dihydroxyindigotin (III).—

In regard to the very small amount of permanganate required for the decolorisation of the indirubin sulphonic acid a similar explanation can be adopted.

The following methods have recently been suggested for the estimation of indigotin. (a) The indigotin is sulphonated and then titrated with formaldehyde sulphonylate (Jones and Spaans, *J. Ind. Eng. Chem.* 1916, 8, 1001).

(b) The indigotin after sulphonation with conc. H_2SO_4 at 70° – 80° is titrated in a highly dilute solution (1 part indigo in 20,000 parts water) with permanganate. In this case constant values are obtained. The constant value corresponds to 9 atoms of oxygen reacting on 5 mols. of indigotin to give a complex oxidation product and not to the oxidation of 1 mol. indigotin by 2 atoms oxygen to give isatin as was formerly supposed (*i.e.* it is found that 1 mg. $\text{KMnO}_4 = 2.3$ mg. indigotin). The end point is obtained by a process of colour matching (Heinisch, *Färber-Zeit.* 1918, 29, 183 and 194).

Analysis of indigos containing starch. It has been shown by Thomson (*J. Soc. Dyers*, 1911, 27, 49) that the indigotin value of samples of indigo adulterated with starch when estimated by the method of sulphonation and titration with permanganate recommended by Rawson and Bloxam give far too low results. Thus an indigo containing starch by Rawson's method gave 18.8 p.c. of indigotin, whereas after removing the starch with 4 p.c. hydrochloric acid, 35.01 p.c. of indigotin was shown to be present. On the other hand, according to this author when hydrochloric acid is employed in this way for the removal of the starch the analytical results are still too low. Frank and Perkin (*J. Soc. Chem. Ind.* April, 1912) corroborated these experiments in so far that indigos containing starch give low figures when directly analysed, and it seems evident that a destruction of the indigotin occurs during sulphonation, and is to be attributed to the reducing action of the starch degradation products. As a result, however, of numerous experiments, no loss of indigotin could be observed even by long digestion of mixtures of starch and indigo with boiling dilute hydrochloric acid, and after removal of starch in this manner correct figures were always obtained by the employment of Bloxam's tetrasulphonate process.

Testing of indigo-dyed woollen materials. An important method for ascertaining the quantity of indigo present on such dyed materials has been devised by Green, Gardner, Lloyd and Frank (*J. Soc. Dyers and Cols.* 1913, 226; 1914, 15). This consists essentially in removing the indigotin from the fibre with boiling pyridine in a modified form of Soxhlet apparatus, and subsequently concentrating the pyridine solution. The main bulk of the indigotin separates as crystals and to complete the precipitation 50 p.c. of alcohol is then added. The product is collected, washed successively with 50 p.c. alcohol, 2 p.c. caustic soda, hot 1 p.c. hydrochloric acid, hot water, alcohol and ether, and

finally dried and weighed. It should test 100 p.c. by the tetrasulphonate method.

For fuller details the original paper should be consulted.

THE ESTIMATION OF INDIGOS RICH IN INDIRUBIN.

It is well known that indirubin is more resistant to oxidation and reduction than indigotin, properties which also apply to the sulphonic acids of these colouring matters. When dealing, therefore, with sulphonated mixtures of these substances and employing either potassium permanganate, titanium chloride, or sodium hydrosulphite, the indigotin sulphonic acid is to some extent preferentially attacked, so that towards the end of the operation the colouring matter consists entirely of indirubin sulphonic acid. In the case of the first-named reagent, however, Koppeschaar (*Zeitsch. anal. Chem.* 1899, 38, 1) finds that it is not possible to obtain trustworthy analytical figures with indigos in which some quantity of indirubin is present, although Rawson (*l.c.*) considers that the indirubin may be approximately estimated in this manner. Bloxam and Perkin (*Chem. Soc. Trans.* 1910, 97, 1462), however, support the view of Koppeschaar. The latter authors, who also experimented with titanous chloride, show that this reagent behaves in an identical manner towards both indigotin and indirubin sulphonic acids, but although the former is somewhat preferentially attacked, it is not possible in this way to differentiate as to the amount of each of the sulphonated colouring matters which may be present in a mixture of the two. On the other hand, according to Knecht, Rawson, and Löwenthal (*A Manual of Dyeing*, 821) indirubin present in mixtures of the two colouring matters may be approximately estimated by the hydrosulphite method.

For analysis of indigos rich in indirubin, processes of extraction based on the greater solubility of the latter have been usually employed.

Extraction with ether (Rawson, *l.c.*). From 0.1 to 0.25 gram of the sample is boiled with about 150 c.c. of ether for half an hour. When cold the solution is made up to 200 c.c. with ether, mixed with 10 c.c. of water and well shaken. The suspended particles of indigotin settle immediately and a clear solution of indirubin is obtained. A measured quantity of the solution is withdrawn, and compared in a colorimeter with a standard solution of indirubin.

Extraction with acetic acid (Koppeschaar, *l.c.*). The indigo is extracted with glacial acetic acid, and the solution, which contains a mixture of indirubin and indigo brown, is treated with caustic soda. The indirubin, which is thus precipitated, is collected, redissolved in acetic acid, and estimated by comparison with a standard solution of the pure colouring matter.

Extraction with acetone (Gardner and Denton, *J. Soc. Dyers*, 1901, 170). 0.2 gram of the indigo is digested for half an hour with 100 c.c. of boiling acetone. After cooling the solution is made up to 100 c.c. with acetone, and then to 200 c.c. with 10 p.c. salt solution, and well shaken. The precipitate of indigotin, indigo brown, and other impurities is removed by filtration, and the indirubin solution estimated colorimetrically with a standard solution of

indirubin prepared with acetone and salt solution in a similar way.

Extraction with pyridine. Bloxam and Perkin (Chem. Soc. Trans. 1900, 97, 1460) find, as the result of experiments on mixtures of indigotin and indirubin, that neither commercial ether nor acetone are reliable solvents for the complete extraction of indirubin, and that their action, especially in the former case, is chiefly due to the presence of alcohol. Whereas acetic acid is efficient in this respect, and Koppe-schaar's process gives approximately good results, pyridine is a much better solvent, and a method for the complete analysis of indigos containing indirubin based on the application of this liquid is described by these authors.

The indigo (0.25–1 gram) evenly incorporated with purified sand (20–30 grams) is introduced into a thin-walled glass tube, termed the 'container,' closed at one end by means of cotton cloth, on which has been placed a layer of asbestos and purified sand or of sand alone. Sufficient sand is then added to form a layer on the surface of the indigo mixture, which is then covered with asbestos, and the container is now placed in a Soxhlet tube and extracted with boiling pyridine. The extract is distilled down to a small bulk, the residue treated with boiling water and again distilled, and this operation is repeated until the last traces of pyridine have disappeared. The precipitate, which consists of indirubin together with a little indigotin and indigo brown, is collected, freed from the latter by means of dilute alkali, and the residue is sulphonated with 5 c.c. of sulphuric acid at 100°. The product is dissolved in water, filtered, and the amounts of indigotin and indirubin present ascertained by means of the Duboscq tintometer.

The residue in the container is percolated with water, followed with boiling dilute hydrochloric acid to remove indigo gluten, and is now introduced into a beaker and dried. The colouring matter present is sulphonated with 20 c.c. of sulphuric acid in the usual way, the product after dilution is filtered, and the solution of the indigotin sulphonic acid is estimated with permanganate, employing the directions given by Bloxam (*l.c.*). Analyses of mixtures of pure indigotin and indirubin, and also of commercial indigos, are given in the paper, and it is also pointed out that by this method an approximate estimation of the indigo brown present in the latter can be carried out.

THE ESTIMATION OF INDICAN IN THE LEAVES OF INDIGO PLANTS.

Although some indication of the indigo-yielding capacity of the plant can be obtained by ordinary steeping experiments, this method was found by Rawson (Cultivation and Manufacture of Indigo, *l.c.*) to possess several drawbacks, and numerous experiments were therefore carried out by him on the quantitative formation of indigo from the leaf extract by the simultaneous action of acids and oxidising agents. As regards the latter, ferric chloride, potassium chlorate, and hydrogen peroxide were tried, but persulphuric acid gave much the best results.

Persulphate method. 20 grams of leaves are extracted for 2 minutes with 250 c.c. of boiling water, the solution is strained through muslin, and the residues squeezed and washed with

boiling water. The solution is treated with 5 c.c. of 20 p.c. hydrochloric acid, and 40 c.c. of a 5 p.c. solution of ammonium persulphate. The persulphate is not added all at once; at first 2 c.c. are added, after half an hour 2 c.c. more, and again 2 c.c. after another half an hour. After 2 hours the remainder of the ammonium persulphate is added, and when the mixture has stood for a further period of an hour, the indigo is collected and estimated by permanganate in the usual manner. Bergtheil and Briggs (J. Soc. Chem. Ind. 1906, 734) point out, however, that this process of Rawson's requires modification, as the addition of the reagents at such a high temperature involves a loss of indigotin. The main features of a modification of the process devised by these latter authors are the addition of acid to the cooled extract, and a determination of the course of the reaction, after addition of small amounts of persulphate, by filtration of a portion of the mixture and the addition to the filtrate of a trace of the oxidising agent.

Orchardson, Wood, and Bloxam (*ibid.* 1907, 40; *cf.* also Bloxam and Leake, Research Work on Indigo, Dalsingh, Serai, 1905), who employ sulphuric acid and persulphate, arrived independently at the same conclusion. To 200 c.c. of the leaf extracts these authors add 100 c.c. of a mixture of equal parts of 2 p.c. ammonium persulphate, and 4 p.c. sulphuric acid, and the mixture is kept at 60° for one hour. A comparison of their methods with that of Bergtheil and Briggs indicated an identical result in each case, and an increase of 20–25 p.c. of pure colouring matter in comparison with that yielded by Rawson's original process.

The isatin method. Beyerinck (Proc. K. Akad. Wetensch. 1899, 120), in discussing indican, suggested the possibility that by warming its solution with isatin and acid a quantitative yield of indirubin might be produced. Orchardson, Wood, and Bloxam (*l.c.*) have employed this reaction for the estimation of the leaf, and have devised the following method for this purpose:—

250 c.c. of extract, equivalent to 5 grams of the leaf, is treated with 0.1 gram of isatin, and the mixture boiled for 5 minutes to expel air, carbon dioxide being passed through the flask. 20 c.c. of hydrochloric acid is then added by means of a tap funnel, and the whole kept boiling for 30 minutes. The precipitate is collected on a tared filter, washed with hot 1 p.c. soda to remove brown compounds, then with 4 p.c. acetic acid and dried. An aliquot portion of the crystalline product is sulphonated, and analysed by the titanous chloride method, adopting the modifications employed by Bloxam (*l.c.*). The indirubin thus obtained is usually almost pure (98.5 p.c.), so that for an approximate estimation the latter part of the process is unnecessary. Gaunt, Thomas, and Bloxam (*ibid.* 1907, 26, 56) have examined the process in greater detail, and point out that by its employment pure indican gives quantitative figures (*cf.* also Perkin and Bloxam, Chem. Soc. Trans. 1907, 91, 90). On the other hand, this method gives considerably higher figures, both with pure indican (15 p.c.) and the leaf extract (25 p.c.), than those which are obtained by the persulphate process (Orchardson, Wood, and Bloxam; and Gaunt, Thomas, and Bloxam, *l.c.*). The unsatisfactory figure_s

in the latter cases arise from a further oxidation of the indigo by the persulphate. That this isatin method does not appear to be affected by other plant constituents was shown by the successful estimation of indican, purposely added to an extract of the leaves of the *Tephrosia purpurea* (Pers.), a plant in which this glucoside is absent.

EFFICIENCY OF THE PROCESS.

The actual yield of indigotin from the plant during the manufacture is not discussed by Rawson (*l.c.*), but this author considers that if the suggestions enumerated in his report are adopted, there is little or no room for a remunerative alteration of the process. Bergtheil, on the other hand, considers that under the conditions he describes (1906, 12) the efficiency is represented by an 82 p.c. yield, or that if to this be added the 5 p.c. believed by Rawson to be retained by the extracted plant, 87 p.c. is thus accounted for. The quantity of indigo estimated refers to the precipitate present in the vat after oxidation, and from this must be, therefore, deducted the indigo (10–20 p.c.) lost by the 'running off' of the 'seeth' water, so that the actual yield of dry colouring matter may thus represent from 62 to 72 p.c. of the theoretical quantity. Recent experiments, however, indicate that by adding aluminoferric to the oxidation a more perfect settlement of the indigo is to be anticipated (*ibid.* 1909).

Bloxam (Dalsingh Serai Report, and J. Soc. Chem. Ind. 1906, 25, 735), who examined the daily output of indigo (as pressed cake) from the Pembrandah factory, found that the first cuttings of the plant (Moorhun mahai) represented an approximate value of 0.1495 p.c. of indigotin from the plant, whereas the second cuttings gave a value of but 0.1526. Assigning to the plant the low value of 0.3 p.c., a considerable and serious loss is thus apparent. Moreover, the estimation of the results given by the 'isatin' method of leaf estimation, and of the finished cake by the 'tetrasulphonate' process (*l.c.*), both of which have been standardised with extreme care, point to a loss during the manufacture much greater than has hitherto been acknowledged (Report to Government of India, 1908).

Apart from the retention of indoxyl by the residual plant in the steeping vat, and the mechanical carrying over of indigo by the 'seeth' water, the deficiency of colouring matter is chiefly to be attributed to the conversion of indoxyl into products other than indigotin. Rawson (*l.c.*) has pointed out that if the fermented liquid is allowed to stand before oxidation a considerably decreased yield of indigo is ultimately observed. Thus, on the large scale, by standing for 6 hours a loss of 16.1 p.c. was apparent. Perkin and Bloxam (*l.c.*) have found as a result of their experiments with pure indican, that this alteration or 'decay' of indoxyl takes place not only in this manner during the fermentation process, but they consider that the indoxyl from the moment of its production by the hydrolysis of indican until its final conversion into indigotin is continually suffering this alteration. This peculiar reaction is, according to these authors, considerably inhibited by the presence of acid.

COMMERCIAL NATURAL INDIGOS.

When natural indigo was at its zenith very numerous varieties of this dyestuff were placed on the market, but more recently, owing to its severe competition with the artificial colouring matter, many of these are now rarely met with. From Asia came the indigos of Bengal, Oudh, Madras, Java, Manilla; from Africa those of Egypt and Senegal; and from America those of Guatemala, Caracas, Mexico, Brazil, South Carolina, and the Antilles.

The best varieties are the Bengal, Java, and Guatemala, although in England the Bengal is now mainly employed. Java indigo, formerly largely esteemed for the manufacture of indigo extract, chiefly because of its general purity, at the present time appears to find its market chiefly in the East.

A good quality of natural indigo has a deep violet-blue colour; it acquires a coppery lustre when rubbed with the finger-nail; it is light, porous, adhering to the tongue, and can be readily broken and ground. Low qualities, which contain much extractive and mineral matter, are dull and greyish in appearance, heavy, tough, and hard, and do not become bronzy by rubbing with the finger-nail.

THE PROPERTIES AND SYNTHESSES OF INDIGOTIN.

The history of the determination of the constitution of indigotin and of the many syntheses which have been devised for its preparation, leading as they have done to the successful manufacture of the artificial product, constitutes without doubt one of the most interesting chapters in the annals of synthetical organic chemistry. This has been dealt with so fully in other manuals that a brief résumé of the main features of the subject will only be given here, and to avoid detail the main reactions are only expressed by constitutional formulæ.

Whereas early work had proved the benzenoid character of indigotin, by the production from it of aniline, anthranilic acid, picric acid and nitrosalicylic acid and isatin, the commencement of a systematic attack on the problem of its structure first dates from the work of Baeyer and Knop (Annalen, 1865, 141, 1).

That isatin $C_8H_5NO_2$ was simply related to indigotin, at that time expressed as C_8H_5NO , appeared probable, and with the hope of reconverting isatin into the latter, its behaviour on reduction was studied by these chemists. The results obtained, though unsuccessful at first in their immediate object, proved to be of considerable importance, and indeed form the basis from which much of our present knowledge of the subject has been derived.

When reduced isatin gives dioxindol (I.), oxindol (II.), and these substances are now known to respectively consist of the inner anhydrides of *o*-amino-phenylglycollic (III.) and *o*-amino-phenylacetic acids (IV.).—

- I. $C_6H_4 \begin{smallmatrix} \diagup CH \cdot OH \\ \diagdown NH \end{smallmatrix} > CO$
- II. $C_6H_4 \begin{smallmatrix} \diagup CH_2 \\ \diagdown NH \end{smallmatrix} > CO$
- III. $C_6H_4 \begin{smallmatrix} \diagup CH \cdot OH \cdot COOH \\ \diagdown NH_2 \end{smallmatrix}$
- IV. $C_6H_4 \begin{smallmatrix} \diagup CH_2 \cdot COOH \\ \diagdown NH_2 \end{smallmatrix}$

By further reduction indole is obtained, and to this, which was subsequently synthesised by Baeyer and Emmerling (Ber. 1869, 2, 680), by fusing *o*-nitro-cinnamic acid with potash and iron filings the formula

was assigned (Ber. 1870, 3, 517).

The same chemists again by heating isatin with phosphorus oxychloride and acetyl chloride under pressure obtained indigotin.

In 1879 Baeyer and Sinda (Ber. 1878, 11, 584) converted oxindole into isatin according to the following scheme:—

And such a series of reactions formed the copingstone of the first artificial synthesis of indigotin.

Isatin (I.) is the inner anhydride of *o*-amino-phenylglyoxylic acid (isatinic acid) (II.)

and such a constitution was predicted for it by Kekule in 1869 (Ber. 2, 748). Isatin, which possesses acid properties and is capable of forming metallic compounds, may exist as pointed out by Baeyer in two modifications. These are known as pseudo-isatin (lactamisatin) (I.) and isatin (lactimisatin) (II.):

A synthesis of isatin from *o*-nitro-benzoyl chloride was announced by Claisen and Shadwell in 1879 (Ber. 12, 350), and the reactions involved may be expressed by the following formulæ:—

The fact that indole can be prepared from *o*-nitro-cinnamic acid (*l.c.*) and that indole is closely related to indigotin, as indeed was shown by Nencki (Ber. 1875, 8, 727), who prepared indigotin by the action of ozonised air upon an aqueous suspension of indole, led Baeyer to experiment on the synthesis of indigo from this same acid (Ber. 1880, 13, 254). This object he eventually accomplished by the two methods given below:

o-nitro-cinnamic acid.

o-nitro-phenylchlor lactic acid.

o-nitro-phenylacrylic acid.

The former method is exceptionally interesting, in that it provided the basis for the first attempt to manufacture indigo on a commercial scale, and though this was hardly successful, the *o*-nitrophenylpropionic acid obtained by this method was of some service to the dyeing industry, as a means for obtaining indigo prints on calico.

Baeyer, again, in 1882 (Ber. 15, 50) announced a further synthesis employing *o*-nitro-phenylpropionic acid which was important in connection with the constitution of indigotin. When boiled with water *o*-nitro-phenylpropionic acid yields *o*-nitro-phenylacetylene

and from the copper compound of this (II.) by oxidation with ferri-cyanide, dinitro-diphenylacetylene (III.) is obtained:

With fuming sulphuric acid this forms diisatogen (IV.), a compound which on reduction gives indigotin (V.):

o-Nitro-phenylpropionic acid, on the other hand, by the action of sulphuric acid (Baeyer, Ber. 1881, 17, 1741) is transformed into its isomer isatogenic acid

Reducing agents convert this into ethyl indoxylate (I.) which by heating gives indoxyl (II.):

and this latter when oxidised readily passes into indigotin.

Indoxyl reacts with aldehydes and ketones to form the so-called indogenides. Thus with benzaldehyde the indogenide of benzaldehyde (benzylidene pseudo-indoxyl)

is produced (Baeyer, Ber. 16, 2188).

In a similar way indoxyl condenses with isatin to form indirubin

a colouring matter present in natural indigo (*l.c.*), and which is to be regarded as the indogenide of isatin.

Baeyer in 1883 reviewing the facts here enumerated was enabled to deduce the following constitution of indigotin:—

which is now accepted as correct.¹ The main arguments he employed in support of this formula are as follows:—

1. Indigotin contains two imido groups.

2. As a result of its formation from diphenyl-acetylene the carbon atoms of indigotin must be arranged in a similar manner to those present in this substance—

3. Indigotin is only formed from compounds in which the carbon atoms adjacent to the benzene ring are united with oxygen.

4. The properties of indigotin point to the fact that it is closely related to indirubin.

As a result indigotin is to be regarded as the α -indogenide of pseudo-isatin, indirubin itself being the β -indogenide. Owing, however, to the lack of activity of the α -oxygen atom in isatin, indigotin cannot, like indirubin, be directly prepared from indoxyl and isatin.

In 1882 (Ber. 15, 2856) Baeyer and Drewsen synthesised indigotin by the action of acetone on *o*-nitro-benzaldehyde in the presence of alkali:

o-nitro-phenyl-lacto-methyl-ketone.

When the acetone is replaced by acetaldehyde *o*-nitro-phenyl-lactic aldehyde (I.) is obtained, whereas with pyroracemic acid *o*-nitro-cinnamyl-formic acid (II.) is produced:

These compounds under the influence of alkali are transformed into indigotin.

¹ The question, as to how far Baeyer's formula for indigotin is in agreement with the chemical behaviour and physical properties of indigotin, and known facts with regard to the relation between colour and chemical constitution, has been discussed by Madelung (Zeitsch. angew. Chem. 1921, 34, 482 *et seq.*), who concluded that the facts are more correctly interpreted by the formula

The important point in this formula is that the carbonyl and imino-groups are at each end of a five-membered conjugated system, thus $\text{O} - \text{C} = \text{C} - \text{NH}$. Such an arrangement is to be found in other vat dyes of both the indigoid and anthracene series. Indigotin may thus be regarded as a derivative of the coloured and stable modification of dibenzoylethylene (J. Soc. Chem. Ind. 1921, 730 A).

Heumann in 1890 (Ber. 23, 2043) devised the synthesis of indigotin from phenylglycocol (phenylglycine). This on fusion with alkali is transformed into indoxyl which passes readily by oxidation into indigotin:

Pseudo-indoxyl.

The yield by this method is extremely small, but this can be improved by employing in the place of phenylglycine, phenylglycine *o*-carboxylic acid (Heumann, *ibid.* 3431):

This important reaction forms the basis of the first economical synthesis of indigo, the large scale manufacturing operations of which were perfected by the Badische Anilin- & Soda-Fabrik in 1897. For the preparation of phenylglycine *o*-carboxylic acid, naphthalene is employed as the starting-point, and the procedure involved will be evident from the following formula:—

Naphthalene. Phthalic anhydride. Phthalimide.

Anthranilic acid. Phenylglycine *o*-carboxylic acid.

Indoxyl carboxylic acid.

Pseudo-indoxyl.

Indigotin.

An improved method for the production of phenylglycine *o*-carboxylic acid from anthranilic acid has subsequently been adopted, the reagents employed being formaldehyde, bisulphite, and potassium cyanide:

Phenylglycine can be prepared directly from aniline by the same method:

More recently it has been recognised that the unsatisfactory yield of indigo by the original process of Heumann is due to the presence of water in the alkali fusion. By the replacement of the sodium hydroxide with sodium amide the destructive action of the water is avoided and the fusion can be successfully carried out at a lower temperature. The manufacture of indigo by such a method has been more recently adopted by the firm of Meister Lucius & Brüning at Höchst.

Interesting is also the fact that by treatment with fuming sulphuric acid phenylglycine is converted into indigotin disulphonic acid.

Of other indigo syntheses that of Sandmeyer, at one time employed on the manufacturing scale, is of importance. The starting-point in this method is thio-carbanilide

obtained by the action of carbon disulphide on aniline. This compound by the action of potassium cyanide and lead carbonate forms hydrocyano-carbodiphenylimide

which on treatment with ammonium sulphide gives the thio-amide

The latter by heating with sulphuric acid is converted into isatin anilide

and from this by reduction with sulphuretted hydrogen in acid solution thio-isatin is obtained:

By the action of dilute alkalis thio-isatin readily passes into indigotin.

A. G. P.

INDIGO, ARTIFICIAL, AND INDIGOID DYE STUFFS. The elucidation of the constitution of indigo, the result of the brilliant and indefatigable researches of A. von Baeyer (*v. supra*), has led to consequences of extraordinary importance. The methods discovered for the synthetical production of indigo offered at first little or no prospect of the artificial production of this most important dyestuff at prices which could compete with the natural product. But the patient and unceasing work carried on for that purpose in the laboratories of the Badische Anilin- & Soda-Fabrik in Ludwigshafen gradually surmounted the existing difficulties. Artificial indigo appeared in the market in the year 1897, and was soon acknowledged to be cheaper, purer, and more easy of application than the natural product. New synthetical manufacturing processes which have since then been introduced, combined with a strong competition between the various manufacturers, led to a steady reduction of prices, so that at present (1911) the synthetical dyestuff may be said to have driven out the natural one everywhere, even in countries in which the indigo plants are grown, such as India, the Dutch colonies, China, Japan, and South America. The history of artificial alizarin has been repeated in all its details in the progress of artificial indigo. But the consequences of this new triumph of synthetical chemistry have gone further, in that they have revolutionised the old-established European industries engaged in the production as well as the application of artificial dyestuffs.

The old, but difficult and uncertain process of vat-dyeing, necessary for the application of

indigo, has been carefully studied by the factories which had taken up the production of the synthetical product. Sodium hydrosulphite, long known to be the best means for reducing indigo in the vat, but unstable and difficult to prepare, has been brought into new forms in which it is quite stable and easily applied. Thus vat-dyeing has become an operation almost as easy and simple as any other process of dyeing, and the consumers of artificial colouring matters became anxious to be furnished with products similar to indigo in its mode of application and its fastness, but differing in shade. This wish has been satisfied almost simultaneously with its being felt. A large and constantly increasing number of new vat-dyes of every conceivable shade has been offered to the dyer and calico-printer, who is able to use them jointly or in mixtures with indigo, and thus to produce goods, the shades of which are quite as durable as the fibre itself. Some of the new vat-dyestuffs not only equal, but actually exceed indigo in fastness to light, air, and all the other influences which attack and destroy the colour of dyed fabrics. The introduction of the new synthetical vat-dyestuffs has inaugurated a new epoch of fast dyeing, the full importance of which will only be recognised in time to come.

The synthetical manufacture of new colouring matters similar to indigo in their properties was at first the natural consequence of the numerous new syntheses of indigo itself gradually discovered by various chemists, and many of which proved applicable to the production of compounds similar to indigo in their constitution, but differing from it in certain details of composition, and consequently also in their shades. Many of these substances could be made on a large scale, and offered to the consumer at moderate prices. They are now known under the name of 'Indigoids,' and the more important of them will be mentioned further on.

The investigation of indigo and the indigoid dyestuffs led, however, to another result of no small importance. The connection existing between the constitution and the properties of indigo as a dyestuff, so long a mystery, was at last recognised, and the atomic configuration was disclosed which causes a dyestuff to be applicable to vat-dyeing. The natural consequence of this discovery was the possibility of producing, by synthetical methods, a vast number of new vat-dyes, which in their constitution have no longer any similarity to indigo, and the majority of which has been derived from anthraquinone, the mother-substance of alizarin, which has thus assumed a new importance.

The description of these dyestuffs supplementing indigo in its applications, and now already exceeding the indigoids in number is dealt with elsewhere (*see* VAT-DYES, MODERN; INDANTHRENE).

The number of vat-dyes now already in practical use or in the stage of being introduced may be estimated at from 80 to 90, and is constantly increasing. Their discovery is due to the inventive genius of many chemists, amongst whom René Bohn may be considered as the pioneer.

A. Artificial indigo. The constitution of indigo is expressed by the formula :

Of the numerous methods which lead to the synthetical production of such a compound very few are applicable to its manufacture, and only the latter will be here mentioned.

The first attempt at a technical synthesis of indigo was made in 1880 by A. von Baeyer in his German patent 11857, which was sold to the Badische Anilin- & Soda-Fabrik and the Höchstler Farbwerke jointly. In this *orthoni-*trocinamic acid is used as a raw material, and transformed into indigo by three different methods. Of these only the one which passes through *orthonitrophenylpropionic* acid as an intermediate product found for a short time a limited and almost experimental application as a means of producing indigo on the fibre in calico-printing.

Another method (1882), which consists in adding caustic soda to a solution of *o*-nitrobenzaldehyde in acetone, when the methyl-*o*-nitrocinnamylketone formed as an intermediate product is immediately condensed into indigo, was also, in spite of its simplicity, unable to compete with the natural product.

In 1890 K. Heumann observed that phenylglycine and its *orthocarboxylic* acid are transformed into indoxyl and indoxylcarboxylic acid by being melted with caustic potash; the orange-coloured melts obtained yield indigo on being oxydised with air in aqueous solution. The patents obtained for these reactions (D. R. P. 54626 and numerous additions; also D. R. P. 56273 and additions) passed into the hands of the Badische Anilin- & Soda-Fabrik, but were not considered very promising by the majority of chemists. Yet they were destined to assume fundamental importance in the subsequent development of the indigo industry. It is true that a good many other inventions were necessary to raise them to that position.

Indoxyl and indoxylcarboxylic acid have the constitution expressed by the formulæ :

These formulæ represent the so-called 'pseudo'-forms, which are the first products of the reaction. Isolated indoxyl and indoxylcarboxylic acid are better represented by the tautomeric formulæ :

(Baeyer.)

On being treated with atmospheric oxygen in alkaline solution the one loses H_2 in the shape of water, the other H_2CO_2 in the shape of carbonic acid (H_2CO_3), and the so-called 'indigo bridge' $>C=C<$ is formed by two such indoxyl complexes being united by double valencies.

Phenylglycine and its *orthocarboxylic* acid are prepared by the action of monochloroacetic acid¹ upon aniline and anthranilic acid :

It was observed, that phenylglycine-*o*-carboxylic acid gave better yields of indigo than phenylglycine itself, which was, on the other hand, cheaper and more easily accessible. Later on it was found that both these glycines are capable of being transformed into indigo with very good yields if *every trace* of water is excluded from the alkaline melt. The glycine itself is in this respect more susceptible than its carboxyl derivative. Not only the water invariably retained by all the caustic alkalis hinders the reaction, but also the water formed in the reaction itself. One of the means of overcoming this difficulty consists in the addition of finely ground lime or baryta to the melt.

In taking up the manufacture of artificial indigo by Heumann's method in the beginning of the nineties the Badische Anilin- & Soda-Fabrik decided to use phenylglycine-*o*-carboxylic acid as a raw material. This decision was prompted not only by the better yields which were obtained from this product, but even more so by considerations of quite a different nature.

If it had been necessary to produce the anthranilic acid required for the manufacture of indigo by the oxidation of *o*-nitrotoluene and subsequent reduction of the *o*-nitrobenzoic acid thus obtained, all the toluene produced by the distillation of coal-tar would probably not have been sufficient for the purpose. There is, however, another way of producing anthranilic acid which consists in treating phthalimide with alkaline hypochlorites (Hoogewerff's and Van Dorp's process; D. R. P. 55988, Badische Anilin- & Soda-Fabrik, 1890). Phthalimide is easily obtained by treating phthalic anhydride with ammonia. Phthalic acid, on the other hand, is best prepared by the oxidation of naphthalene.

Thus it became possible, by using phenylglycine-*o*-carboxylic acid as a starting-point for the synthesis of indigo on a large scale, to base this manufacture on the use of naphthalene as its first raw material, a hydrocarbon which is contained in coal-tar in much larger quantities than any other of its constituents.

Even when these conclusions had been arrived at a great deal remained still to be done. It is now known that the Badische Anilin- & Soda-Fabrik had to invest about 1,000,000*l.* in

¹ Instead of this acid, prepared in the old manner from acetic acid and chlorine, ethyl monochloroacetate may be used, which can be obtained from acetylene by a simple process (D. R. P. 154857, 171900, 216940, 209268, 210502, and 216716, Imbert and Consortium für electrochemische Industrie, Nürnberg). See also Chemikerzeitung, 1911, p. 1053.

experiments and new plant before artificial indigo could enter the world's market as a rival to the natural product, and that the ultimate success obtained is mainly due to the courage, inventive genius and perseverance of Rudolf Knitsch, who superintended the whole development of this new industry. But it must also be said that the latter found its advent well prepared by the development which chemical industry as a whole had taken towards the end of the nineteenth century. One of the principal advantages produced by that development was the possibility of obtaining chlorine (which is required both for the chloroacetic and the anthranilic acid used in the indigo process) and caustic alkalis at extremely low prices owing to the introduction of the electrolytic decomposition of alkaline chlorides.

The oxidation of naphthalene into phthalic acid as practised in former times was cumbersome and difficult, and gave very poor yields. A new method was discovered for the purpose which consists in the oxidation of naphthalene polysulphonic acids by means of very strong pyrosulphuric acid. To obtain the latter a new process had to be worked out, now known to the world as the catalytic or contact process (*see SULPHURIC ACID*). A certain quantity of mercuric sulphate must be added in the oxidation of the naphthalene sulphonic acid; its action is purely catalytic and indefinite. The sulphur dioxide formed by the reduction of the pyrosulphuric acid returns continuously into the manufacture of the latter. The oxidation of the naphthalene thus practically takes place by means of atmospheric oxygen, and phthalic anhydride is exceedingly cheap if manufactured on a large scale by this process.

The employment of naphthalene as a raw material rendered it possible for artificial indigo to compete commercially with the natural product. But it was destined to meet itself with a very serious competition which arose from a discovery made by J. Pfleger of the Deutsche Gold- & Silber-Scheide-Anstalt in Frankfurt o/M., who observed that the destructive influence of water in the alkali melt of phenylglycine could be completely eliminated by using, not sodium hydroxide, but sodamide for effecting the transformation of the glycine into indoxyl. Sodium oxide and gaseous ammonia are instantly formed by the water produced in the condensation of the glycine according to the following reaction:—

The low melting-point of sodamide, which may be diluted with potassium or sodium cyanides (which also have a low melting-point) makes it possible to carry out the process at the low temperature of 180°–230° C., which favours the production of almost theoretical yields. Of course the process is also applicable

to the transformation of phenylglycine-*o*-carboxylic acid into indigo.

It is true, that sodamide can only be prepared by the action of ammonia upon metallic sodium; its price is therefore a high one; on the other hand, the advantages to be obtained by its use are very great and make it possible for this process to compete with the one adopted by the Badische Anilin- & Soda-Fabrik. It was therefore acquired by the Höchster Farbwerke, who are now producing a considerable share of the world's consumption of indigo.

The enormous increase of the world's production of benzene, caused by the general introduction of by-product coke-ovens, and the very low prices of aniline caused by this overproduction, has also favoured the success of Pfleger's invention.

Other synthetic methods have been devised which lead from aniline to indigo, such as Sandmeyer's and Blank's. But they cannot compete with the methods described, and have therefore never been carried out on more than an experimental scale. For details about these processes, some of which are exceedingly interesting from a theoretical point of view, the existing works on the chemistry of colouring-matters and more especially the patent literature should be consulted. Some of these processes may possibly assume considerable importance as a means of producing indigoid dyestuffs.

The complete insolubility of indigo in water and aqueous fluids makes it imperative that the dyestuff should be in a state of extremely fine subdivision, and thoroughly moistened before being introduced into the vat. For this reason the dyers used to grind the natural product with a certain proportion of water in the well-known indigo-mills. The unnecessary trouble caused by this preliminary treatment is spared by the form which has been given to the artificial dyestuff, which is generally sold in the shape of a paste containing 20 p.c. of pure indigotin. For export, where the reduction of carriage, and in many countries also the import duties, have to be considered, stronger pastes may be prepared or even the shape of a dry powder is chosen. Much trouble has been taken to reduce the indigo to the greatest possible fineness. All the modern means of powdering and grinding have been utilised, and also the method of precipitating indigo from its solution in sulphuric acid (in which it is contained as a sulphate) by the addition of water has been resorted to.

The world's annual consumption of indigo is estimated at more than 5,000,000 kilograms of the pure dyestuff. In 1900, that is three years after its introduction, the artificial product had secured about one-tenth of this quantity.

At present the shortage in the supply of indigo, which existed from the outbreak of war until the latter part of 1916, has stimulated in a very marked degree the cultivation of the indigo plant. In British India the total area under indigo in 1916–17 was 756,400 acres, being 114 p.c. in excess of the acreage of the preceding year. The corresponding increase in the total yield of indigo was 73 p.c. In 1915 the amount of natural indigo imported into the United Kingdom was 25,157 cwts., whereas in

ten months of 1916 the import was 28,245 cwts.; the latter is practically equal to the largest amount of synthetic indigo imported into the United Kingdom during the period 1911-15, the maximum being 28,302 cwts. for the year 1912. This increase in the cultivation of the indigo plant is being accompanied by a systematic and scientific inquiry into the agricultural conditions affecting the growth of the plant, and the formation of indican (G. T. Morgan, Reports of the Progress of Applied Chemistry, 1917, vol. ii. 120).

The valuable properties of indigo as a dye-stuff are a function of the peculiar atomic configuration which connects the two phenylene radicles. By the reduction in the vat 2 atoms of hydrogen are taken up by this complex and indigo white is formed, the exact constitution of which is doubtful. But it is now generally acknowledged, that in leuco-indigo hydroxyl groups have replaced the ketonic oxygens of indigo. These hydroxyl groups possess auxochromic characters, and are responsible for the absorption of the indigo white by the fibre. It follows that every other strongly coloured aromatic substance which contains at least two reducible carbonyl groups must be endowed with the properties of a vat-dye. This conclusion has been strictly confirmed by modern investigations and the whole modern development in the production of vat dyes has been built up on it.

B. Indigoids.—The congeners of indigo may be divided into two different classes. One of them contains the true derivatives of indigo, in which one or more of the 8 hydrogen atoms of the two phenylene groups are replaced by other substituents; the other embraces substances which are strictly analogous to indigo in their constitution but different from it in the construction of the complex connecting the two phenylene groups, which in this case as well as in that of indigo may have their hydrogen atoms replaced by other substituents. An enormous variety of new dyestuffs may thus be synthesised, all of which contain the characteristic chromophoric group of indigo:

(a) *Substitution products of indigo.*—These may be prepared by treating indigo with suitable reagents or by using suitably substituted ingredients in any of the synthetical methods for the production of indigo.

One group of these substitution products has been known for almost a century, and used formerly to be manufactured from natural indigo, viz. the sulphonic acids derived from it, commonly known under the name of *Indigo Carmine*. As these cannot be used as vat-dyes, they need only be mentioned here. They are now invariably prepared from artificial indigo and still used to a moderate extent in wool-dyeing, although they have been largely superseded by other soluble blues. Though derived from one of the fastest dyestuffs known, the indigosulphonic acids are, strangely enough, of an extremely fugitive nature.

The halogen derivatives of indigo are very numerous. As many as six atoms of chlorine or bromine may be introduced into the molecule

of indigo. The properties of the products thus obtained, their shade and fastness, vary strongly not only with the number of halogen atoms introduced, but also with their relative position in the molecule. Of the mono- and di-substituted indigos those which contain their halogen atoms in the *p*-position to the imino groups are very similar to indigo itself; those, on the other hand, in which the *p*-positions to the keto groups are taken up are no longer blue but reddish-violet in shade. The dibromo-indigo corresponding to this condition has been proved by Friedländer to be identical with the *purple of the ancients* (q.v.). In spite of the fame which this dyestuff once possessed, modern industry has not thought it sufficiently valuable to be introduced into commerce.

If more than two atoms of halogen be introduced into the molecule of indigo the dyestuffs obtained become more and more brilliant and greenish in shade. The first of these valuable dyestuffs introduced was tetrabromo-indigo; it was prepared by the Gesellschaft für Chemische Industrie in Basle and brought out as '*Ciba-blue*'—'*Ciba*' being the distinctive name adopted for all the vat-dyes of this factory. The corresponding tetrachlorinated derivative is '*Brilliant indigo 2B*' of the Badische Anilin- & Soda-Fabrik. Penta- and hexabromo-indigo are still more greenish, and are now being manufactured by various firms.

It is, of course, also possible to substitute some of the hydrogen of the indigo molecule by organic radicles. Thus we come to the homologues of indigo, several of which have been prepared. They are all very similar to indigo and offer no special interest. This is also the case with naphthylindigo, the shade of which is a dull green. Its dibromo derivative is much clearer in shade; it has been brought out as '*Ciba-Green G*' by the Basle firm already mentioned.

(b) *Indigoids, in which the central complex differs from that of indigo.*—In order to understand the nature of these compounds we must reconsider the constitution of indigo. It consists of two phenylene groups, linked together by the complex

Now in this complex the group —CO—C=C—CO—

is the indigo chromophore which connects all these dyes into one family and it cannot be touched or altered without destroying the whole character of the compound and its nature as a vat-dye. It follows, that the only changes possible in the central complex of the indigo molecule must be confined to the two imino groups, which may either be altered by their hydrogen being substituted, or by their being shifted into other positions, or by being entirely replaced by other atoms or atomic complexes. All these changes have been accomplished.

As an interesting example of the first of these alterations two dyestuffs may be mentioned: *Ciba-Yellow G* and *Ciba-Yellow GG*. They are prepared from indigo and tetrabromo-indigo by the substitution of two benzoyl groups for hydrogen in the imino groups. The constitution

of Ciba-Yellow G is thus expressed by the formula :

Benzoyl chloride does not act upon indigo under ordinary circumstances, but if a trace of metallic copper be added, its catalytic action causes the substitution of the hydrogen by the benzoyl group. This interesting manufacturing process has been invented by G. Engi.

If the imino groups are to be shifted or to be exchanged for other complexes, this cannot be done by starting from ready-formed indigo. The new dyestuff has to be built up synthetically. According to the synthetical methods adopted we can obtain indigoids of either symmetrical or asymmetrical constitution.

One of the first instances of such a synthesis was the process by which A. von Baeyer prepared Indirubin, the red dyestuff always contained in natural indigo and first observed by Berzelius. This substance is formed if alkaline solutions of indoxyl and isatin are mixed in the cold :

Indirubin is an asymmetrical indigoid in which both the chromophoric complex and the two imino groups are still preserved, but they have changed their relative position in the molecule. Indirubin is of no value as a dyestuff, but its tetrabromo derivative, prepared by G. Engi, is a useful violet and sold under the name *Ciba-Heliotrope*.

If the imino groups are to be exchanged for other divalent complexes, oxygen suggests itself as a suitable substituent. 'Oxygen indigo' has been prepared by Friedländer, but it proved to be a very poor dyestuff. But the same chemist observed in 1905, that sulphur, introduced into the position of the imino groups in indigo, has an excellent effect. A dyestuff of a deep bluish red shade and extraordinary intensity and fastness is formed, which is now known as *Thioindigo red* and manufactured by several firms. It was the first really applicable red indigoid and the process by which Friedländer first prepared it was protected by the German patent 194237 by Kalle & Co. who bought Friedländer's invention. This process is in all its stages strictly analogous to the synthesis of indigo from phenylglycine-*o*-carboxylic acid, but the nitrogen occurring in the latter is everywhere replaced by sulphur. Thus in the first stage anthranilic acid is replaced by thiosalicilic acid

Anthranilic acid.

Thiosalicilic acid.

The latter is treated with monochloroacetic acid, and thus transformed into

Phenylthioglycine-*o*-carboxylic acid.

which is, of course, quite analogous to

Phenylglycine-*o*-carboxylic acid.

By melting with caustic soda thioindoxyl-carboxylic acid

is formed, which, on being oxidised, yields

Thioindigo Red.

This process may be simplified by an invention described in the German patent 187586 of the Gesellschaft für Chemische Industrie in Basle, according to which the phenylthioglycine-*o*-carboxylic acid is simply boiled with nitrobenzene. Condensation and oxydation take place simultaneously and the red dyestuff is deposited in glistening crystals.

Another extremely simple method for the production of this dyestuff has been invented by E. Munch, and patented by the Badische Anilin- & Soda-Fabrik (French Pat. 385044; German Pat. application B. 47813). It consists in treating the salts of thiosalicilic acid with dichloroethylene. This compound, as a rule so reluctant to part with the chlorine it contains, in this case acts most readily, connecting two molecules of the acid, thus forming the whole chain of atoms required :

By treating this product with chlorosulphonic acid two molecules of water are eliminated, and the central complex of thioindigo red is formed. It suffices to add water which precipitates the dyestuff in a very pure condition.

Thioindigo red is extremely fast, but unfortunately its shade is not favourable to a very large consumption. An indigoid of a brilliant scarlet shade was required, and this was found in the asymmetrical representative of this group.

Thioindigo Scarlet.—This compound is analogous to indirubin in the same way in which thioindigo red is analogous to indigo, and it is also prepared by the method suggested by this analogy; thioindoxyl

(or, as it is often called, oxythionaphthene) is treated in an alkaline solution with isatin (*see*

equation for the formation of indirubin). It has consequently the constitution

and is not only asymmetrical, but also a mixed indigoid, containing both sulphur and the imino group.

Both thioindigo red and scarlet yield many new dyestuffs by the substitution of halogens and other substituents for hydrogen in their phenylene groups. They dye various shades of scarlets, bluish-reds, and reddish-violets, and several of them have come into use as serviceable vat-dyes.

INDIGO COPPER. Cupric sulphide v. COPPER.
INDIRUBIN v. INDIGO, NATURAL; INDIGO, ARTIFICIAL; INDIOXYL COMPOUNDS.

INDIUM. Symbol In. At.wt. 114.8 (Thiel and Mathers). Indium belongs to the aluminium group of the elements, and was discovered in Freiberg zinc blende by Reich and Richter in 1863 by means of spectrum analysis. It also occurs in small quantities in other zinc blendes, in siderites, and in various tungsten and manganese ores (Hartley and Ramage, Chem. Soc. Trans. 1897, 533). The metal can be obtained from the oxide by ignition in a current of hydrogen or by fusion with sodium (Winkler, J. pr. Chem. 1867, 102, 273). It can also be obtained pure electrolytically from the chloride, nitrate, or sulphate (Dennis and Geer, Ber. 1904, 37, 961; Thiel, *ibid.* 175; Mathers, J. Amer. Chem. Soc. 1908, 30, 209).

Indium is a white, readily malleable metal, softer than lead, and is not attacked by air at ordinary temperature. It can be obtained as regular octahedral crystals (Sachs, Zeitsch. Kryst. Min. 1903, 38, 495; Thiel, *l.c.*), having sp.gr. 7.277 at 20°, and m.p. 155°. It dissolves slowly in hydrochloric, sulphuric, and nitric acids, and when heated in the blowpipe gives a blue colour and an incrustation of the oxide. Indium forms a series of isomorphous mixtures with lead (Kurnakoff and Pushin, J. Russ. Phys. Chem. Soc. 1906, 38, 1146; Kurnakoff and Schemtschuschny, Zeitsch. anorg. Chem. 1909, 64, 149), and alloys with gold, tin, gallium, and sodium. It also combines with selenium and tellurium, forming black masses with a metallic lustre (Renz, Ber. 1904, 37, 2110). In its compounds, indium appears as mono-, di-, and tri-valent, but only the latter are stable in aqueous solution.

Indium oxide In_2O_3 is a pale yellow powder which, according to Renz (Ber. 1903, 36, 1847), is converted into two other amorphous modifications when strongly heated (Meyer, Zeitsch. anorg. Chem. 1905, 47, 281). At 1000° the oxide is partially converted into chlorine-green shining crystals (Renz, *l.c.* 2751; Thiel, *l.c.* and Ber. 1906, 48, 201). A lower oxide, In_2O_4 , also exists.

Indium hydroxide $\text{In}(\text{OH})_3$ resembles aluminium hydroxide, is converted into the oxide by heating, dissolves in potash but not in ammonia and readily forms colloidal solutions in the absence of electrolytes.

Indium hydroxide behaves towards bases as a weak acid; when carefully dried at 100°, the meta acid $\text{In}^{\cdot}\text{O}^{\cdot}\text{OH}$ is obtained, and the corre-

sponding magnesium indate $(\text{InO})_2\text{O}_2\text{Mg}\cdot 3\text{H}_2\text{O}$ is formed by boiling a solution of indium chloride with magnesium chloride (Renz, Ber. 1901, 34, 2763 and *l.c.*).

Halogen salts. Indium forms three chlorides, InCl , InCl_2 , InCl_3 ; the last forms a crystalline compound with pyridine

m.p. 253° (Dennis and Geer, *l.c.*; Chabrie and Rengade, Compt. rend. 1901, 132, 472). Three corresponding bromides (Thiel, Ber. 1904, 37, 175), and iodides, the trifluorides, $\text{InF}_3 \cdot 3\text{H}_2\text{O}$ and $\text{InF}_3 \cdot 9\text{H}_2\text{O}$ (Thiel, *l.c.*; Chabrie and Bouchonnet, Compt. rend. 1905, 140, 90), an oxychloride InOCl , an iodate, and a perchlorate (Schluederberg, J. Amer. Chem. Soc. 1908, 30, 211) are known.

Indium trisulphide In_2S_3 is a scarlet powder with metallic lustre which, when heated in hydrogen, forms the monosulphide In_2S , which is a brown powder. Both sulphides can be obtained in a crystalline form (Thiel, *l.c.*).

Basic indium sulphite $\text{In}_2(\text{SO}_3)_3 \cdot \text{In}_2\text{O}_3 \cdot 8\text{H}_2\text{O}$ is a crystalline powder which is obtained when an indium salt is boiled with acid sodium sulphite.

Indium also forms sulphates, nitrates, the molybdate $\text{In}_2(\text{MoO}_4)_3 \cdot 2\text{H}_2\text{O}$, the platino-cyanide $\text{In}_2[\text{Pt}(\text{CN})_4]_3$ (Renz, *l.c.*), a selenate (Schluederberg, *l.c.*), uranate, tungstate, and silico-tungstates (Wyruboff, Bull. Soc. Franç. Min. 1907, 30, 277).

Indium ammonium alum

(also with $8\text{H}_2\text{O}$) forms well-defined regular octahedra. Similar alums are formed with the sulphates of rubidium and caesium, but the analogous salts with potassium and sodium are not pure alums (Chabrie and Rengade, Compt. rend. 1900, 131, 1300; 1901, 132, 472). For its spark spectrum, v. Schulemann, Zeitsch. wiss. Photochem. 1911, 10, 263.

INDOFORM. Trade name for a mixture of salicylic acid, acetyl salicylic acid, moistened with formaldehyde solution, dried, and perfumed with methyl salicylate (v. SYNTHETIC DRUGS).

INDOINS (*Safranine azo-colouring matters*). The name Indoin blue R is given to the basic tannin colouring matter which is formed by combining the diazonium salt prepared from safranin and nitrous acid with β -naphthol. The compound is of some technical importance and dyes both unmordanted and tanned cotton fast indigo shades of blue.

The name indoin was also given by Baeyer (Ber. 1881, 14, 1741) to a blue compound resembling indigo, having the composition $\text{C}_{32}\text{H}_{20}\text{O}_5\text{N}_4$, prepared by the action of reducing agents, for example ferrous sulphate, on phenylpropionic acid dissolved in sulphuric acid.

J. F. T.

INDOLES. To this class belong a series of compounds, many members of which are of considerable importance from the bio-chemical standpoint.

They are derived from indole $\text{C}_8\text{H}_7\text{N}$, a compound which is related to indene in the manner shown by the following formulæ:—

The indole derivatives which occur in the organism are more or less closely related to tryptophan (*q.v.*), a substance which, according to the latest investigation is an indole-amino-propionic acid.

Indole was first obtained by Baeyer by distilling with zinc dust, either oxindole $C_6H_4<\text{CH}_2>\text{CO}$, or the product obtained by reducing indigo with tin and hydrochloric acid. It is also formed when *o*-nitrocinnamic acid is distilled with caustic potash and iron filings (Baeyer and Emmerling, Ber. 1869, 2, 680):

It can also be produced by passing the vapour of ethyl aniline and other alkyl anilines through a red-hot tube (Baeyer and Caro, Ber. 1877, 10, 692, 1262), but the best method of preparation is by the action of dichlorether

on aniline. A mixture of 50 grams of aniline with an equal bulk of water is heated, and to the boiling liquid 25 grams of dichlorether are gradually added. The boiling is continued for an hour, after which the water and excess of aniline are distilled off and the residue is heated for about 4 hours at 210°–230°. On distilling the product with steam, indole passes over and may be purified by conversion into the picrate. In this reaction, ethylidene di-aniline is first formed which, on heating to a higher temperature, breaks down into indole and aniline, thus:

Indole forms colourless, lustrous laminae, melts at 52° and boils with partial decomposition at 253°–254°. It is readily volatile in steam and is easily soluble in boiling water and in alcohol, ether, and benzene. When nitrous acid is added to an aqueous solution of indole, containing nitric acid, nitrosoindole nitrate is precipitated in the form of small red needles. An aqueous solution, or the vapour of indole, colours a pine chip moistened with hydrochloric acid and alcohol cherry-red, the colour afterwards changing to reddish-brown. Indole suspended in water and oxidised with ozone yields traces of indigo (Nencki, Ber. 1875, 8, 727). Indole is a weak base and forms, with concentrated hydrochloric acid, a sparingly soluble salt which is dissociated by boiling with water; the picrate is precipitated as dark red needles when a solution of indole in light petroleum is treated with picric acid.

Acetylindole $C_6H_5N(C_2H_5O)$, which is formed by the action of acetic anhydride, melts at 182°–183°. Indole accompanies scatole as a product of the putrefaction of albumen.

Derivatives of indole.—The homologues of indole are most readily obtained by heating the phenylhydrazones of ketones of the formula

or the phenyl hydrazones of the aldehydes of the formula $R'\cdot\text{CH}_2\cdot\text{CHO}$, with zinc chloride at

180°. The zinc chloride abstracts the elements of ammonia thus:

but the reaction is difficult to express by means of structural formulæ. Indole itself cannot be prepared by this reaction.

Indole-3-propionic acid (scatole-acetic acid)

This substance was isolated by Nencki (Monatsh. 1889, 10, 506) from the products of the putrefaction of albumen. It has been synthesised by Ellinger (Ber. 1905, 38, 2884) by the action of alcoholic sulphuric acid on the phenylhydrazone of γ-aldehydroisobutyric ester:

The acid crystallises from water as prisms which melt at 134°.

Indole-3-acetic acid (scatole carboxylic acid) $C_6H_4<\text{C}\cdot\text{CH}_2\cdot\text{COOH}>\text{CH}:\text{NH}$. This substance was

isolated by E. and H. Salkowski (Ber. 1880, 13, 2217) from the products of the putrefaction of albumen. It has been prepared by Ellinger (Ber. 1904, 37, 1803) by the action of alcoholic sulphuric acid on the phenyl hydrazone of methyl aldehydopropionate

The acid forms small leaflets from a benzene solution which melt at 165° and at the same time eliminate carbon dioxide, yielding scatole.

Scatole (3-methylindole) $C_6H_4<\text{C}\cdot\text{CH}_3>\text{CH}:\text{NH}$. This

substance occurs as a product of the putrefaction of albumen and is also formed by the fusion of protein substances with potash. It was first discovered in human faeces, of which it forms the chief volatile constituent (Brieger, Ber. 1879, 12, 1986); it also occurs in the wood of the *Celtis cinnamomea* (Linol.), Java (Dunstan, Chem. Soc. Proc. 46, 211). It is formed with indole when the product obtained by reducing indigo by means of stannous chloride is distilled with zinc dust (Baeyer, Ber. 1880, 13, 2339), and can be prepared by heating the phenylhydrazone of propionic aldehyde $\text{CH}_3\cdot\text{CH}_2\cdot\text{CH}:\text{N}_2\text{H}\cdot\text{C}_6\text{H}_5$, with an equal weight of zinc chloride and distilling the product with steam, or by heating

tetrahydroquinoline at 180° in presence of nickel.

Scatole forms lustrous laminæ, melts at 95° and boils at 265°-266° (corr.) under 755 mm. pressure. It usually has a strong fæcal smell, but when pure is stated to be without odour. It dissolves in concentrated hydrochloric acid, forming a violet solution.

1-Methylindole $C_6H_4 \begin{smallmatrix} \text{CH} \\ \text{---} \text{CH} \\ \text{N} \cdot \text{CH}_3 \end{smallmatrix}$ When the

methylphenylhydrazone of pyruvic acid is treated with hydrochloric acid it parts with the elements of ammonia, yielding 1-methylindolecarboxylic acid

On heating this compound to 205° it parts with carbon dioxide, forming 1-methylindole (E. Fischer and Hess, Ber. 1884, 17, 562). According to Carrasco and Padoa (Gazz. chim. ital. 1907, 37, 11, 49), this substance is also formed when dimethyl-*o*-toluidine is dropped into a tube filled with reduced nickel heated to 300°-330°.

1-methylindole is a yellow oil which boils at 240°-241° (corr.) under 720 mm. pressure. It has sp.gr. 1.0707 at 0° and does not solidify at -20°. It colours a pine chip moistened with hydrochloric acid reddish-violet.

2-Methylindole $C_6H_4 \begin{smallmatrix} \text{CH} \\ \text{---} \text{NH} \end{smallmatrix} \text{C} \cdot \text{CH}_3$. This

compound is formed from *o*-nitrophenylacetone by reduction with zinc-dust and ammonia, when the *o*-aminophenylacetone, which is first formed in the reaction, eliminates water and passes into 2-methyl indole (Baeyer and Jackson, Ber. 13, 187). It can also be formed by heating acetone phenylhydrazone with five times its weight of zinc chloride for half an hour on the water bath and then for a few minutes at 180° (E. Fischer, Annalen, 236, 126). 2-Methylindole forms needles or laminæ, melts at 59°-60° and boils at 272° (corr.) under 750 mm. pressure. It has a smell resembling that of indole, is sparingly soluble in boiling water, but readily dissolves in alcohol and in ether. It colours a pine chip moistened with hydrochloric acid red.

INDONES *v.* INDENE.

INDOPHENOLS *v.* INDAMINES AND INDO-PHENOLS.

INDOPYRIN *v.* SYNTHETIC DRUGS.

INDOXYL COMPOUNDS. When the hydrogen atom attached to one or other of the two carbon atoms present in the five-membered ring of indole is replaced by hydroxyl, two isomeric compounds may be formed which are represented by the two formulæ:

The presence of the complex $CH : C(OH)$ in these compounds causes them to react in two forms,

which may be represented by the further formulæ:

The two modifications are, in these cases, tautomeric, that is to say, only one form can be isolated (stable form), but this variety can, under certain conditions, yield derivatives of the other modification (labile form).

As shown by the above expressions, the enol (or hydroxy) form of indoxyl is the stable variety of indoxyl substance, whereas the stable form of oxindole (*q.v.*) is represented by the keto structure.

Indoxyl $C_6H_4 \begin{smallmatrix} \text{C} \cdot \text{OH} \\ \text{---} \text{NH} \end{smallmatrix} \text{CH}$. The isolation of

indoxyl was first effected in the following way. It had been noticed in the 18th century that under certain conditions human urine deposited a blue colouring matter, and the first recorded observation of this fact is ascribed by Thudichum (A Treatise on the Pathology of Urine, London, 1877) to Janus Planchus, in the year 1767. Schunck, in 1857, suggested that the chromogen of this blue colouring matter, which had previously been identified as indigo by Heller and Kletzenski, was the same as indican which he had isolated from woad. This was, however, disproved by Baumann (Pflüger's Archiv. 13, 291), who, with Brieger (Zeitsch. physikal. Chem. 1879, 111, 258), isolated the chromogen from urine and showed it to be indoxyl sulphuric acid.

Subsequently, Baumann and Tiemann (Ber. 1880, 13, 415) showed that, like phenol sulphuric acid, indoxyl sulphuric acid is decomposed by acids into sulphuric acid and a phenolic substance—indoxyl—and that this compound is quantitatively converted into indigo on oxidation. Subsequently, the synthesis of indoxyl was effected by Baeyer (Ber. 1881, 14, 1741) by the following series of reactions. Ethyl *o*-nitrophenyl propiolate is first converted by shaking with concentrated sulphuric acid into ethyl isato-genate (molecular rearrangement):

This substance on reduction yields ethyl indoxylate, which is then hydrolysed by caustic soda to the sodium salt of indoxyllic acid, and the free acid from this, when boiled with water, is transformed into carbon dioxide and indoxyl.

Indoxyl when pure forms pale yellow crystals which melt at 85°, but crystallisation cannot be effected in the presence of even slight traces of impurities. It dissolves in water, forming a fluorescent solution and is readily soluble in most organic solvents. It is very unstable and

readily oxidises when exposed to the air; the oxidation to indigo takes place rapidly in alkaline solution. It is volatile with steam and when treated with isatin in the presence of potassium carbonate is converted into indirubin, a reaction which may be represented by the following equation:

This substance occurs as the potassium salt (*indicaurin*) in human urine as well as in the urine of certain carnivora. It occurs to a considerable extent in the urine of a dog which has been fed on indole. It can be prepared synthetically from the potassium compound of indoxyl by treatment with potassium pyrosulphate (Baeyer, Ber. 1881, 14, 1744) and also by fusing phenylglycine-*o*-carboxylic acid and treating the melt with potassium pyrosulphate (Baumann and Thesen, Zeitsch. physiol. Chem. 1896, 23, 23). The free acid is unstable, but the potassium salt forms characteristic glistening leaflets from alcohol in which it is sparingly soluble.

when a solution of its sodium salt is acidified as a white crystalline precipitate which melts at 122°–123° with vigorous evolution of carbon dioxide. J. F. T.

INDULINES. A very numerous class of blue colouring matters belonging or closely related to the safranine group of colours. They are prepared by heating an aminoazo compound with an amine in the presence of the chloride of the latter. As might be expected, such a process allows of an almost infinite series of variations, and a great number of the colours have at various times been made and used.

By far the most important is also the earliest known; the details of its preparation, described below, are practically those of all the others.

250 kilos. of aniline are mixed with 24 kilos. of hydrochloric acid (35 p.c.) and a solution of 14.4 kilos. of sodium nitrite is run in. The mixture is allowed to remain for some time and then heated with steam to 40°–50° in order to complete the transformation of the diazoaminobenzene into aminoazobenzene. The product is then transferred to a cast-iron still capable of holding twice the volume of the melt made in it and provided with an agitator, swan neck, charging hold, thermometer tube, and discharge valve. 60 kilos. of aniline salt (aniline hydrochloride) are added and the mixture is heated gradually so that at the end of about 4 hours the temperature of the melt has reached 175°–180° (Schultz, Chemie des Steinkohlentheers, 3rd edit. 1901, ii. 343). The mass is now rendered alkaline with aqueous sodium hydroxide, the excess of aniline distilled off with a current of steam and the residue ground, washed, and dried. A medium shade, as produced by this

method, is known as **Induline 3 B spirit soluble**; the formula of its chief constituent is

Red shade indulines (*e.g.* **Fast blue R spirit soluble**) are formed by heating the mixture for a short time only and at a lower temperature (160°–170°). The bluer shades *e.g.* **Fast blue spirit soluble**; **Induline 6 B spirit soluble**) are obtained by more prolonged heating.

Much of the induline base prepared in this way is sulphonated, but some is dissolved in acetic, lactic acid, or ethyltartaric acid, forming blue to violet-blue liquors which are used for printing (**Printing blue**, **Acetian blue**, **Lævulin blue**, &c.). When spirit-soluble induline is sulphonated it is converted into a sulphonic acid, the sodium salt of which is soluble in water. In this form, various brands of water-soluble indulines are placed on the market under the names of **Induline** (various marks), and **Fast blues**. Another series of blue to blue-grey or black dyes, called **Nigrosines**, is produced by heating aniline and aniline hydrochloride with nitrobenzene or nitrophenol or both in the presence of iron borings. Typical processes are (a) *With nitrobenzene*: 175 parts of aniline, 175 parts of nitrobenzene, 200 parts of hydrochloric acid, and 16 parts of iron borings are heated for 8 hours at 160°–200° until a test portion can be drawn out into a thread. The melt is then run out into an iron tray and ground. (b) *With nitrophenol*: 100 parts of aniline hydrochloride, 50 parts of aniline, 50 parts of nitrophenol, and a little iron are heated for 10 hours to 180°. (c) *With nitrobenzene and nitrophenol*: 183 parts of aniline hydrochloride, 183 parts of nitrobenzene, 137 parts of aniline, 12 parts of crude nitrophenol, and 3 parts of iron borings are slowly heated for a day, the final temperature being about 215°. Towards the end the melt must be constantly tested and run out immediately it begins to thicken, otherwise it will set in the pan and then must be chipped out when cold. The spirit-soluble nigrosines produced, as described above, are sulphonated as in the case of the indulines, the products being known as **Nigrosine soluble**. J. C. C.

INDURITE *v.* **EXPLOSIVES**.

INFUSORIAL EARTH *v.* **KIESELGUHR**.

INGRAIN BROWN, -ORANGE, -RED, v.
AZO-COLOURING MATTERS.

INGRAIN COLOURS *v.* **PRIMULINE** AND ITS DERIVATIVES.

INK. A coloured fluid used in writing, printing, &c. (*Gr. engkauston—engkaio*, to burn in; *Lat. encustum*, the purple-red ink used only in the signature of the emperors; *It. inchiostro*; *Fr. encre*; *Dutch, inkt*.)

The writing ink of the ancients consisted of lampblack suspended in a solution of gum or glue. Such inks are still used to a limited extent in the East. Iron-gall inks have been known since the eleventh century. Such ink, as commonly prepared, is a ferroso-ferric gallate suspended in a solution of gum in water, obtained by adding a decoction of substances

containing tannin (usually nut-galls) to a solution of ferrous sulphate.

Galls contain gallotannic and gallic acids, which, with ferric salts, form a black precipitate; with ferrous salts the precipitate is white, but becomes black when oxidised by exposure to air. A proportion of gum is added for the purpose of suspending the precipitate equally throughout the solution and of preventing its deposit.

Although other materials may be used, it has been found that the best properties of writing ink—viz. fluidity, penetration, and permanence—are obtained by the use of the ingredients above-named. Such inks fall into two main classes.

Tannin-iron inks are manufactured from the above materials without additions and without previous treatment of the materials. The following typical recipes are taken from the sources named:—

No. 1 (Cooley's Cyclopædia).—Aleppo galls, well bruised, 4 oz.; clean soft water 1 quart; macerate in a clean corked bottle for 10 days or a fortnight, or even longer, with frequent agitation; then add 1½ oz. of gum arabic dissolved in a wineglassful of water and ½ oz. lump sugar; mix well, and afterwards further add of ferrous sulphate (green copperas), crushed small, 1½ oz.; agitate occasionally for 2 or 3 days, when the ink may be decanted for use, but is better if the whole is left to digest together for 2 or 3 weeks. *Product*: 1 quart of excellent ink, writing pale at first, but soon turning intensely black.

No. 2 (Ure).—12 lbs. of nut-galls, 5 lbs. ferrous sulphate, 5 lbs. Senegal gum, 12 gallons of water. The bruised nut-galls are to be put into a cylindrical copper of a depth equal to the diameter, and boiled during 3 hours with three-fourths of the above quantity of water, taking care to add fresh water to replace what is lost by evaporation. The decoction is to be emptied into a tub, allowed to settle, and, the clear liquid being drawn off, the lees are to be drained. The gum is to be dissolved in a small quantity of hot water, and the mucilage thus formed, being filtered, is added to the clear decoction. The ferrous sulphate must likewise be separately dissolved and well mixed with the above. The colour darkens by degrees in consequence of the peroxidation of the iron on exposing the ink to the action of the air. *Product*: 12 gallons.

No. 3 (Lehner, Ink Manufacture, p. 28).

Ingredients—

Galls	1200 parts by weight.
Ferrous sulphate	800 " "
Gum arabic	800 " "
Water	24,000 " "
Creosote	3 " "

Cover the galls with part of the water and dissolve the green vitriol, gum, and creosote separately in the rest of the water. Pour the solution on to the galls, cover up the vessel, and allow to stand for 3 weeks, stirring every day. The ink will then have reached its full blackness and can be bottled for use.

In other processes the galls are repeatedly extracted with boiling water and the extracts united and then mixed with the other constituents; or the tannin is extracted from the

bruised galls with ether and the dry product dissolved in water for ink-manufacture. The quality of the product seems to be equally good whatever method is used, provided the ratio between the weights of galls and of ferrous sulphate taken is always about 3:2. The addition of an antiseptic substance such as carbolic acid is to be recommended, as the ink is thus preserved indefinitely from the attacks of mould.

Gallic acid inks are also made from galls, ferrous sulphate, gum, and water, with the difference that the galls are first allowed to ferment, whereby the quercotannic acid is converted into gallic acid. The following is a typical recipe:—

Gall nuts	50 parts.
Ferrous sulphate	10 "
Gum	10 "
Water	2000 "
Carbolic acid	2 "

The crushed galls are soaked in the water and allowed to ferment. The mass may be inoculated with mould from a mouldy piece of bread or leather. After 8 to 10 days, boiling water is poured on to kill the ferment and the liquid drawn off and used to dissolve the other ingredients.

These inks have a fine blue-black colour and are not so susceptible to change as the tannin inks, but they have fallen into disfavour because they must be partially oxidised before use and thus take a considerable time to manufacture, and even then give a very pale impression on paper. Most of the inks now used contain a 'provisional colouring matter,' such as indigo and aniline blue, the function of which is to render the ink easily visible at the time of writing and until such time (7–10 days) as it shall be completely oxidised to black ferric gallate.

Logwood tannin inks have been in use since the eighteenth century, and are made by substituting logwood chips or logwood extract for part of the galls in a tannin-ink recipe, e.g.:

Galls	36 parts.
Ferrous sulphate	36 "
Logwood extract	9 "
Gum	36 "
Water	300 "
Vinegar	60 "

The method of preparation is similar to that already described.

Logwood gallic acid inks are similarly made but with preliminary fermentation of the galls. These inks have a deep blue-black colour and attack steel nibs less than pure tannin inks.

Alizarin inks are those inks which contain a provisional colouring matter other than logwood. They contain a sufficient proportion of acid (sulphuric or acetic) to keep the iron gallate or tannate in solution, and therefore may be prepared with much less gum than those previously described.

Of the colouring matters used the most important is indigo-carmin, which is prepared by dissolving dry indigo in fuming sulphuric acid, and after 24 hours neutralising with potassium carbonate. The free acid in the indigo solution may also be used to dissolve

metallic iron, thus dispensing with the use of green vitriol.

The following recipe is stated to produce an excellent ink:—

Galls	40 parts.
Iron solution	15 "
Indigo-carminé	5 "
Gum	10 "
Pyroligneous acid . . .	10 "
Water	100 "

The galls are powdered and soaked in the water and half the acid for a week. The iron solution is prepared from scrap iron and crude pyroligneous acid left together for a week. These solutions are then mixed and the other ingredients added.

At the present time, many other tannin-containing substances, besides galls, are used in the manufacture of inks. It has been shown that *sumach*, *valonia*, and *logwood* produce an ink which is indistinguishable from gall-inks (Hinrichsen and Kedesdy, J. Soc. Chem. Ind. 1909, 831), and good inks may be produced from tanner's barks (elm, oak, pine, poplar, willow, &c.), cutch, gum kino, fustic, elder-berries, the unripe fruit of the chestnut, walnut, &c.

In many cases other and cheaper synthetic dyes are substituted for the indigo-carminé, but this is not necessarily detrimental to the quality of the ink.

Mitchell (Analyst, 1908, 33, 81) has analysed a large number of English writing inks and finds that, although the composition of any one manufacturer's ink remains fairly constant over long periods, there are marked differences between the inks of different manufacturers. The total solid matter ranges from 1.89 to 7.94 p.c., the ash from 0.42 to 2.52 p.c., and the iron from 0.18 to 1.09 p.c.

The age of handwriting can be estimated up to the seventh or eighth day, when oxidation is complete, but after that no distinction can be made until the provisional colour begins to fade, usually after about a year.

The bleaching effect of air and light on ordinary writing ink is probably due to the action of hydrogen peroxide, and the permanence of writing by most modern writing inks may be tested by this reagent. Carbon inks are but little affected by hydrogen peroxide or other bleaching agents, and hence afford the most permanent writing (cf. Mitchell, Analyst, 1920, 247).

It is probable that in oxidised ink the iron exists as the tannate

described by Wittstein (J. 1848, 28, 221) and by Schiff (Annalen, 1875, 175, 176). (See also Ozorowitz, Chem. Zentr. 1908, 2, 1024.) As the oxidation proceeds the successive precipitates contain more iron, and eventually approximate in composition to

obtained by Pelouze by prolonged exposure of a solution of ferric sulphate and gallotannic acid to air (Mitchell, l.c.).

Runge prepared a writing fluid, under the

name of 'chrome ink,' which was cheap, intensely coloured, non-corrosive to steel pens, and extremely permanent on paper. The manner of preparing chrome ink is as follows: 1 part of potassium chromate (not dichromate) is added to 1000 parts of a saturated solution of logwood made by boiling 22 lbs. of logwood in a sufficient quantity of water to give 14 gallons of decoction. The potassium chromate is introduced gradually when the solution is cold, the mixture being constantly stirred during the addition. Gum is injurious to the mixture. It may be prepared more simply by dissolving 2000 parts of logwood extract in a solution of 10 parts of pure potassium chromate in 100,000 parts of water.

Prussian regulations for official tests of ink. According to the Prussian regulations of May 22, 1912, inks are classified into (1) 'documentary,' and (2) 'writing inks,' the latter being subdivided into (a) iron-gall inks, and (b) logwood and dyestuff inks. (1) A 'documentary ink' is defined as an iron-gall ink which gives dark writing after 8 days' exposure to light and air. It must contain at least 27 grams of anhydrous gallotannic and gallic acids, and 4 grams of iron (calculated upon the metal) per litre. On the other hand, the amount of iron must not exceed 6 grams, so that the ratio of gallotannic and gallic acid to iron must lie within the limits 4.5:1 and 6.75:1. The ink must not alter for at least 14 days in the ink-pot, and must flow readily from the pen. The writing done with it must not be sticky immediately after drying, and after 8 days it must remain deep black when washed with water and with alcohol (85 and 50 p.c.). (2) Iron-gall 'writing inks' must contain at least 18 grams of gallotannic and gallic acids, and at least 2.6, and not more than 4 grams of iron per litre (ratio 4.5:1 and 6.75:1). In other respects they must comply with the requirements of 'documentary inks.' Inks of Group (b) are not officially tested.

Analysis of inks.—The proportion of gallotannic and gallic acids is determined by shaking the sample with ethyl acetate and weighing the residue left on evaporating the extract. The residue is regarded as gallotannic and gallic acids when 0.1 gram thereof absorbs, in the presence of 2 grams of sodium bicarbonate, at least 0.5 gram of iodine. If less iodine is consumed, the ink is not up to the official requirements. Hinrichsen (Chem. Zeit. 1913, 36, 275) discusses the reasons for the changes from the official regulations of 1888, and gives the following details of the methods of applying the official tests:—

Determination of gallotannic and gallic acids.—10 c.c. of the ink are mixed with 10 c.c. of concentrated hydrochloric acid, and the mixture shaken with successive portions of 50 c.c. of ethyl acetate in Rothe's shaking apparatus, until the aqueous layer gives no reaction for gallotannic or gallic acids after treatment with sodium carbonate and addition of ferric chloride and ferrous sulphate. The ethyl acetate extract is shaken several times with semi-saturated potassium chloride solution (10 c.c. each time), to remove iron salts, and then evaporated *in vacuo*, and the residue is taken up with a little water, transferred to a weighed crucible, and dried at 105°–110° or, preferably, *in vacuo*

at about 60° until constant in weight. In determining the iodine absorption about 0.1 gram of the residue is mixed in a stoppered flask with 2 grams of sodium bicarbonate and 25–50 c.c. of a solution of iodine (about 50 grams per litre), and the flask closed and allowed to stand over night, after which the unabsorbed iodine is titrated with standard thiosulphate.

Iron.—10 c.c. of the ink are evaporated to dryness, and the residue ignited until free from carbon and then heated with 1–2 c.c. of hydrochloric acid (sp.gr. 1.124) until dissolved. The solution is treated with 1–2 c.c. of chlorine water and evaporated to dryness, the residue treated with 0.5 c.c. of strong hydrochloric acid to dissolve basic iron salts, and the solution cooled and diluted with 20 c.c. of water. About 1 gram of potassium iodide is then added, and the separated iodine titrated with *N*/10-thiosulphate solution, the liquid being meanwhile rapidly warmed to 55° to promote the separation of iodine.

Testing the writing.—Pieces of standard paper are stretched in a frame inclined at an angle of 45°, and a definite amount of ink made to flow down them from a pipette fixed in a special position with regard to the paper. At the same time a parallel test is made upon the same papers with Schlüttig and Neumann's standard iron-gall ink containing 23.4 grams of gallotannic acid, 7.7 grams of crystalline gallic acid, 30.0 grams of ferrous sulphate, 10.0 grams of gum arabic, 2.5 grams of hydrochloric acid, and 1.0 gram of phenol per litre. This ink is allowed to stand for at least 4 days at 10°–15°, and decanted from any deposit. For comparison in the test it is coloured with a suitable dyestuff to match the ink under examination. The paper with the colour strips of the two inks upon it is exposed to the air for 8 days in diffused daylight, and is then cut horizontally into strips which are immersed in water, 50 p.c. alcohol and 80 p.c. alcohol respectively. No perceptible bleaching of the ink should take place (*J. Soc. Chem. Ind.* 1913, 32, 281).

For the American standards for iron writing, duplicating, and cancelling inks, their composition, manufacture, and methods of testing, see Circular No. 95, U.S.A. Bureau of Standards, *Abstr. in Analyst*, 1921, 61.

Ink powders are very little used but can easily be made either by cautiously evaporating an ordinary ink to dryness and powdering the residue, or by mixing the carefully dried and powdered ingredients in the proportions used for the fluid ink.

Indelible or safety inks. Compositions passing under these names consist of finely divided carbonaceous substances, such as Indian ink or lampblack, held in suspension in a glutinous or resinous liquor. They are devised so as to resist the action of strong acid or alkaline solutions. An ink having these properties may be made of Indian ink rubbed into ordinary writing ink.

A suspension of lampblack in sodium silicate solution makes an excellent safety ink, but has the disadvantage that it must be kept in airtight bottles.

Vanadium ink is prepared very simply by adding a small proportion of ammonium vanadate to a filtered decoction of galls. It is a deep

black ink, which flows freely from the pen and cannot be removed without destruction of the paper.

Copying/ink. Any ink which retains enough solubility to give an impression from the written sheet on to a sheet of damp paper may be used for copying. Runge's chrome ink described above may be so used. Other logwood inks and ferrous gallate inks being soluble only until oxidised by exposure to the air, require the addition of some substance which forms a glaze, arresting the action of the air. This glaze must be soluble when brought into contact with the damped copying paper; the pigment is then freed so as to produce the impression. Such substances are gum arabic, gum Senegal, dextrin, and glycerol. Where several copies are required, the ink employed should contain more staining matter in proportion.

Hektograph inks are used to give a large number of copies, and must therefore contain a powerful colouring matter. The original is written on ordinary paper with the ink and is laid face-down on a sheet of a composition of glue and glycerol (about 1:5) until the ink has been absorbed into the surface of the composition.

By applying sheets of paper with slight pressure, 60 to 100 copies can then be obtained.

A typical ink contains: water-soluble blue 10 parts, glycerol 10 parts, and water 50–100 parts.

Dyes not easily soluble in water or glycerol are first dissolved in alcohol and then mixed with the other ingredients. Thus a red hektograph ink may contain: magenta 20, alcohol 20, acetic acid 5, gum 20, and water 40; or magenta 10, alcohol 10, glycerol 10, and water 50.

Red ink was formerly prepared from Brazil wood or extract of Brazil wood, with the addition of alum or stannous chloride: *e.g.*

(1) Brazil wood, 280 parts; tin-salt, 10 parts; gum, 20 parts; boiled with 3500 parts of water and evaporated down until the proper depth of colour is attained.

(2) Extract of Brazil wood, 15 parts; alum, 3 parts; tin-salt, 2 parts; tartaric acid, 2 parts; water, 120 parts.

Cochineal or carmine inks are prepared by boiling cochineal in water, precipitating the colour with alum and tin salt and dissolving this carmine in the requisite amount of strong ammonia. Another method is to dissolve 2 parts of ammonium carbonate in 200 parts of water and macerate for 3–4 hours with 40 parts of cochineal and 2 parts of alum.

Most of the red inks now used are solutions of magenta or eosin in water, together with a little gum. Glycerol also is added if the ink is to be used for copying.

Blue ink. Prussian blue is the colouring matter commonly employed. The pigment is placed in an earthen vessel, and either strong hydrochloric acid, nitric acid, or sulphuric acid is added to it. After the mixture has remained 2 or 3 days, much water is added, and after settling, the supernatant liquor is drawn off from the sediment. This sediment is well washed until all traces of iron and free acid disappear from the water, after which it is dried and mixed with oxalic acid in the proportion of 8 parts of Prussian blue to 1 part of acid. The pigment

being now soluble in water, so much of this latter is added as will bring it to the required intensity.

An excellent blue ink can be made by dissolving 10 parts of indigo-carmin and 5 parts of gum in 50-100 parts of water. Solutions of blue aniline dyes may be used, but are easily effaced by bleaching agents and fade on exposure to light.

Inks of other colours can be made from decoctions of dyestuffs mixed with alum (used as a mordant) and gum Senegal or gum arabic; as, e.g., brown ink from catechu or logwood, to which a little potassium dichromate is added; violet and purple inks from logwood with a small admixture of chloride of tin or of alum; yellow ink from gamboge, &c., &c. Aniline colours also offer a selection of tints for this purpose.

Gold and silver inks are prepared from gold and silver, or from cheaper substitutes such as bronze powder and Dutch leaf. The leaf metal mixed with honey is carefully ground down to the finest possible condition; it is then well washed and dried. A medium is furnished by a preparation consisting of 1 part of pure gum arabic and 1 part of soluble potash glass in 4 parts of distilled water. As a rule, 1 part of the powder is sufficient for 3 or 4 parts of the medium.

Imitation silver ink is best made by rubbing up aluminium foil or powder with gum.

Sympathetic, Diplomatic, or Secret inks. These preparations are devised to trace words or figures which are invisible when written but which become visible when subjected to heat or appropriate chemical reagents. Examples:—A weak infusion of galls is colourless on paper, but becomes black when moistened with a solution of copperas; and if a weak solution of copperas be used, the writing will be invisible, till the paper is moistened with a weak solution of galls. Equal parts of copper sulphate and sal ammoniac dissolved in water form a colourless ink, the writing of which turns yellow on the application of heat. Weak solutions of silver nitrate or of auric chloride when exposed to the sunlight become dark brown and purple respectively. Solutions of cobalt chloride or nitrate give tracings which become green or blue when heated and disappear again as the paper cools.

Ink for indiarubber stamps. The following preparation produces ink adapted for this purpose. It does not easily dry upon the pad, and is readily taken up by the paper:—Aniline colour in solid form (blue, red, &c.), 16 parts; boiling distilled water, 80 parts; glycerol, 7 parts. The colour is dissolved in the water, and the other ingredients are added whilst agitating. The 'carbon papers' used for giving two or more copies of written or typed matter are coated on one side with a mixture of yellow wax and tallow containing a suitable pigment such as lampblack or Prussian blue, or some aniline colour.

Ticket-writer's ink is made of good black ink, with liquid gum added to produce a gloss.

Ink for writing on glass is a solution of gum arabic in strong hydrofluoric acid coloured with some matter which can withstand the acid: cudbear is used for this purpose.

For enamelled cards ordinary printing ink is

mixed with a few drops of equal parts of copal varnish and mastic varnish.

Lithographic ink ought to conform to the following requirements. It should be flowing on the pen, not spreading on the stone; capable of forming delicate tracings, and very black to show its delineations. The most essential quality of the ink is to sink well into the stone, so as to reproduce the most delicate outlines of the drawing and to afford a great many impressions. It must therefore be able to resist the acid with which the stone is moistened in the preparation without letting any of its greasy matter escape.

Lithographic ink may be prepared as follows:—Mastic (in tears) 8 oz., shellac 12 oz., Venice turpentine, 1 oz.: melt together; add of wax 1 lb., tallow 6 oz.; when dissolved, add further of hard tallow soap in shavings 6 oz.; and when the whole is perfectly incorporated, add of lampblack 4 oz.; lastly, mix well, cut in moulds, and when cold cut it into square pieces.

Another recipe is as follows:—Melt together wax, 18 parts; soap, 18 parts; shellac, 14 parts; resin, 6 parts; and tallow, 10 parts. Then stir in 2 parts of india-rubber dissolved in 5 parts of oil of turpentine, and 6 parts of lampblack. The whole is heated till the smell of turpentine has nearly disappeared and is then cast into sticks.

Autography is the operation by which a writing or a drawing is transferred from paper to stone. For autographic ink:—White wax 8 oz., white soap 2 oz. to 3 oz.; melt, and add lampblack 1 oz.; mix well, heat strongly, and add shellac 2 oz.; again heat strongly and stir well together. On the mixture cooling pour it out as before. With this ink lines may be drawn of the finest and fullest class, without danger of its spreading; and the copy may be kept for years before being transferred. These inks are rubbed down with a little water in the same way as Indian ink.

Printing ink. Ink prepared for use with type, copper-plates, &c., is composed of a vehicle and pigment. The chief properties required in a good printing ink are:—

- (1) A perfectly uniform syrupy consistency.
- (2) Must be easily transferred from the ink-rollers to the type, and from the type to the paper.
- (3) Must not smudge types, and must be easily washed off them with printer's lye.
- (4) The ink must not dry so quickly as to set on types or rollers, but must not dry so slowly on the paper as to hinder folding, &c., of sheets.
- (5) When dry, the ink must not set off from the paper on to anything with which it comes in contact.
- (6) The printed characters should not show a greasy margin.
- (7) The ink should not have a strong smell.

The ink which most nearly fulfils all these requirements is composed of the finest quality of lampblack incorporated with a pure linseed oil varnish. The demand for cheap inks for the printing of newspapers and cheap books has been met by using cheaper qualities of lampblack and substituting for the varnish various compositions of oils and resins with soap, which

may or may not contain a proportion of linseed oil.

The linseed oil varnish used for good ink was formerly prepared by heating a quantity of linseed oil in a boiler until the vapour evolved could be ignited. A light was then applied and the whole allowed to burn for about half an hour, until a trial showed that the oil was of the right consistency. The practice of burning the oil gave a dark-coloured product and has now been discontinued.

The present practice is to heat the oil to about 330° to 400°, taking every precaution to avoid its ignition. The boiler is provided with a closely fitting lid or, better, with a cover of wire-gauze, which extinguishes a flame while allowing the vapours to escape.

Provision is made for lifting the boiler from the fire or withdrawing the fire from the boiler, or, in some cases, for running off the oil into a cold vessel. A gutter round the furnace above the fire-door prevents any chance of the oil reaching the fire, even should it boil over the top of the pot. In some modern plant the oil is heated by means of superheated steam. A varnish so prepared is insoluble in water or alcohol, but it mingles readily enough with fresh oil and unites with mucilages into a mass diffusible in water in an emulsive form. The oil loses from one-tenth to one-eighth of its weight by boiling into the thick varnish (Watts).

An average letterpress ink may be made by reheating a varnish produced as above and adding for each gallon of the original oil 4 lbs. resin and 1 lb. brown soap in slices. This is then mixed with the requisite quantity of pigment—rather less than $\frac{1}{3}$ of its weight in the case of lampblack—and the whole thoroughly ground and incorporated in a suitable machine, usually between rollers of polished granite or steel, as in Lehmann's apparatus. The presence of soap in the ink causes it to 'lift' well, i.e. to be completely transferred from the type to the paper. The following recipes represent vehicles of a cheaper class:—

Linseed oil and resin vehicle.—Resin 50, boiled linseed oil 100, resin soap 10, partly boiled oil, 6 parts by weight.

Resin oil vehicle.—Resin oil 50, resin 50, boiled linseed oil 50, resin soap 5, thin boiled linseed oil 6 parts.

Cheap mineral oil vehicle.—Resin is dissolved in about an equal weight of heated mineral oil (petroleum) of sp.gr. 0.880–0.920 (Wass, Fr. Pat. 322298, 1908).

Composition vehicles.—5 kilos. Venice turpentine, 15 kilos. castor oil, and 1 kilo. white wax, mixed at 100° (Knecht). 9 kilos. thick turpentine, 10 kilos. soft soap, and 4 kilos. oleine, mixed hot (Rösl).

The lampblack used is of various qualities according to the price of the ink. The proportion used is just sufficient to give a full black impression, and this is less with the better qualities of lampblack. The ink for rotary machines contains about 28 p.c. of lampblack, that for high-speed newspaper printing about 24 p.c., that for book-printing about 21 p.c., and that for illustration work about 19 p.c. with 2 p.c. of Prussian blue and 1 p.c. of indigo.

Brackenbusch's inks consist of 25 parts paraffin oil, 45 parts of fine colophony, and

15 parts of lampblack. The amount of colophony is reduced in soft inks for high-speed work.

It has been proposed to use oxides of iron or manganese as black pigments for printing inks, in which case the paper could be bleached and subsequently re-made into white paper. This cannot be done with the lamp-black inks now used (see e.g. Fireman, U.S. Pat. 802928, 1905).

It is said that so marvellously thin is the layer of ink on small type that one pound weight even of cheap newspaper ink will cover no less than 7000 square feet of type matter.

Coloured printing inks. These inks are made from the varnishes above described by the addition of dry colours, taking great care that the colours are thoroughly well ground and assimilated with the varnish, since lumps of any kind not only clog the type but alter the tint. Some tints which are exceedingly light will require an admixture of white powder to give the necessary body to the ink.

The following pigments are eligible for incorporation in printing inks:—

White.—Heavy spar (barium sulphate) and zinc white.

Red.—Orange lead, vermillion, burnt sienna, Venetian red, Indian red, lake vermillion, orange mineral, rose pink, and rose lead.

Yellow.—Yellow ochre, gamboge, and lead chromate.

Blue.—Cobalt, Prussian blue, indigo, Antwerp blue, Chinese blue, French ultramarine, and German ultramarine.

Green.—Usually mixtures of yellow and blue, but sometimes chrome green, cobalt green, emerald green, or *terre verte*.

Purple.—A mixture of those used for red and blue.

Deep brown.—Burnt umber with a little scarlet lake.

Pale brown.—Burnt sienna: a rich shade is obtained by using a little scarlet lake.

Lilac.—Cobalt blue with a little carmine added.

Pale lilac.—Carmine with a little cobalt blue.

Amber.—Pale chrome with a little carmine.

Pink.—Carmine or crimson lake.

Shades and tints.—A bright red is best got from pale vermillion with a little carmine added; dark vermillion when mixed with the varnish produces a dull colour. Orange red and vermillion ground together also produce a very bright tint, and one that is more permanent than an entire vermillion colour. Cheaper substitutes are orange mineral, rose pink, and red lead. Lead chromate makes the brightest colour. For dull yellow, use yellow ochre. Indigo is excessively dark, and requires a good deal of trouble to lighten it. It makes a fine showy colour when brightness is not required. Prussian blue is useful, but it dries very quickly, hence the roller must be frequently cleaned. The objection to Prussian, Antwerp, and Chinese blues, is that they are hard to grind and likely to turn greenish with the varnish when used thin. For green any of the yellows and blues may be mixed. The varnish itself having a yellow tinge will produce a decidedly greenish tint with a small quantity of Antwerp blue. Emerald

green is got by mixing pale chrome with a little Chinese blue, and then adding the mixture to the varnish until the tint is satisfactory.

In using painter's colours it is advisable to avoid as much as possible the heavy ones. Some colours require less oil in the varnish than others. For the comparative permanence of colouring matters, *v.* **PIGMENTS**. For methods of analysis, see Tuttle and Smith, (*J. Ind. Eng. Chem.* 1914, 6, 659).

A bronze of changeable hue may be given to inks with the following mixture (Southward):—Gum shellac $1\frac{1}{2}$ lbs. dissolved in one gallon of 95 p.c. alcohol or Cologne spirits for 24 hours. Then add 14 oz. aniline red. Let the mixture stand for a few hours longer, when it will be ready for use. When added to good blue, black, or other dark ink, it gives a rich hue to it. The quantity must be carefully apportioned.

Bronzing. The production of printed matter having the colour and lustre of gold or silver, is carried out by printing with a varnish which remains 'tacky' for a time, and then dusting over the whole surface with bronze powder or aluminium powder or similar substances. The powder adheres only to the varnish and thus produces the desired effect.

Such a varnish may be produced by melting into a good linseed oil varnish sufficient beeswax to give it the consistency of lard or tallow. (See *Ure's Dict. of Arts, Manufactures, &c.*; *Cooley's Cyclop. of Practical Receipts*; *Lehner's Ink Manufacture*; *Southward's Practical Printing*; *Noble's Principles and Practice of Colour Printing*; *L. E. Andés' Oil Colours and Printer's Inks*; and *Seymour's Modern Printing Inks*.)

INKANI FAT. A fat obtained from the seeds of the East African tallow tree, *Steatodendron Stuhlmannii* (Engl.).

INOSIC ACID, INOSINE *v.* CARNINE.

INOSITOL (*Inosite*). A number of natural substances having the composition of cyclic polyalcohols, *e.g.* hexahydroxycyclohexanes $C_6H_8(OH)_6$, are often classed with the carbohydrates since they have the same formula, taste sweet, occur along with them in nature, and possibly have been formed from them by the junction at the ends of the six carbon chain, although such transformation has never been realised in the laboratory. Typical of the class is inositol. No less than nine stereoisomeric inositols:

are possible, of which seven are inactive and two optically active and enantiomorphous. Four of these have been described, *viz.* optically active *d*- and *l*-inositol, and inactive inositol, and cocsitol or scyllitol. Similar pentahydroxycyclohexanes are likewise found in plants. These are *d*- and *l*-quercitol.

The formation of furfural on distillation of *meso*inositol with phosphoric anhydride in a copper vessel (Neuberg, *Biochem. Zeitsch.* 1908, 9, 551) is the only instance in which a complex substance has been obtained common to both the carbohydrates and inositol.

d-Inositol (*matezodambose*) is prepared by demethylation (boiling with concentrated hydriodic acid) of the naturally occurring methyl ether, pinitol. It crystallises in anhydrous

prisms, m.p. 247° – 248° , $[a]_D +65^{\circ}$ without mutarotation and forms hexacetyl and hexabenzoyl derivatives.

The methyl ether, **Pinitol** (*pinite*) $C_7H_{14}O_6$, also called *matezite* and *sennite* was discovered in the resin of the Californian *Pinus lambertiana* (Doug.) (Berthelot, *Compt. rend.* 1856, 41, 392). It occurs in the residues of the manufacture of coniferin, in senna leaves, and in the liana of Madagascar rubber (*mateza roritina*). It crystallises in colourless rhombs, m.p. 186° $[a]_D +65.5^{\circ}$. The structure of pinitol was established by Maquenne (*Compt. rend.* 1889, 109, 812).

l-Inositol was obtained by Tanret (*Compt. rend.* 1889, 109, 908) by demethylation of quebrachitol. It crystallises in needles; m.p. 247° $[a]_D -65^{\circ}$.

The methyl ether, **Quebrachitol** (quebrachite) occurs in quebracho bark. It crystallises in prisms; m.p. 186° $[a]_D -80^{\circ}$.

r-Inositol, obtained by mixing the *d*- and *l*-isomerides in equal quantities, is optically inactive, m.p. 253° . Tanret (*Compt. rend.* 1907, 145, 1196) has obtained both racemic- and *meso*-inositol from fresh ripe berries of mistletoe.

Meso- or *i*-inositol (*dambose*, *anite*) is widely distributed in both plants and animals. It occurs in muscles, in the heart, lungs, and liver, in beef and horseflesh, and in the urine in cases of Bright's disease. In plants, it is found in beans, peas, &c., in the leaves of asparagus, oak, ash, walnut, &c., in all parts of the grape vine and hence in wines and in fungi. The chief source is the leaves of the walnut tree (Tanret and Villiers, *Compt. rend.* 1877, 84, 393; 1878, 86, 486), but very much larger quantities are afforded by mistletoe. It may also be prepared from cochineal mother liquors. It crystallises in bunches of needles, m.p. 225° , and does not reduce Barreswil's solution. Yeast is without action, but certain fungi decompose it. The hexacetate forms monoclinic plates, m.p. 212° . Hugo Müller (*Chem. Soc. Trans.* 1907, 91, 1780) has described and measured the crystals of the monobromopentacetate, minute crystals, m.p. 240° , the dibromotetracetate, broad transparent prisms, m.p. 140° , and scaly crystals, m.p. 235° ; also of inositoldibromohydrin, m.p. 210° .

When inositol is evaporated with nitric acid almost to dryness and then again carefully evaporated with ammoniacal calcium chloride, a rose-red coloration is obtained which enables 0.0005 gram to be detected with certainty (Scherer, *Annalen*, 1850, 73, 322). With ammoniacal strontium acetate, a still more delicate violet coloration is obtained.

The monomethyl ether, **Bornesitol**, occurs in Borneo rubber; it forms rhombic prisms, m.p. 199° – 203° .

The dimethyl ether, **Dambonitol**, is found in Gabon rubber; it crystallises in hexagonal prisms, m.p. 195° .

Phytin, which is present in many plant seeds, *e.g.* cotton seed meal, oats, maize, and has been isolated from rice bran, is a magnesium calcium compound of inositol phosphoric acid (Winterstein, *Zeitsch. physiol. Chem.* 1908, 58, 118).

Phytic acid from maize meal is a yellow viscous mass which decomposes when heated with water at 155° into phosphoric acid and

inositol. Inositol tetra- and pyrophosphoric acids have been synthesised by Anderson (J. Biol. Chem. 1912, 11, 471; 12, 97). Contardi (Gazz. chim. ital. 1912, 42, 408) obtained the hexaphosphate by the action of phosphoric acid on inositol at 120°–130° in absence of air. This is regarded as identical with the phytin found in seeds (cf. Clarke, Chem. Soc. Trans. 1914, 535). See art. PHYTIN.

New forms of inositol are produced by the action of hydrochloric or hydriodic acids in acetic acid solution upon inositol (Hugo Müller, Chem. Soc. Trans. 1912, 101, 2383).

Iso-inositol is crystalline, m.p. 246°–250°, readily soluble in water, insoluble in ether, benzene, or chloroform, or alcohol, but soluble in boiling 50 p.c. aqueous alcohol. It has a very faint sweet taste. Its hexa-acetate melts at 112°, and its tetrabenzoate at 213°.

ψ-Inositol is an amorphous or microcrystalline mass, very soluble in water, but very sparingly so in alcohol. Its nitrate is moderately explosive.

Scyllitol (scyllite) $C_6H_{12}O_6$, discovered by Staedler and Friedrichs (J. pr. Chem. 1858, (i), 73, 48) in various organs of the *Plagiostomi* (dog-fish) has been investigated by J. Müller. It is inactive, crystallises in hard lustrous monoclinic prisms, m.p. above 339° and is sparingly soluble in water. It gives Scherer's reaction and forms a hexacetyl derivative.

Cocositol (cocosite) $C_6H_{12}O_6$, was discovered by Hugo Müller in the leaves of *Cocos nucifera* (Linn.) and *Cocos plumosa* (Hook.) (Chem. Soc. Trans. 1907, 91, 1767). It crystallises from water in large transparent lustrous monoclinic crystals, m.p. about 345°–350°, and is optically inactive. It forms a hexacetate, giving prismatic crystals, m.p. about 300°, also a benzoate and nitrate. It gives the red coloration characteristic of inositol (Scherer's reaction). H. Müller (Chem. Soc. Trans. 1912, 101, 2383) has shown scyllitol, quercine from acorns, and cocositol to be identical, and names all three scyllitol; the occurrence of this substance in two such different organisms as the cocoa-nut palm and the dog-fish is most remarkable.

d-Quercitol $C_6H_{12}O_5$ is found in the acorn and in minute quantity in the cork and bark of the oak. Hugo Müller (Chem. Soc. Trans. 1907, 91, 1766) has also obtained it from the leaves of *Chamaerops humilis* (Linn.), the only European representative of the palm family, which was formerly used like esparto for making paper. The leaves contain 1.35 p.c. of quercitol. They are crushed, extracted with boiling water, and the extract precipitated first with neutral and then with basic lead acetate. The lead in solution is removed and the filtrate evaporated until crystals appear. It crystallises in prisms, m.p. 234° [α_D] +20.16°. It is not fermentable and forms acetyl and similar esters, showing that it contains five hydroxyl groups. Potassium permanganate oxidises it to malonic acid and other products, confirming the structural formula as $CH_2 < \begin{smallmatrix} CH(OH)CH(OH) \\ CH(OH)CH(OH) \end{smallmatrix} > CH(OH)$.

l-Quercitol was obtained by Power and Tutin (Chem. Soc. Trans. 1904, 85, 624) from the leaves of *Gymnema sylvestre* (R. Br.). It crystallises in prisms from water or needles from alcohol, m.p. 174° [α_D] –73.9°, and forms penta-acetyl

and penta-benzoyl derivatives. On oxidation with potassium permanganate, malonic acid is formed; with sodium hypobromite, the product is diketotrihydroxyhexahydrobenzene $C_6H_5O_2(OH)_3$. It is not the optical antipode of *d*-quercitol.

Quercitol contains 4 asymmetric groupings, and therefore 8 optically active and two unresolvable inactive modifications are possible.

E. F. A.

INSECTICIDES *v.* PLANT-SPRAYS.

INSIPIN. Trade name for the glycollic ester of quinine sulphate.

INTERFEROMETER. The interferometer, or rather the interference refractometer, is an instrument for measuring small differences in refractive power between two gases or two liquids; this it does with much greater refinement than other forms of refractometer, and consequently it can be used to measure small differences in composition between two gaseous mixtures or between two solutions, and in one of its forms it has been used to find the refractive indexes of new gases by comparison with air. It takes advantage of the set of bands produced by the phenomenon of interference and employs such sets as pointers or indexes.

If the white light from a single source is broken up into two beams, and if these are made to unite again either on a screen or as viewed through a telescope, a set of interference bands is observed having a central white band with a series of dark bands to the right and left. These bands are caused by the light waves of the two beams meeting and in some places reinforcing, and in others obliterating one another according as they are in the same phase or in opposite phases. The dark bands are fringed with colour owing to white light being made up of coloured lights of various refrangibilities; if monochromatic light is used only bright and dark bands are seen. The two beams must come from the same source or no bands will be formed. The phenomenon is discussed in textbooks on Light.

Shifting of the central band is observed when a different material is introduced into the path of one beam and not into that of the other; it is on this shifting that the measurement depends. When both beams pass through exactly the same lengths of the same materials their 'optical lengths' are equal and the central band is seen in a certain place, but if a new material with a different refractive index is introduced into the path of one beam, its 'optical length' is now changed and the central band is shifted to a new position. A material of higher refractive power diminishes the velocity of light more than a material of lower refractive power and increases the 'optical length' of the path traversed by the rays. The optical length of the path of a ray between two points is equal to the actual distance multiplied by the index of refraction of the material through which it passes. If the ray passes through several materials the total optical length is the sum of the several optical lengths.

Different ways of restoring the central band to its former position are employed in various forms of the instrument and so measuring the difference in refractive indexes, and further

there are different methods of effecting the division of the beam of light.

Jamin (Ann. Chim. 1858, [3] 52, 163 and 171) used reflection and refraction in a thick glass plate to separate the beam and send it through two tubes; but Lord Rayleigh, using a modification of an arrangement investigated by Fraunhofer, effected the separation in an easier way.

Rayleigh's Interference Refractometer for Gases.

—This was used by Lord Rayleigh when determining the refractive power of argon and helium by comparison with air (Proc. Roy. Soc. 1895-96, 59, 201; 1898-99, 64, 97; also Traver's Experi-

mental Study of Gases, 1901, 292; also Watson, Practical Physics, 1906, 343). The way in which it acts can be seen from Fig. 1, but various forms of it have been described. The plan adopted is to render the rays of light from a slit parallel by means of a collimating lens, then to divide them into two beams by passing through two narrow apertures, and finally to unite them again by means of a telescope in which the interference bands will be seen. The rays of light from a lamp on the right pass through a very fine vertical slit and are rendered parallel by the lens *B*. The lamp and slit are not shown in the figure. The rays

FIG. 1.

then pass through the two tubes *D* and *E*, and on to the two vertical and parallel apertures *CC* in the cap of a telescope having a lens at *Q*. These apertures are parallelograms about $\frac{1}{4}$ inch wide and $1\frac{1}{2}$ inches apart, and are exactly opposite the ends of the tubes. The figure shows the arrangement in plan, the slit and apertures being perpendicular to the plane of the paper. Instead of viewing the bands through the lenses of an ordinary eyepiece, much greater magnification was obtained by employing a glass cylinder, shown at *R*; it appears there as a circle, since it is perpendicular to the plane of the paper and parallel to the

slit and apertures. It was cut from a piece of plate glass, glass rod being unsuitable; it has the advantage of magnifying the bands in width only. At first a web was used as the reference mark for measuring the shift of the bands, but a much better plan was found to be allowing light from *B*, travelling not through but in the air above the two tubes, to form a set of reference bands which are stationary and not affected by the materials in the tubes. Each pair of ends of the tubes is closed by a glass plate, the faces of which must be optically worked so as to be parallel. The appearance in elevation can be gathered from Fig. 2, which

FIG. 2.

represents the next instrument; it shows how the top half of the beam passes above the tubes and the lower half through them. Each of the tubes *D* and *E* has a side tube through which it can be filled, and these side tubes are in connection with mercury manometers with adjustable reservoirs by which the pressure in each tube can be varied and ascertained. The tubes are filled with air and the gas under investigation respectively, and the pressures are adjusted until the central band is brought to a definite position in relation to the reference bands. The pressures in the two tubes are, of course, different when this is attained. Other experiments are made with other pressures, the central band being always brought back to the same position as regards the reference bands. The relative refractivity is calculated from the relation between the pressures in the air tube and in the other gas; the refractivity being $(\mu-1)$, where μ is the index of refraction.

Löwe's Interference Refractometer for Liquids

and Gases.—An instrument employing Lord Rayleigh's method of dividing the beam, his cylindrical lens, and his plan of using a second set of bands as a reference mark is described by Löwe (Zeitsch. für Instrumentenkunde, 1910, 30, 321; Zeitsch. Physikalische, 1910, 11, 1047) as made by Zeiss. Fig. 2 shows the mode of action of the instrument, though not the actual dimensions; *A* is the slit and *B* is a collimating lens; the materials under examination are contained in two tubes, *D* and *E*, placed side by side; of these the near tube *D* is seen in the figure, which shows the apparatus in elevation. Rayleigh's apparatus could only be used for gases, and required two mercury manometers with accessories to bring the central band back to the right position; Löwe dispensed with these by means of a compensator, and made the apparatus applicable for both liquids and gases. The compensator is an arrangement of glass plates something like an arrangement used by Jamin (*l.c.*). It consists of two glass plates,

one placed in the path of the beam from each tube and at an angle of about 45° to the beam. One of them, *L*, is movable about an axis, and can be inclined at a greater or less angle to the beam by means of the lever *O*, which is moved by the micrometer screw *N*. The other plate, *K*, is exactly like *L*, but is fixed; it is hid by *L* in the figure and lies in the path of the beam from the further tube *E*, which is hid by *D*.

If a ray of light passes through a glass plate, it will traverse the minimum of glass when the plate is perpendicular to the ray, the more the plate is inclined from this position the greater will be the length of glass traversed. Thus by the device described above, when the optical length of the beam coming through the material in the near tube *D* is less than that of the beam coming through the other tube *E*, a further inclination of the glass plate *L* serves to increase the length of glass traversed, and thus the central band can be brought back to the reference band by turning the micrometer screw *N*. Attached to this screw there is a drum, the graduations on which serve to measure the inclination given to the plate *L*, and so to

estimate the difference in refractive power of the materials in the two tubes.

The upper part of the light from the collimating lens *B* passes above the tubes and forms the stationary reference bands. On its way it meets the inclined glass plate *H* which is fixed and serves to direct the light into the telescope *RQ*. This, as in Rayleigh's apparatus, has two apertures at *CC* and a cylindrical eyepiece *E*. Without the plate *H* the top of the tubes *D* and *E* would appear in the eyepiece as a thick dark line, making it difficult to bring the two sets of bands into exact concordance, but the effect of *H* is to blot out or diminish this line (Rayleigh, Proc. Roy. Soc. 1898-99, 64, 97).

The instrument in the above form is long and suitable for a laboratory bench, but besides this Löwe describes a shorter and less sensitive form. In this, when used for liquids, the tubes or chambers are immersed in a water-bath in order to maintain a uniform temperature in both. Irregularities in temperature interfere with the setting of the bands and reference bands together, and also make the bands crooked (Wolff, Chem. Zeit. 1915, 39, 106).

FIG. 3.

An instrument on the plan of the long form is made by Adam Hilger of 75a, Camden Road, N.W.1, for use with gases, and is shown in Fig. 3. The lettering corresponds to that of Fig. 2, but the two apertures *CC* are placed close to the collimating lens *B* instead of on the telescope *QR*. Of the further letters, *F* and *G* indicate standards supporting the tubes; *T* and *T* are nuts for raising or lowering the tube, which can also be adjusted laterally by a screw at *S*; *K* is the fixed glass plate and *Q* is the object glass of the telescope; *V* is a knurled ring for focussing the telescope, and *P* is a spring opposing the micrometer screw. The apertures are 4 mm. wide and 12 mm. apart; the two gas tubes are made of brass and are 1 metre long and 1 cm. square in section, and are closed by glass plates with parallel faces. It is claimed that with this instrument settings can be made to less than one-fortieth of a band, and that it is possible to detect the presence of 0.01 p.c. of hydrogen in air, corresponding to a difference in refractive index of 0.000,000,015.

Hilger also makes a much shorter instrument for use with liquids; it has a cell 1 cm. long and the range is about 0.006 instead of about 0.000017, which is that of the long form.

Both long and short forms of the instrument have to be graduated empirically, that is to say, the values corresponding to the readings of the drum have to be found by experiments using liquids and gases of known composition. The tubes are first both filled with the material

taken as a standard, the compensator is adjusted so that both sets of bands coincide and the drum is read off. This reading gives the starting-point and has to be deducted from subsequent readings; it may vary a little from day to day. The tube opposite one of the plates is now filled in succession with prepared mixtures containing known additional quantities of the substance it is wished to measure, the compensator is adjusted and read and a table or curve is prepared, by the use of which the amount in a sample under examination can be found. Which tube or chamber to use will depend on which material has the greatest refractive power and also on the way the instrument is made; if the movable plate is inclined away from the lever as in Fig. 2, raising the lever increases the path through glass; but if, as in some instruments, it is inclined towards the lever, raising the lever diminishes the path. It is best that the water used for comparison and for making standard solutions should be parts of the same lot. Several settings and readings of the drum should be made with each portion of liquid or gas tested, and for the greatest accuracy it is advisable to repeat this with other portions of the same lot.

Another way of making a determination is to prepare two mixtures of known strength, one a little stronger and one a little weaker than the sample under examination. The end points are found by testing these mixtures first with both tubes or chambers filled with the same

mixture, and then with one mixture alongside the other. Having found the end points, which should not be far apart, the sample is compared first with one mixture and then with the other, and its strength is calculated by interpolation. Using this plan the shifting of the colours described below is less likely to cause difficulty.

Besides Rayleigh's and Löwe's there are other forms of interferometer which are of interest to the physicist rather than to the chemist.

Corrections.—Care must be taken to identify the central white band correctly and not to mistake a side band for it. Further, in using the compensator there is an action, which as the glass plate is more and more moved and as the readings on the drum get higher and higher, shifts colours on to the original central band and makes it harder to identify, and which then whitens in turn first one and then another neighbouring band so that it appears like the original central band. The effects of this action have to be ascertained and allowed for. It is caused by differences in dispersive power between the glass plate and the solutions, so that the corrections vary with the substances in solution and with different instruments. The action is discussed by Marc in *Chem. Zeit.* 1912, 36, 537, by Valentiner and Zimmer in *Ber. Deutsch. Physik. Gesell.* 1913, 15, 1301, and by Adams in *J. Washington Acad. Sci.* 1915, 5, 265, and in *J. Amer. Chem. Soc.* 1915, 37, 1181, where many directions are given. This correction has also to be considered in the case of Rayleigh's instrument (Valentiner and Zimmer, *l.c.*, p. 1316).

Different intensities of the two black bands in the centre indicate a faulty adjustment of the light.

In other kinds of refractometer it is important to maintain a constant temperature during an observation, as temperature greatly affects refractive power, but with the interference refractometer this is less important, as any variation in temperature affects both tubes, and it is only when temperature has distinctly more effect on the refractive power of the material in one of the tubes than on that of the material in the other tube that a difference can be noticed between observations at different temperatures. It is advisable to make sure that errors due to difference of temperature between that of graduation and that of observation are negligible (Edwards, *Chem. and Met. Eng.* 1919, 21, 562).

It should be noted that the readings on the drum are not in simple proportion to the differences in refractive power. Adams (*J. Amer. Chem. Soc.* 1915, 37, 1191) gives formulæ for calculating values that are directly proportional; they involve finding a constant for the particular instrument used; but as each instrument is graduated empirically as described above, it is not essential to employ these formulæ.

Edwards (*J. Amer. Chem. Soc.* 1917, 39, 2382) proposes in the case of gases to prepare calibration tables for the interference refractometer by an experiment with air at different pressures and then by calculation from the known refractive indexes of various gases, but certain points have to be taken into account.

Uses.—The interference refractometer can be used for comparing two liquids or two gases together which differ in that one contains more of a certain known substance than the other, and for ascertaining the amount of this excess. The longer the tubes or chambers containing the materials the greater is the sensitiveness, and the shorter the tubes or chambers the greater is the range of differences that it will determine. Further, the greater the difference in refractive power between the standard substance and the substance to be determined the greater is the sensitiveness; thus when carbon monoxide with refractive index 1.00034, nitrogen with 1.000297, oxygen with 1.00027, dilute air with 1.000293, the sensitiveness is not nearly so great as when hydrogen with 1.000139 is the diluent; in which case it is claimed, as stated before, that 0.01 p.c. of hydrogen in air can be found.

In the case of liquids Adams (*J. Amer. Chem. Soc.* 1915, 37, 1187) says that with his instrument, using a 4 cm. chamber through which the light was reflected back, and which consequently was equivalent to an 8 cm. chamber, a difference of 2 parts per million of sodium chloride in aqueous solution could be found.

The following applications of the interference refractometer have been made or suggested:

In the case of gases for examining: (1) Air in ventilation systems. (2) Flue gases for boiler control. (3) The gas in airships. (4) Illuminating gas. (5) Ammonia in distillation gases. (6) The gas evaporating from liquid air. (7) Mine air for methane. Küppers (Glückauf, 1913, 49, 47) gives directions for testing mine air; this and the ordinary air used for comparison should be freed from carbon dioxide and water vapour by means of soda-lime and calcium chloride. If the mine air is deficient in oxygen a correction must be made (Seibert and Harpster, U.S. Bureau of Mines Tech. Paper No. 185, 1918, p. 11). In testing gases by Löwe's instruments the pressure must be the same in both tubes; this can be effected by making them both communicate with the atmosphere during an observation, but with some device to check diffusion.

In the case of liquids: (1) Examination of seawater, for variations in saltness (Löwe, *Annalen d. Hydrographic.* 1912, 40, 303). (2) The analysis of colloid solutions and the investigation of the phenomena of adsorption (Marc, *Chem. Zeit.* 1912, 36, 537). (3) The determination of the efficiency of filtering materials in water works (Marc, *l.c.*). (4) Standardising solutions for volumetric analysis. (5) Determining potassium and sodium in a mixture of their sulphates (Adams, *J. Amer. Chem. Soc.* 1915, 37, 1194). (6) Testing the activity of diastase and yeast (Wolff, *Chem. Zeit.* 1915, 39, 105 and 197).

INVAR. A steel containing 35.4 p.c. nickel having an extremely low coefficient of thermal expansion (*v.* NICKEL).

INVERTASE (*Sucrase*). Invertase is the enzyme which hydrolyses or inverts sucrose to dextrose and levulose. It is present in all yeasts except *S. octosporus*, *S. capsularis*, and *S. membranaefaciens* (Hans.), and is extremely active. According to O'Sullivan and Tompson (Chem. Soc. Trans. 1890, 57, 834), whose contribution to the subject is still a classic, it can hydrolyse 200,000 times its weight of sucrose, and probably this figure is much understated. As is the case with other enzymes, but little is known of its nature.

O'Sullivan purified invertase by fractional precipitation so long as it remained active, and found that the proportion of carbohydrate increased. He identified this as mannose, as was also done by Koelle (Zeitsch. physiol. Chem. 1900, 29, 429). A very pure preparation was obtained by Osborne (*ibid.* 1899, 28, 399) which gave none of the protein reactions, except precipitation by copper sulphate, lead acetate, and phosphotungstic acid; it gave the biuret, xanthoprotein, and Millon's test faintly, and could not be freed completely from carbohydrate. It also always contained nitrogen and ash. Salkowski (Zeitsch. physiol. Chem. 1909, 61, 124) considers that invertase does not contain carbohydrates and that the yeast gum which accompanies it is an impurity. *Cf.* Willstätter and Racke, Annalen, 1921, 425, 1.

According to Mathews and Glenn (Bio-Chem. J. 1911, 9, 29), the most active preparation contains about 2 p.c. of ash and 2.2 p.c. of nitrogen. It consists of a gum and a nitrogenous portion yielding 70–76 p.c. of mannose on hydrolysis. These authors consider invertase to consist of a union of an inactive colloidal gum with an active protein ferment; by the action of acid, the ferment is freed from the carrier and rendered active.

Mathews and Glen (J. Biol. Chem. 1911, 9, 29) consider that as ordinarily prepared invertase is a combination of a protein and a mannosan. All attempts to free the protein from the gum and retain enzymic activity were a failure. The parallelism between activity and nitrogen content is taken as indicating that the active substance is a protein.

Nelson and Born (J. Amer. Chem. Soc. 1914, 36, 393) find that highly purified invertase does not show the protein reactions until after hydrolysis with dilute sulphuric acid, indicating

that the properties of the protein are effectually masked in the invertase itself.

Invertase appears to be effective in all cases where dextrose and lævulose are united, even when a third sugar molecule is attached to these. Thus it hydrolyses raffinose, gentianose, melicitose, and stachyose, splitting off lævulose in each case.

Invertase is of common occurrence in the vegetable kingdom; it is present in buds, flowers, and leaves of the higher plants and in numerous mould fungi. It is not so widespread in the animal body as maltase, being practically limited to the mucous membranes of the alimentary canal.

The laws regulating the velocity of invertase action are dealt with elsewhere (*v. FERMENTATION AND HYDROLYSIS*).

It is very sensitive to the minutest quantities of alkali, which retard or stop its action, and for this reason its action is accelerated by dilute acids or acid salts, although probably, like diastase, it is most active in truly neutral solution. Quantitative work with invertase must be carried out in hard glass vessels and with solutions which have been stored and measured in such vessels. It is the neglect to avoid alkaline impurity which has occasioned many of the controversial statements in the extensive literature relating to this subject.

The rate of action is much influenced by temperature: 55°-60° being that of maximum activity, beyond which it becomes weakened by heat (*see also papers by Euler, Zeitsch. physiol. Chem.* 1910 and 1911). It is destroyed between 65° and 70°. The power of the enzyme to resist heat is considerably increased by the presence of sucrose: according to O'Sullivan, it will withstand a temperature 25° higher.

An active solution of invertase is readily obtained by extracting dried yeast with water or by shaking up living yeast with chloroform water. A very active permanent preparation may be prepared by setting aside washed pressed yeast with a little water to autolyse at 37° for a few days. The liquid is filtered and alcohol added a few cub. cm. at a time to the filtrate so as to keep the precipitate in a granular form. The liquid is decanted, the precipitate washed first with a little 60 p.c. and then with 80 p.c. alcohol and at once dissolved in a minimum quantity of water. The precipitation process may be repeated and the final product dissolved clear in the smallest quantity of water and bottled with a little toluene. This solution, which is of very high activity, may be kept for years without its activity materially changing (*v. FERMENTATION*).

Investigations made by Euler, and later by Meisenheimer (*Biochem. Zeitsch.* 1913, 54, 122), have shown that the amount of invertase in yeasts is largely increased by allowing them to remain in contact with various sugars for one or two days. The invertase was prepared from the expressed juice by the acetone method. Under these conditions the zymase content of the yeasts diminished. Invert sugar or fructose caused a larger increase in the invertase than glucose or cane sugar, a fact which is explained on the assumption, previously made by Armstrong, that a fructose-invertase combination is somewhat more stable than the combination of

invertase with other sugars, and the ferment is thereby more efficiently guarded against change during the autolysis of the yeast. Euler (*Zeitsch. physiol. Chem.* 1913, 88, 430) claims that it is the process of fermentation as such, and not the substrate or the products of the reaction, which influences the formation of new invertase. Enzyme formation is closely correlated with the formation of fresh protoplasm.

The hydrolysis of cane sugar by active invertase preparations is complete, and the most careful experiments made by Armstrong (*v. THE SIMPLE CARBOHYDRATES*), and later by Hudson and Paine (*J. Amer. Chem. Soc.* 1914, 36, 1571), have failed to detect any evidence of synthetic activity. E. F. A.

IODALBACID, IODALBIN, IODANISOL, IODEIGONS, v. SYNTHETIC DRUGS.

IODEMBOLEITE v. EMBOLITE.

IODGLIDIN, IODIN, v. SYNTHETIC DRUGS.

IODINE. Symbol I. At.wt. 126.93. This element was discovered in 1812 by Courtois in the mother liquor of kelp. The discovery was first announced to the French Institute in 1813. The properties of the new element were further investigated by Clement and Desormes, Gay-Lussac, and Davy.

Iodine is a crystalline solid of greyish-black colour and bright metallic lustre resembling plumbago. Its sp.gr. is 4.948. It is obtained by sublimation in brilliant rhomboidal plates, or in elongated octahedrons belonging to the trimetric system. In very thin plates it transmits light of a red colour. It melts at 114.15°, and boils at 184.35° (Ramsay). It volatilises at ordinary temperatures spontaneously in the air, diffusing an odour resembling chlorine. It is sometimes employed in this way in hospitals as a disinfectant. Its vapour pressure at 50° is 2.15 mm.; at 60°, 4.29 mm.; at 70°, 8.20 mm.; at 80°, 15.09 mm.; at 90°, 26.78 mm. (Baxter and Grose, *J. Amer. Chem. Soc.* 1915, 37, 1061). The vapour has an intense blue or rich violet colour, and is one of the heaviest of all known gases, having a sp.gr. of 8.801. A stratum 4 inches thick presents a black mass quite impervious to light. Heated above 700° the sp.gr. of the vapour begins to diminish until at 1700° it is half that at 700°, and the vapour is monatomic. It is very slightly soluble in water, requiring about 3616 parts for solution at 18°. It is soluble in chloroform, bromoform, carbon disulphide, light petroleum, and benzene, forming violet solutions; also in ethyl, methyl, and amyl alcohols, and in ether and glycerol, forming brown solutions. It is very soluble in potassium iodide, of which 1 part in 2 parts of water will dissolve 2 parts of iodine, forming potassium triiodide KI₃. In reactions it resembles chlorine and bromine, but is less energetic, and is displaced by these elements from its compounds with hydrogen and the metals. It has a strong affinity for most of the metals, and in the presence of water, attacks and dissolves gold. The most characteristic reaction of free iodine is the dark blue compound formed with starch; this test is extremely sensitive, and will reveal the presence of one-millionth part in any liquid containing it. Another characteristic reaction is to liberate the iodine from a solution by nitrosulphuric acid, and dissolve it out by carbon disulphide; this

affords an accurate and easy method of estimating it by the depth of the crimson colour of the solution; it is also extremely sensitive, and well adapted to estimate small quantities of the element.

Istopes of iodine.—By the method of positive ray analysis, iodine is shown to be a simple element of atomic weight 127 (Aston, Chem. Soc. Trans. 1921, 119, 677).

Iodine in minute quantities is very largely distributed throughout the animal, vegetable, and mineral kingdoms. The thyroid gland of the sheep contains, for example, on the average, when dry, 0.34 p.c. of iodine, or on the fresh gland 0.09 p.c. (Martin, Pharm. J. 1912, 89, 144). As a mineral it occurs in combination with silver, mercury, and lead, in ores from Mexico, Chile, and Spain, with zinc in Silesia, and with lead in South America. It is also found in dolomite from Saxony, in limestone from Montpellier, in shale from Sweden, and in calcium phosphate from France. It exists also in the 'caliche' of Chile in the form of sodium iodate. This is the only mineral source from which it is manufactured, and has been for many years the most important of all the commercial sources.

Many mineral waters contain iodine, notably those of Carlsbad in Bavaria, Hall in Austria, Marienbad in Bohemia, Holberg in Pomerania, Halle in Saxony, Sales in Piedmont, Nix in Savoy, Kreuznach in Galicia, Halse in Java, and Jallien in France. It is also found in the waters of Friedrichshall, Castellamare, Heilbrun, Homburg, Seidchutzh, and Vichy; and in this country in those of Leamington, Bonington, Bath, Cheltenham, and Woodhall. It is a valuable remedy in skin diseases. The sea is an abundant source. Iodine is always present in seawater, but in such a very minute proportion that it is difficult of detection except by operating on large quantities. It has been estimated in the Atlantic at 1 part in 280,000,000 (Stanford). Iodine in organic combination is not found in Atlantic ocean water. According to Winkler (Zeitsch. angew. Chem. 1916, 29, i. 205), the total iodine content of the water is approximately 0.05 mg. per litre. Near the surface where the water is exposed to air and sunlight, the iodate-ion predominates; at a greater depth the relation between the iodate and iodide changes, the proportion of the latter increasing. All fishes and all animal products from the sea appear to contain iodine, but in very minute quantity. The following table shows a few of the marine products in which it has been estimated:—

Cod-liver oil . . .	0.000322 p.c. iodine.
Cod-liver . . .	0.000817 "

Sponge (Turkey) .	0.200000 "
Sponge (Honeycomb) .	0.054000 "

VOL. III.—T.

Nearly all seaweeds or marine algæ contain it. It may be extracted from seaweed by a solution of aluminium sulphate. This when treated with copper sulphate and sulphurous acid or a sulphite yields cuprous iodide. It is present even in the *Zostera marina* (L.) or grass wrack, natural order *Naiadaceæ*, a flowering plant growing only in the sea; but there are some remarkable exceptions. The gelatinous species of algae, the *Chondrus crispus* (L.) (or Irish moss), and *Gelidium corneum* (Lam.) of British species, and the *Eucheuma spinosum* [(L.) J. Ag.], or *Agar agar* of foreign species, do not contain iodine. The *Enteromorpha compressa* [(L.) Grev.], or common sea grass, when dry has a strong odour of the sea, but does not contain iodine. The salsola or salt wort, *Salsola Kali* (L.), natural order *Chenopodiaceæ*, growing on the seashore, and from which barilla was made, contains no iodine. Some of the algæ are comparatively rich in iodine, and the ash of these plants, known as kelp, for many years formed the only commercial source of this important element. For the distribution of iodine in plant and animal tissues, see Cameron, J. Biol. Chem. 1915, 23, 1.

Manufacture.—By far the greater bulk of all the iodine produced is now extracted from the mother liquors of the nitrate works in Chile, but the manufacture of iodine from kelp has for long been carried on in Scotland and in France, and within recent years has been started in Norway and in Japan. Courtois, a saltpetre maker in Paris, who discovered iodine, obtained it from the kelp liquors which were used to furnish the salts of potash required in his manufacture, and this was for many years the only commercial source of iodine. The manufacture was unsuccessful commercially in the hands of the discoverer, and he died in poverty. It was afterwards successfully carried out by MM. Cournerie, of Cherbourg, and has continued to be an important manufacture on the Normandy coasts. In this country it was first made on the small scale by Dr. Ure of Glasgow, and the manufacture has since been almost exclusively confined to that city, where it has assumed considerable importance. It was first made there in quantity in 1841, and the imports of kelp into the Clyde in that year amounted to 2565 tons. In 1845, there were four small works engaged in the manufacture of iodine. Kelp was then used for soap making on account of the sodium carbonate it contained, and the iodine was extracted from the lyes of the soapboilers. In 1846 there were twenty makers of iodine in Glasgow, who then treated the kelp directly, extracting also the potash salts which had a high value in the market. The fall in the price of potash salts owing to the discovery of the Stassfurt mineral, which reduced the price to one-third, the very variable character of the kelp used, and the extreme fluctuations in the price of iodine, ranging from 4s. to 34s. per lb., soon reduced the number of makers, and now there are only three works in Scotland. The produce of iodine from kelp was so limited that it offered unusual temptations to speculators, who derived most of the benefit from the high prices, the manufacturers suffering the losses during the low prices.

Moreover, the Scottish kelp industry, so far at least as the production of the kelp is

concerned, has always been primitive and badly organised. Since 1905, however, there has been a marked increase in production, and under better conditions as regards organisation and methods the industry might well attain a state of prosperity (*cf.* Hendrick, *The Value of Seaweeds as Raw Materials for Chemical Industry*, J. Soc. Chem. Ind. 1916, 35, 13; also Scott, *The Kelp Industry*, Report to the Board of Agriculture for Scotland on Home Industries in the Highlands and Islands, 1914).

The history of kelp, or *varec* as it is called in France, is extremely interesting. It is a crude rough slag made by burning seaweed in long shallow pits. For many years it was a large and valuable article of commerce, and greatly enriched the proprietors of the West Highland estates where it was principally made. It was then the only source of soda. At the beginning of last century it realised 20*l.* to 22*l.* per ton, and the Hebrides alone yielded 20,000 tons per annum, worth upwards of 400,000*l.* It was largely used in soap making and in glass making, and within the last hundred years there were glass works at Dumbarton using this material, which were celebrated for the quality of their glass. At a glass works in Drontheim in Norway, it was still used for this purpose up to about forty years ago. The importation of barilla gave the first blow to kelp, and it fell in price, and for the twenty-two years ending 1822, the average price was 10*l.* 10*s.* The duty was then taken off barilla, and the price of kelp again fell to 8*l.* 10*s.*; in 1823, the salt duty was repealed and kelp fell again to 3*l.*, and in 1831 to 2*l.*, at which price there was no further profit on the manufacture. In the meantime soda was being largely made by the Leblanc process, and kelp was superseded altogether as a source of soda. It must have been a most expensive source, as it yielded only about 4 p.c. of alkali and often less than 1 p.c.; and at one time must have cost the soap makers what would have been equal to 100*l.* per ton for soda ash, worth now about 9*l.* 10*s.*

The manufacture of iodine and potash salts then began to assume some importance, but the kelp required was not the same, that which contained the most soda containing the least potash and iodine. Moreover the kelpers had been taught to burn at a high temperature, which improves the yield of sodium carbonate but volatilises much of the potash and some of the iodine. The seaweed employed by the kelpers was of a kind containing little iodine, and not very rich in potash. They used almost exclusively the black wrack, cut in large quantities in the Highland lochs, and consisting of the three fuci, *Fucus vesiculosus* (L.), *Ascophyllum nodosum* (Le Jol.), and *F. serratus* (L.), which are all uncovered at low tide. This is now entirely unutilised: the kelp made from it was known as *cut-weed kelp*. The average analysis from numerous cargoes of the kelp is shown top of next column.

Drift kelp is the only variety now employed as a source of iodine. It is made from the red wracks, the *Laminaria digitata* [(L.) Lamx.], or tangle, and the *L. stenophylla*, which are always submerged by the tide, and contain about ten times as much iodine as the fuci. These seaweeds are torn up by the storms from the rocks

on which they grow, and cast ashore; unlike the black wrack, these plants suffer much from rain, the more valuable salts being completely washed away, and are often after drying quite valueless, the kelper losing all his labour. From the time of its discovery, the iodine was the most important product, but the potash salts were also very remunerative at first. Potassium chloride, or 'muriate,' as it is technically called, was worth 25*l.* per ton. The discovery of the Stassfurt mineral reduced its value to about one-third, and the further discovery of bromine in the same mineral reduced the price of that element from 38*s.* to 1*s.* 3*d.* per lb. The amount of bromine in kelp is small, only about one-tenth of the iodine, and it has not been extracted from this source for the last forty years. It is remarkable that the algæ should select iodine, as bromine is a much larger constituent of sea-water, which usually contains about 6 parts in 100,000, and according to Dittmar appears to bear the constant relation to the chlorine of 0·34 to 100, whereas iodine exists only as a minute trace, difficult even of detection, although the aggregate amount in the ocean must be enormous.

The algæ differ considerably in the proportion of iodine which they take up from the sea-water, and only two species, the *Laminaria digitata* and the *L. stenophylla*, are worth burning for kelp.

It is remarkable that the giant algæ of the Falkland Islands contain very little iodine, although these are the largest sea-plants in the world. The *Duvillaea utilis* (Borg.), a marine tree with a stem a foot in diameter, and the *Macrocystis pyrifera* (Turn.) which grows to the length of 1500 feet, contain only traces of iodine; in some samples it can scarcely be detected.

The table (col. 1, p. 643) shows the average yield of the most important varieties. The kelp plant figures are taken from a large number of analyses, from seaweed gathered all around the shores of Great Britain and Ireland; also Denmark, Norway, and Iceland.

The seaweeds chiefly used in Japan for the extraction of iodine are *Laminaria* sp., *Ecklonia cava*, *E. bicyclis* (Kjellm.), and *Sargassum* sp. The iodine content varies with the age of the algæ and also with the time of year, being greatest during June to September; the following figures give the iodine content of some of the raw seaweeds: *Ecklonia cava*, 0·23 p.c.; *E. bicyclis*, 0·27 p.c.; *Sargassum* sp., 0·05 p.c.; *Laminaria angustata* (Kjellm.), 0·18 p.c.; *L. longissima*, 0·17 p.c.; *L. ochotensis*, 0·19 p.c.

According to Okuda and Eto (J. Coll. Agric. Tokyo, 1916, 5, 341), the greater part of the iodine in algæ is in organic combination. Of the total iodine found in *Ecklonia cava* 90 p.c.

was in a soluble organic form, and was not liberated by boiling with dilute sulphuric acid or potassium hydroxide. Fresh samples of *Ecklonia bicyclis* contained under 5 p.c. of the iodine as iodide, and 95 p.c. organic, of which 90 p.c. was soluble. The amount of iodine increases from winter to summer; old plants contain more than young plants. *Turbinaria fusiformis* (Yendo), *Sargassum enerve* (Ag.), and *Sargassum horneri* (Ag.) contained, respectively, 50, 78, and 66 p.c. of soluble organic, and 22, 16, and 17 p.c. of the soluble inorganic element. The Japanese food 'dashikombu,' made from *Laminaria* by partially fermenting and drying, contains 95 p.c. of its iodine in an inorganic state. Boiling with formalin, which converts the iodine into an inorganic form, is a test for the detection of organic iodine in algæ. The soluble iodine of *Ecklonia bicyclis* is precipitated by basic lead acetate, and by Stutzer's copper reagent, but the chief iodine compound in the aqueous extract is not combined with protein. Algæ from the open sea apparently contain more iodine than the same species from inland seas.

It will be seen that even in the drift weeds the quantity of iodine is inconsiderable, but if the plants are properly burnt to a loose ash at a low temperature, they ought to yield a kelp containing 25 to 30 lbs. of iodine to the ton. 12 lbs. per ton is, however, above the average yield from ordinary drift kelp. The kelpers often neglect to protect the seaweed from the action of rain, which washes out the soluble iodides, and moreover it is difficult to prevent them from burning it into a hard slag by working it up, when molten, with iron clauts. Sand and stones are thus mixed up with it, and the great heat employed drives off some of the iodine. The result is a hard slag of great density, and this density forms one of the difficulties in inducing the kelpers to burn the weed to a loose ash, which they imagine, from the lightness, will not give them the weight they expect. As an actual fact, of course, the total weight of the ash so produced is considerably more, from the same quantity of weed used; but old fallacies die hard, especially amongst the poor and

ignorant people who do this work. There is the further disadvantage that the sulphates are reduced to sulphides or oxysulphides, and a considerable extra expenditure of oil of vitriol to decompose these is entailed; sulphur is thus obtained as one of the by-products of the lixiviation of kelp, in which it ought not to exist at all. The presence of silica as sand greatly assists the volatilisation of the iodine.

The following table shows the analyses of very good samples of Irish and Scotch kelp, and also of the latter burnt into loose ash, and the comparison of these indicates clearly the effect of the heat of burning:—

	Kelp		Ash

Carbon in insoluble part .	15½	14½	28
	Nil	Nil	9·00

A different method of manufacture was introduced by Stanford in 1863, when works were erected in the Outer Hebrides for the carbonisation of the stems of tangle (*L. digitata*) in closed retorts, thus converting the tangle into charcoal and collecting the products of destructive distillation, consisting principally of tar and ammoniacal liquor, in suitable condensers. A very porous charcoal is thus produced which contains all the iodine present in the seaweed employed; when lixiviated it gives very white salts containing no sulphides. The residual charcoal, after lixiviation, does not resemble that from wood, which is principally carbon with a small percentage of ash, but in its composition and general character approaches animal charcoal obtained from bone. The following table shows the comparison:—

	Seaweed	Bone
Carbon . . .	52·54	11·77
Calcium phosphate . . .	10·92	77·70
„ carbonate . . .	15·56	1·43
„ sulphate . . .	—	0·35
Magnesium carbonate . .	11·34	—
Alkaline salts . . .	5·70	1·09
Silica, &c. . .	3·94	0·66
	100·00	100·00

The presence of magnesium carbonate is a peculiar characteristic of this charcoal, as all seaweeds are rich in magnesium salts. Seaweed charcoal, as might be expected from its composition, is an excellent decoloriser and deodoriser. As compared with animal charcoal it is much lighter and more bulky, and therefore has not replaced it as a decoloriser, although from its high percentage of carbon it would well stand the constant re-burning required in sugar works, and be improved by this treatment.

This process of carbonisation was in use in the islands of Tyree and North and South Uist for a number of years, with great benefit to the crofters and cottars of these islands. It required, however, the erection of separate carbonising works in each island, and, as the winter tangle only was used, it was difficult to secure sufficient supplies except from a large area. Moreover, it was found in practice very troublesome to completely extract the soluble iodides from the charcoal, and ultimately the process was abandoned in favour of the older and simpler method of kelp burning. A wet process of extracting iodine from seaweeds has also been tried. It had been noticed by Stanford that the whole of the alkaline salts present in the seaweed, and a considerable quantity of extractive matter containing dextrin and mannite, could be extracted from the fronds of the *Laminaria* or red seaweeds by simple maceration in cold water. The residue, which is the plant apparently unaltered, consists of a nitrogenous substance resembling albumen, to which the name of 'algin' has been given, and the algic cellulose or algulose, which represents the cellular fabric of the plant. The algin or alginic acid is removed by digestion with a solution of sodium carbonate, which dissolves it as sodium alginate, leaving the algulose. Dissolution can be effected in the cold, but it is necessary to employ heat, otherwise it is impossible to filter off the algulose. A Taylor filter is the only one that can be employed, the filtration being extremely difficult on account of the great viscosity

of the algin or sodium alginate and the extreme fineness of the cellular algulose. The process adopted is to boil the seaweed with sodium carbonate, and filter; the algulose is separated by filtration, and the filtrate is mixed with hydrochloric acid, and the alginic acid is then easily filtered off; the solution is neutralised with caustic soda, evaporated to dryness, and carbonised, the residue forming the 'kelp substitute.' The alginic acid, which has a slight amber colour, is washed, bleached, and redissolved in sodium carbonate; the resulting liquor, evaporated in a vacuum pan, forms the commercial alginate of soda or 'soluble algin.' By evaporation on glass plates or porcelain slabs, the algin is obtained in the form of a transparent flexible sheet, which, however, tends to crack as it approaches dryness, and by immersing this in a very dilute solution of hydrochloric acid it is converted into alginic acid or 'insoluble algin,' which, without altering its appearance, renders the sheet perfectly insoluble in water. The soluble algin is a definite salt of sodium, having the composition, when pure, $C_7H_7O_{22}N_2Na_5$.

Commercial algin or sodium alginate resembles gum arabic, and in the sheet form can scarcely be distinguished from gelatin, from which it differs by the solution not gelatinising, and by giving no reaction with tannin. It is distinguished from albumen by not coagulating on heating; from starch by giving no colour with iodine; from dextrin and gum arabic by its insolubility in dilute acids. All mineral acids, and citric, tartaric, lactic, oxalic, and picric amongst the organic acids, precipitate alginic acid in a gelatinous form.

It precipitates all the alkaline earths as alginates, with the exception of magnesium, the alginate of which is soluble. It precipitates nearly all the heavy metals as alginates, but gives no precipitate with mercuric chloride, nor with potassium silicate. The following analyses show the usual composition of the commercial algin:—

	No. 1	No. 2	Average
Water	17.13	19.30	18.22
Organic matter	59.97	58.13	59.05
Sodium carbonate	18.32	17.78	18.05
Neutral salts	2.98	2.77	2.87
Insoluble ash	1.60	2.02	1.81
		per cent. ash	per cent. ash
	100.00	100.00	100.00
Soda, Na_2O	10.71	10.40	10.55

This substance, known as soluble algin, is sodium alginate, but potassium, ammonium, lithium, or magnesium alginate are all soluble algin, and scarcely distinguishable in appearance. These all present the form of thin flexible sheets, resembling gelatin, and having the same colour, but none are gelatinous. The solution of algin resembles that of gum arabic, which in many of its applications it may be expected to replace; it is quite soluble in cold water, but the solution takes about 12 hours to complete. It is so extremely viscous that a 2 p.c. solution is as thick as a 50 p.c. solution of gum arabic, and a 5 p.c. solution is poured with difficulty out of a

wide-mouthed bottle. Nearly all the mineral acids precipitate alginic acid ($C_7H_8O_{22}N_2$) from the solution as a very gelatinous precipitate; a 2 p.c. solution becomes semi-solid when thus treated. In this respect, it resembles a strong solution of egg albumen, and it can be employed for thickening colours in printing, or as a mordant in the same manner. Alginic acid is insoluble in water, so that in dressing fabrics the soluble algin forms a flexible varnish, which can be converted into a lustrous hard glaze by passing it through a weak mineral acid. This process, which would destroy the ordinary starch and gum dressings, renders it also permanent

and insoluble in water, the fabric becoming waterproof. As the alginates of calcium, aluminium, iron, &c., are all insoluble, the same effect is obtained by the use of solutions of these metals for the final wash. Alginic acid when dry resembles albumen, but it can be obtained also in thin transparent sheets, and readily coloured like gelatin, from which, however, it differs in being insoluble in hot water. It can also be obtained in blocks. Calcium alginate ($C_{76}H_{74}O_{22}N_2Ca_3$) resembles it, but is whiter, like bone.

Aluminium alginate is very soluble in ammonia, and the aluminium ammonia-alginate is insoluble when dry, so that it makes a cheap waterproof varnish. It forms a good mordant or dung substitute in dyeing. Copper alginate is soluble in ammonia, forming a beautiful blue copper ammonio-alginate, which is also insoluble when dry, and makes a varnish useful for waterproofing fabrics which are liable to decomposition or to attacks of insects.

Ferric alginate is also soluble in ammonia, forming a bright red ferro-ammonio-alginate; insoluble when dry, and proposed as a styptic, and for administering iron internally. These metals are most completely precipitated from solution by sodium alginate.

Nickel, cobalt, zinc, cadmium, manganese, chromium, uranium, silver, platinum, tin, arsenic, and antimony all form soluble ammonio-alginates, some of which are beautiful salts. Sodium alginate, mixed with a dichromate, is sensitive to light in the same way as gelatin, the mixture becoming insoluble in water after exposure to light.

Alginic acid is a moderately strong acid, liberating carbon dioxide in the cold from the alkaline carbonates and from magnesium carbonate; in the latter case, the two insoluble substances in the presence of water form soluble magnesium alginate. The use of algin requires a thorough knowledge of its properties, on account of the numerous metallic salts which precipitate it, and with which it is therefore incompatible; these reactions limit to a great extent the application of the substance in solution as a substitute for gum and other bodies used for thickening purposes.

Algulose or algin cellulose contains no fibre, but consists of fine cellular tissue, which makes a transparent and very tough paper. It dries to a hard mass resembling ebony, but denser.

The kelp substitute in this wet process was obtained by evaporating and carbonising the acid liquor from which the alginic acid has been precipitated, after neutralising it with caustic soda. It should contain all the iodine and potash salts of the weed but no sulphides, and should yield about 30 lbs. of iodine to the ton. At the same time, in spite of the advantages which apparently would attend the adoption of this process, the manufacturing costs are so high and the demand for the products, other than iodine and potash salts, is so limited, that the process has not met with success on the commercial scale.

Lixiviation of kelp.—Little improvement has taken place in this process; the same simple method which has been in use for many years is still adopted in the Scotch works.

The kelp reaches the factory in large masses ;

these are first broken up into pieces about the size of road metal. The lixiviation is effected in rectangular iron vats with false bottoms; the vats are coupled together and heated by steam, and treated exhaustively. The whole arrangement is similar in every respect to that adopted in the lixiviation of black ash in the Leblanc process of soda manufacture. The solution is run off at about 40° at 45° Tw. This is evaporated in open hemispherical cast-iron boiling pans, about 9 feet in diameter, and the salts which deposit are fished out. In some works this boiling down is effected in cylindrical wrought-iron closed pans, heated by a coil of steam pipes round the inside of the pan, and provided with mechanical stirrers to keep the deposited salts in suspension. When the liquor is concentrated to 62° Tw., the whole is run out into a settler to allow the salts to deposit, and the supernatant liquor is run off hot into the crystallisers. In both cases the salt fished out or deposited is a crude potassium sulphate, which adheres a good deal to the pan and contains 50 to 60 p.c. of potassium sulphate, mixed with sodium sulphate and chloride. The liquid is run into cylindrical iron coolers, and a crop of potassium chloride crystallises out in two or three days. The mother liquor is again boiled down, and the salt deposited is fished out; this salt is known as 'kelp salt,' and consists of sodium chloride, containing sodium carbonate equal to 8 to 10 p.c. of alkali (Na_2O). The hot liquor is again run into the cooler, and another crop of potassium chloride is obtained. This process is repeated several times, kelp salt being fished out in the boiling pan, and potassium chloride crystallised out in the cooler. These successive crops of 'muriate,' as it is technically called, range in strength from 80 to 95 p.c. of potassium chloride.

The mother liquor is now rich in iodine, and is treated for its extraction. The several salts all contain iodine, and require careful washing to obtain it. These salts are known as 'Kelp salt,' which was formerly used for reducing the strength of soda ash, but is now unsaleable, 'Sulphate,' which is sold at a low price for manurial purposes, and 'Muriate,' which is largely used for the manufacture of saltpetre, potassium carbonate, chlorate, and dichromate, and the prussiates. The residual kelp waste formerly realised about 5s. per ton, and was employed in the common bottle glass manufacture; it consists principally of the carbonates of lime and magnesia, and some phosphates. It is all used as a manure in France, but in this country the farmers have always rejected it.

The following is the analysis of an average sample :

Salts of sodium and potassium	1.50
Carbon	3.09
Calcium sulphate	3.06
„ sulphide	1.70
„ carbonate	20.50
*Calcium and magnesium phosphates	6.72
Magnesium carbonate	6.89
Magnesia	2.22
Silicic acid and sand	20.82
Water	33.50
Total	100.00
*Containing phosphoric acid	2.70

The mother liquor, containing the iodides and bromides, also contains considerable quantities of sulphides, sulphites, and thiosulphates of sodium and potassium; it is mixed with about one-seventh of its volume of sulphuric acid, free from arsenic, about 145°Tw. (sp.gr. 1.725), and allowed to settle for 24 hours. This is effected in a closed lead-lined wooden vessel, provided with means to collect any sulphuretted hydrogen which may be given off. The sulphur compounds are decomposed, and a considerable deposit of sulphur takes place. This is known as 'Sulphur waste'; when dry it contains about 70 p.c. of sulphur, and is used in vitriol making. It also

obstinately retains iodine, and long steaming is required to extract it. The liquor is strained off from the sulphur and run into the iodine still. This was formerly made of lead, but it now assumes the form of a deep hemispherical iron pot, heated by an open fire, and covered with a strong leaden lid, to which are luted two earthenware arms; these are connected with two series of stoneware udells, about ten in each set. These udells have stone stoppers beneath to allow any water containing chlorine, bromine, and iodine to drain off. The apparatus is shown in Fig. 1. Manganese dioxide is added at intervals to the contents of the still, and the

Fig. 1.

iodine is carried over with the steam. The reaction is as follows:

Repeated distillations go on, without changing the udells, until these are full of iodine, the bulk of which, and the best, is found in the udells forming the centre of the series. The deposition of the iodine in successive layers squeezes much of the moisture out, and it is obtained in a firm, well crystallised form. The iodine on removal from the udells still contains moisture, and requires further treatment before the state of purity now demanded by consumers is attained. This old-fashioned process is the only one adopted in this country; many others have been proposed and tried, but have not been commercially successful. Commercial iodine is always sent out in 1 cwt. kegs; the consumption is usually reckoned in kegs, which means 1 cwt. It improves by keeping, becoming perfectly dry; and as it can be stored in a small compass, and often represents considerable value, it has been a favourite commodity for small speculative buyers. Bromine does not pay for the collection, but if it were required the arms would be changed and a simple worm-condensing arrangement of lead or earthenware, or a series of stoneware Woulff bottles attached: a further quantity of manganese dioxide would be added to the still, and the bromine distilled over. The liquor remaining in the still, and known as 'waste still liquor,' is a dense acid liquid of sp.gr. 1.235 to 1.500, containing sulphates of iron, manganese, potassium, and sodium; it is very troublesome to deal with and is run away as useless.

The following is the analysis of an ordinary average sample. One gallon contained 3.327 lbs. of dry salts:—

—	Liquor per cent.	Dry salts per cent.
Potassium sulphate .	5.13	15.42
Sodium sulphate .	9.10	27.36
Sodium chloride .	6.80	20.43
Manganous sulphate .	3.75	11.27
Ferric sulphate .	3.00	9.02
Calcium sulphate .	0.19	0.57
Magnesium sulphate .	0.04	0.12
Sulphuric acid, free .	5.26	15.81
	33.27	100.00

The iodine used for medicine is resublimed in small earthen or porcelain covered pans, and is then known as 'resublimed iodine'; it is obtained in large brilliant plates, and is anhydrous. The pans employed must be shallow, as the vapour is very dense.

When iodine is badly made it may contain white needles, which consist of cyanogen iodide; it is now a rare impurity, but a very poisonous one.

In France a different method is adopted. After the precipitation of the sulphur in the mother liquor by addition of hydrochloric acid in slight excess, and boiling for some time, the clear liquor is drawn off and diluted with water to 40°Tw. Chlorine is then passed into the solution, until saturated, and the iodine is precipitated in a pulverulent form. Sometimes, instead of passing in chlorine, the calculated quantity of potassium chlorate is added to the solution; by interaction with the hydrochloric acid this salt yields the chlorine necessary for the liberation of the iodine. Great care must be taken that too much chlorine is not added, as iodine chloride may be formed, and go off as vapour. The clear liquor is then drawn

off, and the iodine repeatedly washed by decantation to remove the salts. It is drained in earthen vessels with perforated bottoms, and finally dried on porous tiles. It is then resublimed. This is effected in ordinary earthenware retorts with short necks, and heated in a sand-bath in which they are completely immersed, the iodine being sublimed into earthen receivers. To recover the bromine from the liquor after extraction of the iodine, it is evaporated to dryness, and the residue is distilled in a leaden retort with sulphuric acid and manganese dioxide; it is collected in a receiver under strong sulphuric acid. The production of iodine in France has fallen off considerably; it is all used locally, either resublimed or made into potassium or other iodide, for which purpose the precipitated damp iodine suffices.

In Norway there are now nine or ten works engaged in the extraction of iodine from kelp. In Japan the chief kelp-producing districts are the province of Shima and the island of Hokkaido, but nearly all fishery districts yield a little. The industry is more or less scattered along the coast of Japan and is in the hands of many small producers, from whom the firms of iodine makers procure their supplies.

The Scottish seaweeds are considerably richer in iodine than the giant algae of the Pacific and the Japanese seaweeds. In the United States the weed is collected at sea by a boat fitted with a power-driven cutting device which can be lowered to about 8 feet below the keel. From the boat the weed is delivered to an elevator, and carried to a closed drier, in which it is kept in constant motion at not above 100°. The dried weed is calcined at not above 400° in a brick kiln having a fire-clay lining, and a cast-iron grate through which air enters. The volatile products pass to condensers through a tar chamber, kept at a uniform temperature at the top, and superheated at the bottom. The ash is treated for the recovery of potassium salts, iodine, &c. (Board of Agriculture for Scotland Report, 1914, 118; *cf.* Turrentine, *Met. & Eng. Chem.* 1917, 16, 196; Higgins, *idem*, 1918, 19, 432).

Iodine from caliche. This mineral, the crude sodium nitrate of Peru and Chile, now forms by far the most important source of iodine. It contains iodine in the form of sodium iodate, which accumulates in the mother liquors from which the sodium nitrate has been crystallised. The proportion of iodine in the caliche varies considerably in the different deposits; in some it is absent altogether, in others it runs as high as 0.17 p.c. or 3.8 lbs. per ton; usually it does not exceed 0.02 p.c.

There are about 150 nitrate factories in Chile, but many of these are old and well worked out, and some are so badly situated as regards position and the raw material is of such a low grade, that they cannot work at a profit, and consequently are closed. At present about 100 factories are in operation, and their production of nitrate amounts to from 2,400,000 to 2,500,000 tons annually. Most of the factories are provided with plant for the extraction of iodine from the mother liquor, but, as their power of production of iodine is largely in excess of the world's power of consumption, the manufacturers have combined to restrict the output. The basis of the

power of production of these factories is put down at 115,000 Spanish quintals (about 5100 tons) per annum, whilst the total quantity consumed is only a fraction of this amount. A certain percentage of the iodine sold in Chile year by year is allotted to each factory, and consequently there are rarely more than a few months in each year during which iodine is made, and there is always a very large stock in hand. The exports are naturally kept as nearly as possible equal to the requirements, but if any large increase in consumption took place there is no doubt that Chile could supply four or five times the quantity at present exported annually. The cost of recovering iodine as a by-product of the sodium nitrate industry is, in many cases, not more than from 1½d. to 2d. per oz.

It first came over in quantity in 1874, about 497 kegs. In the following year, 900 kegs were exported, and since then the export has continually increased. It was at first a very crude article, containing little over 50 p.c. of iodine, and a good deal was exported in the form of copper iodide. It is now, however, sent over in a pure state.

The following is the analysis of one of the samples of iodine sent from Peru in 1874:

Iodine	52.53
Sodium iodate	1.26
" nitrate	11.62
Potassium nitrate	2.49
" sulphate	1.78
Iodine chloride	3.34
Magnesium chloride	0.36
Insoluble matter	1.52
Water	25.20

100.10

In 1877 the total production of iodine in Scotland was estimated at 1200 kegs; in France at 800 kegs. The present output does not reach these figures.

Japan began to export iodine in 1902, when 35 cwt. were sold. In 1904 the quantity exported was 612 cwt., in 1906 (consequent upon a fall in the price of iodine) only 196 cwt., and in 1907, 305 cwt.

In 1882, the export of iodine from Chile was 4116 cwt., in 1901 it had risen to 5280 cwt., and in 1912 it amounted to 7900 cwt., of a value of about 350,000*l.* This is about four times the present total production of the rest of the world.

The quantity of iodine sold throughout the world in 1887 was 6375 cwt., of which about 1000 cwt. were used in colour making. The present average annual consumption may be taken at nearly 10,000 cwt.

The final mother liquor, or 'aqua vieja,' from which the sodium nitrate has been crystallised, contains sodium iodate, nitrate, chloride, and sulphate, and magnesium sulphate. A good liquor contains about 0.3 p.c. of iodine.

It is run into wooden vats and the iodine is precipitated; the agent employed is sodium bisulphite in solution. The exact amount of iodine in the mother liquor is estimated, and a definite quantity of the solution is added to completely precipitate the iodine. As the bisulphite solution is run into the 'aqua vieja,' the liquid is stirred either by wooden paddle-wheels or by air forced up from perforated pipes

at the bottom of the tanks. The latter method is quicker and more efficient, but the air carries away some of the iodine from the solution. The

solution is then neutralised by addition of 'sal natron' liquor and again well stirred. After some time, most of the iodine settles to the

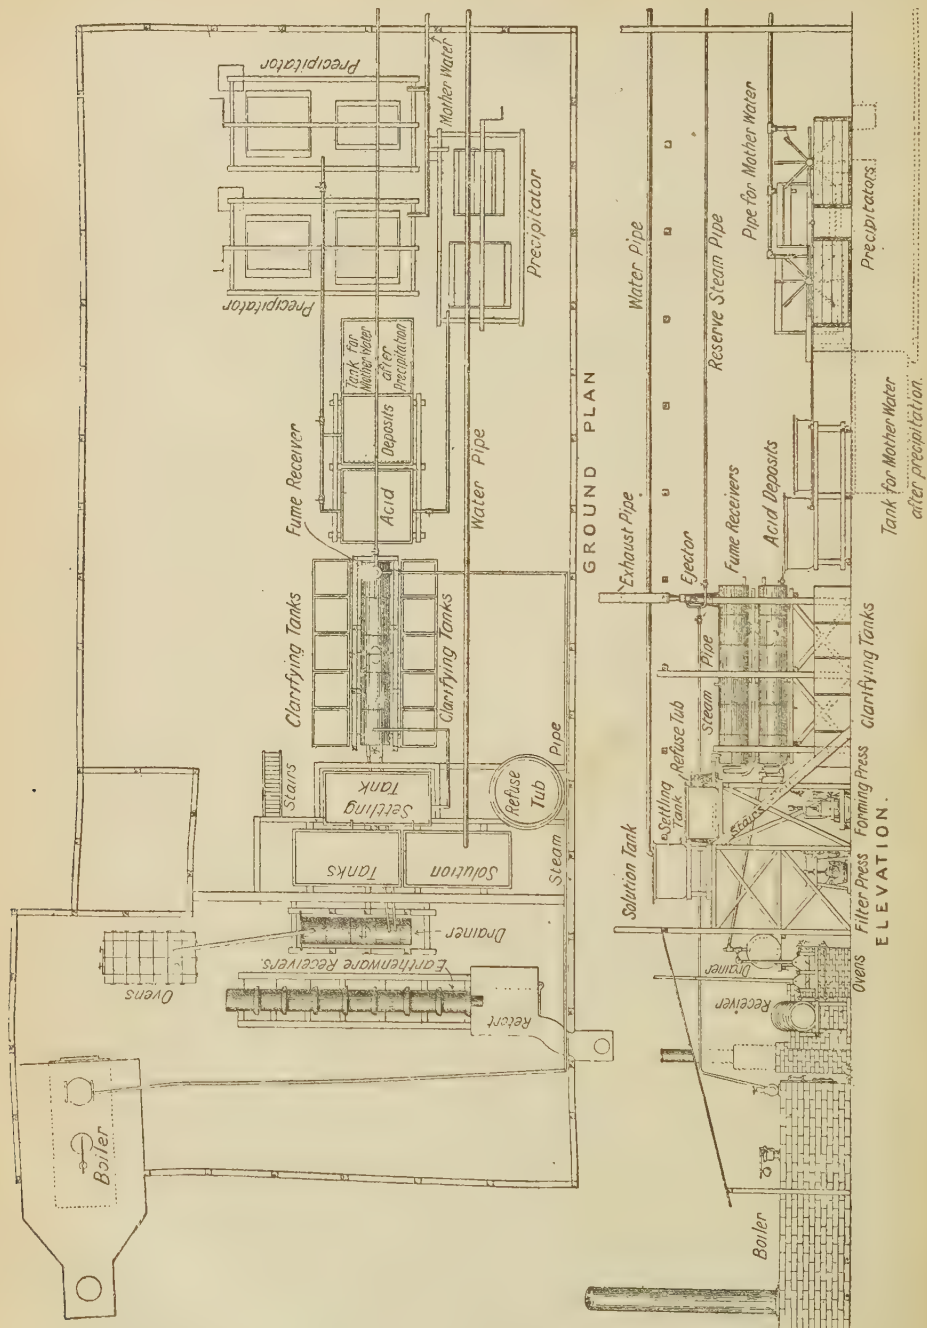

Fig. 2.

bottom of the tank; any little that remains floating is removed by a calico bag at the end of a stick. The supernatant liquid is drawn off and used over again with the nitrate liquors.

The iodine is washed with water, and pressed into thick cakes. It then contains 80 to 85 p.c. of iodine and 6 to 10 p.c. of mineral matter, and requires to be purified by resublimation. This

is effected in a cast-iron retort, to which eight earthenware condensers or udells are attached in series. The retort is heated by a slow fire, and when the operation is completed the retort is allowed to cool, and the iodine removed from the udells. It is thus obtained pure. The complete plant is shown in the descriptive plans Figs. 2 and 3.

The sodium bisulphite is prepared by passing the fumes of burning native sulphur into a solution of 'sal natron' or sodium carbonate. The

sulphur, which is one of the many minerals found in this interesting region, is burned on an iron plate in a plain iron oven, and the fumes drawn by a steam injector into perforated pipes in the solution of sal natron. The manufacture of this substance is also peculiar to the district. It is obtained by burning together 85 parts of crude sodium nitrate, obtained from the 'aqua vieja' tanks, and 15 parts of coal. The mixture is made in the form of a cone 5 feet high, with a space of 2 feet dug out round the base. It is

FIG. 3.

saturated with water and ignited; the sodium carbonate thus formed fuses and runs out into the pit. It is dissolved in water, and the solution is pure enough for use in this process, the impurities consisting of sodium sulphate and chloride, the unburnt coal being left in the residue undissolved.

Uses of iodine.—About one-fifth of the total consumption of iodine is employed in the manufacture of aniline colours; a good deal of this is recovered and used again. It is principally used in the manufacture of Hofmann violet, and aniline green in the form of methyl iodide; also for making erythrosin and the blue shade eosins, in which iodine is made to react upon fluorescein. Some substitution products are occasionally made, such as the ethylated chrys-aniline. A small quantity is used in photography, but the bulk of the iodine of commerce is employed in medicine. Iodine, iodoform,

and the iodides of arsenic, iron, lead, mercury (red iodide), potassium, sodium, and sulphur are all official in the British Pharmacopœia; the preparations employed will be referred to under their respective names. Hydriodic acid, ethyl iodide, and iodides of ammonium, cadmium, mercury (green iodide), and starch are also used in medicine, and each will therefore be noticed. Iodine, if pure, should sublime without residue, and the portion subliming first should not include any slender colourless prisms emitting a pungent odour (cyanogen iodide). A solution in chloroform should be perfectly clear, denoting absence of moisture. The British Pharmacopœia directs that 0.5 gram dissolved in 50 millilitres of water, containing 1 gram of potassium iodide, should require for complete decoloration at least 39 millilitres of the *N*/10-solution of sodium thiosulphate.

It is employed in the B. P. in the form of

Tinctura iodi fortis and *Tinctura iodi mitis*, and *Unquentum iodi*. In the tincture it is dissolved with potassium iodide in rectified spirit and water. In the ointment the same ingredients are employed, substituting lard and glycerin for the spirit.

A volumetric solution of iodine dissolved in potassium iodide is used in the laboratory for titrating solutions of arsenious acid, sulphurous acid, and sodium thiosulphate. It contains 12.7 grams of iodine in 1000 c.c., and corresponds to 1.7 gram of sulphuretted hydrogen, 3.2 grams of sulphur dioxide, and 4.95 grams of arsenious oxide. Iodine is also used for testing oils, which differ as to the amount absorbed, and some can be distinguished from others by this means (*v. OILS, FIXED, AND FATS*).

Other unofficial preparations of iodine are also employed in medicine. *Glycerinum iodi* is iodine dissolved in glycerol, used for external application. *Pigmentum iodi*, Coster's paste, is iodine dissolved in light oil of wood tar, and used for ringworm. *Tinctura iodi decolorata* is a tincture made with rectified spirit, and in which the iodine is decolorised by ammonia. It is used for chilblains. *Collodium iodi* is flexible collodion containing 30 grains of iodine to the ounce, and is very useful for painting on wounds. Carbolic iodine solution is a colourless mixture of tincture of iodine, phenol, and glycerol in hot water; it is used as a gargle or pigment in diphtheria, and internally for Asiatic cholera.

Medicinal properties of iodine.—Iodine was first employed in medicine in the form of burnt sponge, a remedy long used in treating goitre. When administered internally it is usually in combination with an alkali; taken alone it is an irritant poison. It is a most powerful alterative, improving the blood and stimulating the absorbents. It is antisyphilitic and antiscrofulic. In syphilis, scrofula, and chronic rheumatism it is largely used, and especially in swellings of the joints and enlarged glands, which are also treated by painting externally with tincture of iodine, in which it acts as a counter-irritant. It has a remarkable power in expelling both mercury and lead from the system. The vapour mixed with steam from hot water is useful in inhalation for many affections of the air passages. Long-continued use may give rise to the depressing nervous train of symptoms known as iodism, and for which belladonna is employed as an antidote. Copious drinks of solution of starch form the antidote in cases of poisoning. Used alone, iodine is a powerful disinfectant and decoloriser, acting in the same way as chlorine. It may be allowed to evaporate spontaneously, but is very apt to colour the sheets, blinds, or anything dressed with starch; it is also used in candles, the burning of which volatilises it.

Hydrogen iodide HI is a colourless gas, very soluble in water and resembling hydrogen chloride; it forms dense white fumes in the air; its sp.gr. is 4.3737. Mixed with dry oxygen and exposed to bright sunshine it is rapidly decomposed with liberation of iodine. It liquefies under pressure, b.p. -35.5° ; m.p. -50.9° ; latent heat of vapourisation, 21.6×10^{10} ergs. It is composed of equal volumes of iodine and hydrogen, and contains 99.2 p.c.

of its weight of iodine. The aqueous solution is colourless, but on exposure to air it becomes coloured by the deposition of iodine from oxidation. It is decomposed by sulphuric and nitric acids, and by chlorine and bromine, which set the iodine free. By passing the gas into ice-cold water a solution may be obtained of sp.gr. 1.99.

The following table shows the relative percentage of hydriodic acid at different specific gravities:—

Sp.gr. at 15°	Per cent. of acid
1.708	51.9
1.551	47.2
1.442	39.2
1.297	30.3
1.175	18.5
1.083	5.9

It is usually prepared in solution by passing sulphuretted hydrogen into water in the presence of iodine: $\text{H}_2\text{S} + \text{I} = 2\text{HI} + \text{S}$. At first the action is slow on account of the deposition of sulphur covering up the iodine and preventing its solution; the hydriodic acid when formed, however, dissolves an increasing proportion of iodine, and by the gradual addition of iodine and water as the action progresses, large quantities of hydriodic acid may thus be obtained up to a sp.gr. of 1.56.

A modification of this process for very pure acid has been proposed by Winkler. The iodine is dissolved in carbon disulphide, and the solution covered with a stratum of water; when the sulphuretted hydrogen passes into the mixture, the hydriodic acid dissolves in the water, and the sulphur in the carbon disulphide. The aqueous solution only requires boiling for a few minutes to expel the sulphuretted hydrogen, and to obtain the hydriodic acid quite pure.

Another method was suggested by Kolbe. One part of amorphous phosphorus is added to 15 parts of water in a tubulated retort filled with carbon dioxide, and 20 parts of iodine gradually added. The resulting liquid is allowed to stand and then heated for a short time, cooled, mixed with 4 parts of water and distilled. It yields a colourless acid free from uncombined iodine: $\text{P} + 5\text{I} + 4\text{H}_2\text{O} = 5\text{HI} + \text{H}_3\text{PO}_4$. It may also be obtained by heating potassium iodide with a syrupy solution of phosphoric acid. Hydriodic acid is employed in the manufacture of some of the iodides, and is used in medicine in the form of syrup.

Iodic acid HIO_3 . This acid is usually prepared by boiling iodine in strong nitric acid, free from nitrous acid. It is, however, best obtained by the oxidation of iodine by chloric acid in about 25 p.c. strength:

Iodic acid is deposited in crystals of sp.gr. 4.487. When heated it gives off water, and iodine pentoxide I_2O_5 is obtained in small white crystals. It is very soluble in water, and easily decomposed by reducing agents forming hydriodic acid and free iodine. For reduction of iodic acid solutions with sulphurous acid, see Landolt, Ber. 1886, 19, 1340; 1887, 20, 745; Patterson and Forsyth, Chem. Soc. Trans. 1912, 101, 40.

The normal iodates have the general formula MIO_3 . Acid iodates are also known.

Potassium iodate KIO_3 forms small white cubic crystals. It may be obtained by carefully heating a mixture of 2 mols. potassium chlorate and 1 mol. iodine $2\text{KClO}_3 + \text{I}_2 = 2\text{KIO}_3 + \text{Cl}_2$, or by the electrolysis of potassium iodide in presence of potassium chromate. Sodium iodate NaIO_3 crystallises in small eight-sided prisms. Both salts are poisonous. Both are obtained in considerable quantity in the manufacture of the respective iodides by No. 2 process as described below. The iodates can easily be separated by taking out the first salts deposited on evaporation, as these are less soluble than the iodides. If iodic acid were required on the large scale, it could be easily made as a by-product of the iodide manufacture by crystallising out the iodate before fusion, and precipitating it with barium chloride as barium iodate. This is then decomposed by sulphuric acid.

Iodine iodate $\text{I}(\text{IO}_3)$ may be prepared by the action of ozone on iodine, or by warming iodic acid with concentrated phosphoric acid (D 170). Oxygen and then iodine are evolved and a yellowish-white precipitate formed.

Periodic acid is known only in the form of a hydrate $\text{HIO}_4 \cdot 2\text{H}_2\text{O} (\text{H}_5\text{IO}_6)$. It is a colourless crystalline deliquescent solid, m.p. 133° . On heating it is completely decomposed into iodine pentoxide, water, and oxygen. It may be obtained by electrolysis an aqueous solution of iodic acid contained in a porous cell immersed in dilute sulphuric acid, the lead anode coated with lead peroxide being placed in the iodic acid solution and a platinum cathode in the sulphuric acid. The various periodates may be grouped as derived from *metaperiodic acid*, HIO_4 ; *diperiodic acid*, $\text{H}_4\text{I}_2\text{O}_9$; *mesoperiodic acid*, H_3IO_5 ; and *paraperiodic acid*, H_5IO_6 .

Iodine trichloride ICl_3 is obtained in orange-yellow crystals by passing chlorine into a flask containing iodine vapour sublimed from a small retort. It is a very active disinfectant and germicide in solution of 1 to 1000. It has been used in medicine internally. In contact with organic matter, chlorine and iodine are liberated in a nascent state.

Iodine perchlorate $\text{I}(\text{ClO}_4) \cdot 2\text{H}_2\text{O}$, greenish-yellow needles, formed by dissolving iodine in anhydrous perchloric acid, cooled by ice and salt, and oxidising with ozone. The water is due to the reaction with ozone:

Cyanogen iodide CNI . This very poisonous substance is interesting as forming an occasional impurity in commercial iodine; it is very seldom met with now, and ought never to be present if the manufacture is properly carried out. Its occurrence is probably due to an insufficient addition of oil of vitriol to the saturating vat or to the iodine still. It is usually prepared in the laboratory by the distillation of iodine with mercuric cyanide, or by dissolving iodine in concentrated solution of potassium cyanide. It presents the appearance of exceedingly fine silky needles, colourless, and very volatile, even at ordinary temperatures, and with a penetrating pungent odour which excites tears. It sublimes without change. It is sparingly soluble in water, easily so in alcohol, and in ether, and also in fixed and volatile oils. The aqueous solution

does not give the starch reaction of iodine, nor does it precipitate silver nitrate.

Sulphur iodide S_2I_2 is a dark crystalline substance, obtained by gently heating in a glass flask 1 part of sulphur with 4 parts of iodine until the mixture liquefies; the flask is then broken, and the crystalline mass removed. It appears to be a solid solution of sulphur and iodine. It is insoluble in water, but soluble in glycerol. It has the odour and staining properties of iodine. It is occasionally used in medicine externally in skin diseases applied in an ointment.

Arsenic tri-iodide AsI_3 . This substance forms small orange-coloured crystals, soluble in water and in alcohol; it has a neutral reaction, and gives a yellow precipitate with sulphuretted hydrogen. Heated in a test-tube it almost entirely volatilises, violet vapours of iodine being set free.

It is prepared by direct combination of metallic arsenic and iodine, or by evaporating together to dryness solutions of arsenious and hydriodic acids. The Pharmacopœia preparation is *Liquor arsenii et hydrargyri iodidi*, 1 gram of each ingredient in 100 millilitres, and the dose is 3–12 decimils.

Nitrogen iodide $\text{N}_2\text{H}_3\text{I}_3$ or $\text{NH}_3 \cdot \text{NI}_3$ is a dark brown powder, obtained by adding iodine to excess of solution of ammonia, or by the action of ammonia on iodine chloride containing free hydrochloric acid. It is a most violent explosive, but its action is uncontrollable, and it is impossible to keep it in safety. It has therefore found no commercial application, but has been proposed as a chemical photometer on account of the ease with which it is decomposed by light in presence of excess of ammonia (v. Guyard, *Ann. Chim.* [vi.] 1, 368).

Iodo-azoimide N_3I is formed by the action of an ethereal solution of iodine on silver azoimide at 0° . It is a white solid and very explosive, forming nitrogen and iodine.

Ammonium iodide NH_4I . This is a white crystalline salt, very deliquescent and becoming yellow on exposure to air. It is prepared by saturating hydriodic acid with ammonia, by shaking powdered iodine with hydrogen peroxide solution and gradually adding ammonia solution, or by decomposing iodide of iron with ammonium carbonate and filtering off the iron precipitate. The solution in each case is evaporated and set aside to crystallise. It is used in photography, and also in medicine instead of potassium iodide, especially in rheumatism, as causing less depression than the potassium salt. It must be kept from the access of light and air, as iodine is freely given off. It is soluble in alcohol.

Bromine acts upon it with formation of ammonium bromoiodobromide $\text{NH}_4 \cdot \text{BrI}_2\text{Br}$, crystallising in large ruby-red prisms, green by reflected light. Similar compounds are formed by the iodides of potassium, caesium, and rubidium, but not with sodium.

Potassium iodide KI . This is the most important of the iodides, and forms a considerable article of manufacture, as the greater portion of the iodine of commerce goes into consumption in this form. It is a colourless and odourless salt crystallising in large cubes,

and permanent in the air. It contains no water of crystallisation, and is very soluble in water, dissolving in two-thirds of its weight. It is also soluble in alcohol. There are three methods employed in the manufacture.

1st. Hydriodic acid is saturated with potassium carbonate, and the solution evaporated and crystallised. This is the most direct method, and there is no loss; it gives a pure product, but it is expensive and tedious.

2nd. Iodine is dissolved in solution of caustic potash. This produces a mixture of potassium iodide and potassium iodate; the reaction is $3\text{I}_2 + 6\text{KOH} = 5\text{KI} + \text{KIO}_3 + 3\text{H}_2\text{O}$. The solution is evaporated to dryness, a little charcoal is added, and the product fused in an iron pot at a red heat until all the iodate is decomposed, and potassium iodide alone remains. The mass is dissolved in water, the solution filtered and crystallised.

3rd. Iodide of iron is first prepared by the addition of iron borings and iodine to water; the latter must be added gradually to keep down the temperature; the solution is filtered, mixed with potassium carbonate and the iron precipitate washed and filter-pressed. The solution is then evaporated to dryness and the residue redissolved and crystallised.

This process is that most commonly adopted by manufacturers. The crystallisation is performed in enamelled iron pans, surrounded by a steam jacket in brickwork, and very gradually cooled. The best crystals are obtained on fluted glass rods suspended in the liquid.

Potassium iodide is used in photography, but medicine is the principal outlet, and requires a large consumption. It is a powerful alterative, diuretic, and absorbent; and is much administered internally, especially in rheumatism and syphilis. Its properties are similar to those of iodine. As iodine is freely soluble in potassium iodide solution, it presents an excellent form for its internal administration.

It must contain no iodate; this is easily detected by the addition of tartaric acid and starch solution, which sets free hydriodic acid, and if there be any trace of iodate present, free iodine is liberated, as shown by the blue colour of the iodide of starch. Potassium iodide should not contain water, and therefore should not lose weight when heated; it should contain no sulphate, and therefore give no precipitate with barium chloride insoluble in nitric acid. A feeble alkaline reaction from the presence of a slight trace of carbonate, indicated by cloudiness with lime or baryta water, soluble in nitric acid, is allowed by the London Pharmacopœia (but not by the German) as tending to retain the colour of the iodide when long kept. Chlorides of potassium or sodium are a common impurity; the presence of a chloride is shown by precipitating with silver nitrate, and agitating the precipitate with ammonia. The ammonia solution should give no precipitate with nitric acid. 0.5 gram should require for complete precipitation not less than 29.8 or more than 30.5 millilitres of N/10-solution of silver nitrate. It is almost impossible to obtain this salt, when made on the large scale, quite free from chloride (the B.P. allows a 'very little') as potassium carbonate cannot be prepared in quantity without it; a good iodide contains:

Potassium iodide	99.4
„ chloride	0.2
Water	0.4
	<hr/> 100.0

This salt is official in the following preparations. *Linimentum potassii iodidi cum Sapone*, *Liquor iodi*, *Tinctura iodii*, *Unguentum iodi*. Potassium iodide is sometimes administered in large doses, and it is important medicinally that it should contain no iodate, as this salt is poisonous; it must not be prescribed in mixtures containing potassium chlorate, for this salt decomposes it, forming iodate.

Sodium iodide NaI. This salt is obtained as a deliquescent white crystalline powder, soluble in two-thirds of its weight of water. It may be prepared by the same methods as the corresponding potassium salt; that from ferrous iodide is usually employed, and the solution is simply evaporated to dryness. It crystallises in anhydrous cubes and also in hexagonal plates, having the formula $\text{NaI} \cdot 2\text{H}_2\text{O}$. It is used in medicine for the same purposes as potassium iodide, but the principal application is as a precipitant of silver and gold from the weak copper ores of the Tharsis and other copper-extracting companies. The same tests as with the potassium salt may be used for its purity; 1 gram requires 66 c.c. of the volumetric solution of silver nitrate for complete precipitation.

All the alkali iodides when dry absorb bromine and chlorine forming additive compounds of the type MIX_2 and MIX_4 , where X is the added halogen, see Wells and Wheeler (Amer. J. Sci. 1892, [iii.] 44, 42; Filhol, J. Pharm. Chim. 1839, 25, 435, 506; Rae, Chem. Soc. Trans. 1915, 107, 1286; 1918, 113, 880).

Ferrous iodide FeI_2 is a crystalline green deliquescent mass. It is employed in medicine in the form of syrup of iodide of iron, in which it can be better preserved. It is a tonic alterative useful in anæmia of scrofulous patients, especially children.

A similar syrup of manganese iodide is also sometimes used in medicine.

Zinc iodide ZnI_2 . An easily fusible compound which sublimes in needles. It is prepared in the same way as the iron salt, and obtained by evaporation as a white crystalline deliquescent salt. It is sometimes used in photography.

Lead iodide, or Plumbic iodide, PbI_2 , is a brilliant yellow powder, made by precipitating a solution of lead nitrate with potassium iodide, and washing and drying the precipitate. By boiling the powder in water, and allowing the solution to cool, it is obtained in bright yellow crystalline scales. It is employed in medicine externally in the form of ointment.

Mercurous iodide HgI_2 , or Green iodide of mercury, is a green insoluble powder, which darkens on exposure to light. It is prepared by rubbing together in a porcelain mortar the equivalent proportions of mercury and iodine, and moistening the mixture with alcohol until the metallic globules cease to appear and a green powder is obtained. This must be dried in the air in a dark room, and preserved in a bottle put away from the light. It can be obtained in yellow crystals by sublimation. It is insoluble in water and alcohol (*v. MERCURY, COMPOUNDS OF*).

Mercuric iodide, or *Red iodide of mercury*, HgI_2 . This is a brilliant scarlet powder, known as Chinese vermilion. It may be prepared in the same manner as the green iodide, using double the equivalent of iodine; but a better product is obtained by precipitation. A solution of mercuric chloride, or corrosive sublimate, is precipitated with potassium iodide, both salts being dissolved in boiling water; the precipitate is washed and dried over the water-bath. By sublimation it may be obtained in large and beautiful crystals, which when hot are yellow, but reassume their scarlet colour on cooling. It is insoluble in water, but very soluble in solution of potassium iodide. This solution contains a double iodide of mercury and potassium and is used in analysis as a precipitant for alkalis. It forms a pigment more brilliant than vermilion, but it is not much used for this purpose, as it is easily altered by exposure. It is employed in medicine, especially in syphilis, in doses of a thirty-second to an eighth of a grain, and also externally as an ointment. The official preparations are *Liquor arsenii et hydrargyri iodidi* and *Unguentum hydrargyri iodidi rubri*. It has been used as a germicide for washing wounds, instead of corrosive sublimate, which is not so effective and is more poisonous. It has also been used as an antifermentive in tanning (*cf.* MERCURY, COMPOUNDS OF).

Bismuth iodide BI_3 is a red powder obtained by precipitation from bismuth nitrate by potassium iodide. It has been introduced into medicine as a substitute for iodoform in treating wounds. It has no odour. This iodide is soluble in potassium iodide, forming a double iodide employed in analysis as a precipitant for alkalis.

Silver iodide AgI . This salt occurs native, in hexagonal crystals, as *iodargyrite* or *iodyrite*. It is obtained by precipitation from a solution of silver nitrate and any soluble iodide. This salt is not employed commercially in this form. It is the active salt of iodine which is used in photography. It is the form in which iodine is often precipitated and weighed. It is almost insoluble in ammonia, but soluble in potassium iodide and cyanide, and in sodium thiosulphate.

Palladium iodide PdI_2 . This is a dark-brown powder, interesting as a form in which palladium is estimated in analysis.

Cuprous iodide Cu_2I_2 . When solutions of potassium iodide and cupric sulphate are mixed, only half the iodine is precipitated as cuprous iodide, the other half being set free, according to the following equation:

It is necessary, therefore, to add a reducing agent as sulphurous acid or sodium thiosulphate, but ferrous sulphate is usually employed; the whole of the iodine is then thrown down as cuprous iodide

The former reaction was proposed by Soubeiran as a method of obtaining iodine from kelp liquors, but it has not been much used.

Cuprous iodide is a white crystalline solid, insoluble in water; on exposure to a red heat it fuses to a brown mass. The iodine can be

separated from it by heating it with manganese dioxide or strong sulphuric acid. Or it may be decomposed by boiling with water and zinc, which yields zinc iodide and metallic copper. Or it may be treated with potassium or sodium hydroxides or carbonates, which decompose it, forming cuprous oxide and potassium or sodium iodide. With ammonia it combines, forming ammonio-cuprous iodide $\text{CuI} \cdot 2\text{NH}_3$; a white crystalline powder.

Iodide of starch, or *Iodised starch*, is a dark blue powder obtained by triturating iodine with a little water and adding gradually starch in powder until it assumes a deep and uniform colour, and drying at a low temperature. It is decolorised at 100° . It has been used in medicine as a mild form of administering iodine internally, and in the form of a paste to cleanse and heal foul sores and ulcers.

Estimation of iodine.—The violet vapour of free iodine is characteristic, and there are also four very sensitive tests for iodine and iodides: for the former the blue colour test with starch, and the crimson solution in chloroform, benzene, or carbon disulphide; for the latter the precipitation as silver or palladium iodide. All these can be employed in estimating iodine, the colour tests by comparison with standard solutions, and the gravimetric tests by weighing the iodine as silver iodide or palladium iodide. Insoluble iodides must be converted into alkaline iodides before precipitation by silver nitrate or palladium chloride. This may be effected by fusing with sodium carbonate, or preferably by a mixture of this and potassium carbonate. Another method for a metallic iodide is to suspend it in water and pass sulphuretted hydrogen through the mixture; the metal is precipitated as a sulphide, and hydriodic acid formed. Silver iodide is generally heated with zinc and dilute sulphuric acid, the silver is reduced to the metallic state, and zinc iodide remains in solution.

If the iodine exists in the form of a soluble iodate it must be reduced to an iodide by sulphurous acid. With organic iodides it is usual to ignite with pure sodium hydroxide.

In the colour tests, the iodine must be set free by bromine, chlorine, or, preferably, nitrosulphuric acid. The starch method, owing to the easy decomposition of the iodide of starch, is not generally available, but the separation of the iodine from solution by a solvent forms a process of great accuracy, of easy and rapid execution, and of general application. In estimating the iodine in kelp or seaweed ash, or kelp substitute, the following process is adopted. Kelp is not an easy cargo to sample. There is often great difference in the value of the large masses forming the cargo. Stones and sand are a frequent cause of annoyance; stones are often found fused into the centre of a block of kelp, and forming most of the block. These can only be detected by breaking up all the large pieces. With seaweed ash, or charcoal, or kelp substitute there is no difficulty. Where there is much sand the kelp is more friable. The sand is generally composed of shells, and is mostly carbonate of lime; but it is sometimes quartz, flint, or other forms of silica. To ensure an accurate sample, about 100 lbs. are carefully picked from a cargo of, say, 100 tons, and ground up. A portion of this is finely powdered and

kept as a sample for reference. Of this, 5 grams are taken to estimate the moisture, another 5 grams are taken to estimate the soluble matter, the carbon, and the ash, also the potash and the iodine in the soluble matter. The kelp is treated with about 75 c.c. of hot water, which dissolves little or none of the oxysulphides. This operation is repeated and the residue washed, and the solution made up to 250 c.c. In a portion of this the potash is estimated by platinum tetrachloride. For estimating the iodine, one-tenth part or 25 c.c., equal to 0.5 gram of kelp, is taken. This will not contain more than 5 milligrams of iodine, generally about 2 milligrams, often only 0.5 milligram. If the amount exceeds 5 milligrams, it is advisable to dilute the solution with an equal bulk of water. Five c.c. of carbon disulphide are then added and a few drops (one to three) of nitro-sulphuric acid dropped in. This reagent is prepared by treating starch with nitric acid, and passing the nitrous fumes into sulphuric acid of 1.843 sp.gr. to saturation. The mixture keeps perfectly well. The testings are performed in large even test-tubes, and compared with graduated standard solutions of potassium iodide treated in precisely the same manner. By this method $\frac{250000}{250000}$ th part of iodine is easily detected and measured, and up to $\frac{1}{100000}$ th part the estimation is very accurate. It has several advantages over the use of starch, as besides the introduction of an organic substance liable to change, the blue colour of the iodide of starch is distributed over the whole liquid, and when dilute can only be seen by looking down the length of the tube. Moreover, the solution is not transparent, and the indications are not sharp enough for accurate quantitative work, though useful often in testing. The carbon disulphide method is quite as sensitive, and the iodine is removed from the solution and concentrated in a sixth of the volume at the bottom of the tube. The maximum effect, which takes time with the starch, is immediate in this case. The carbon disulphide solution of iodine can be removed, and the iodine recovered from it by an alkali for further experiment if desired, but it is quite unnecessary for accurate results. It is usual to remove it from the disulphide by zinc in the presence of water, so that the reagent can be used over and over again. Many years of experience of this and other processes have shown that this is the only one to be relied on where many such estimations have to be performed daily, especially in kelp and its products, which contain such a small proportion of iodine. If the iodine is to be determined in a seaweed or other organic material, the sample must always be carbonised in a small iron retort or close crucible, and not burnt to ash in an open crucible. The salts are washed out from the charcoal, and the carbon and ash estimated by burning the residue. If this be not done, it is almost impossible to completely burn away the carbon in the presence of so much alkaline salts which at a high temperature fuse and cover it over. If, moreover, a long time is taken, as it must be, over an ordinary Bunsen burner, a large portion of the potash and all the iodine may be easily burnt off. If the salts contain magnesium, as all those from seaweeds do, it is necessary to make sure that there is an excess of alkali pre-

sent, or the iodine will be rapidly burnt off. In kelp and seaweed there always is sufficient alkali, and this precaution is unnecessary, but where the object is to estimate iodine in organic substances containing it in minute traces, more caustic soda should always be added before carbonising. As all seaweeds also contain soluble sulphates which become reduced to sulphides and oxysulphides when burnt to ash, carbonisation presents another advantage, as it prevents this change.

Palladium chloride is the only reagent which can be relied on for the direct gravimetric estimation of iodine in mixed liquors containing chlorides and bromides. The kelp liquor must be mixed with hydrochloric acid and set aside in a warm place till the sulphur compounds are decomposed, it is then filtered off and precipitated with palladium chloride, and allowed to stand for some time. The black precipitate of palladium iodide may be washed with hot water, and lastly with a little alcohol, dried at a gentle heat, and weighed on a tared filter; 100 parts contain 70.45 parts of iodine. Or it may be ignited in a platinum crucible, and the iodine calculated from the weight of the palladium left; 100 parts of palladium are equal to 237.9 parts of iodine. If chlorine is also to be estimated in the same liquid, palladium nitrate must be substituted for the chloride. If bromine is also present the chloride must be used, or a soluble chloride must be added, or the bromine will be precipitated with the palladium iodide. This method gives discordant results with kelp, on account of the cyanides often present. Free alkalis, chlorine, and bromine also prevent the precipitation.

In 'caliche' the iodine exists as an iodate, and this must be first reduced to an iodide by sulphurous acid or sodium bisulphite. There are several methods of estimating iodine, bromine, and chlorine, directly and indirectly, when present together. A very simple method of separating these elements directly is to distil over the iodine first by boiling with ferric sulphate; it may be condensed in solution of potassium iodide and titrated with sodium thiosulphate. The bromine is then separated from the residue in the retort, which has been allowed to cool, by gently warming the solution after addition of potassium permanganate, and distilling it into solution of ammonia in excess, in which it is titrated with an acid; or estimated gravimetrically by precipitation as silver bromide. The chlorine can be estimated in the residue or by difference from a determination of the total quantity of chlorine, bromine, and iodine in the original substance by precipitation as silver salts. Another method is to distil over the iodine with a concentrated solution of potassium dichromate; after the iodine is removed the addition of a little sulphuric acid to the retort will set free the bromine, the chlorine can then be determined as in the last process.

Field's method of separating these three halogens is to divide a solution into three equal parts; each portion is precipitated by silver nitrate. No. 1 is washed, dried, and weighed. No. 2 is digested with potassium bromide, then washed, dried, and weighed. No. 3 is digested with potassium iodide, then washed, dried, and weighed. No. 1 contains the silver chloride, bromide, and iodide. No. 2 contains only silver

bromide and iodide, the chloride having been by this process converted into bromide. No. 3 contains silver iodide only, the chloride and bromide having been both converted into iodide. The exact quantities of each in the solution can therefore be easily calculated. The valuation of commercial iodine has been alluded to already; the sodium thiosulphate is usually standardised by titrating it with a potassium iodide solution of pure iodine. 100 c.c. = 2.48 grams ($\frac{1}{100}$ th of $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$) and is equal to 1.27 grams of iodine ($\frac{1}{100}$ th of atomic weight in grams). Another method of volumetrically estimating the strength of an iodine solution is to pass sulphuretted hydrogen into it until decolourised; the hydriodic acid formed is then titrated with decinormal soda, using methyl orange as an indicator.

Commercial iodine seldom contains any impurity but moisture; it is almost impossible to estimate the water by drying in the ordinary way. An easy method is to rub it up with five times its weight of pure dry mercury, adding a little alcohol. It is then dried for 12 hours, or until it ceases to lose weight, over sulphuric acid in a desiccator. This process is accurate to about 0.1 p.c., but most suitable for very damp iodine. Another method is to add a weighed quantity (about double the weight of the iodine) of zinc sheet in small pieces in a tared capsule, along with a little water, when the iodine is all converted into zinc iodide; the contents of the capsule are gradually evaporated to dryness and weighed, the weight then includes that of the dry iodine. It is better, however, in all cases to estimate the iodine by titration. The same may be said of the valuation of potassium iodide; but in this case it is often also necessary to estimate a small quantity of chloride which is always present; and silver nitrate is the best reagent for this purpose, as the chloride ought to represent so small a percentage as to be difficult of detection. Bromine as a rule need not be looked for. Should it be present, however, some other process must be employed. It is necessary to take at least 3 grams of the potassium iodide, and add to it not less than 3.1 grams of pure silver nitrate; the precipitate is digested in strong ammonia, then filtered off, washed, dried, and fused with the usual precautions. The solution is concentrated by evaporation, and the silver chloride precipitated by nitric acid. This gives accurate results, even when the potassium chloride is under 0.5 p.c.

For the determination of small proportions of chlorine and bromine in iodine, the following process is recommended by Tatlock and Thomson (J. Soc. Chem. Ind. 1905, 24, 187). 10 grams of the sample are triturated with 100 c.c. of water, and finely granulated zinc, or zinc-dust, is added in small portions, with agitation, until all the iodine is converted into zinc iodide. The temperature of the solution must not be allowed to rise sensibly during the process. The solution is now filtered, the residue washed two or three times, and to the filtrate 7 grams of pure sodium nitrite are added. The solution is carefully acidified with dilute sulphuric acid, the precipitated iodine is collected and washed two or three times with cold water, and the filtrate is agitated with benzene in a small separator. The aqueous layer is run into another small separator, mixed with a little more sodium

nitrite and dilute sulphuric acid, and again shaken with benzene. To the aqueous solution excess of silver nitrate and some nitric acid are added, the liquid is heated to boiling, and the precipitate is collected on a weighed filter and well washed with hot water. A solution containing 2 grams of silver nitrate, 90 c.c. of water, and 10 c.c. of ammonia of sp.gr. 0.88 is prepared. About 60 c.c. of this solution are poured back and forward through the filter containing the precipitate, and the latter is finally washed with the remaining 40 c.c. The silver bromide on the filter is now washed with warm dilute nitric acid and with hot water, dried, and weighed. The ammoniacal filtrate is acidified with dilute nitric acid, and the precipitate of silver chloride is collected as usual. G. G. H.

IODIPIN, IODOVAL, IODLECITHIN, v. SYNTHETIC DRUGS.

IODOCAFFEIN v. SYNTHETIC DRUGS.

IODOFAN. Trade name for monoiodo-dihydroxybenzene-formaldehyde.

IODOFORM AND SUBSTITUTES. Iodoform (B.P. and U.S.P.), *tri-iodomethane* CHI_3 was discovered in 1822 by Serullas (Ann. Chim. Phys. [ii.] 20, 165), and Dumas in 1834 (*ibid.* [ii.] 56, 122) determined its exact composition. Serullas obtained it by acting on alcohol with iodine in presence of caustic or carbonated alkalis. The reaction may be stated thus:

Numerous other compounds (acetone, lactic acid, turpentine) containing the group

yield iodoform (Lieben, Annalen, Suppl. 7, 218 and 377). Methyl alcohol and acetic acid do not, when pure. The only practical sources are ethyl alcohol and acetone. Acetylides, acetylene mercuric chloride, acetylene (and coal-gas), also yield iodoform, Le Comte (J. Pharm. Chim. 1902 [vi.] 16, 297), but this source does not appear to have been used practically.

To prepare iodoform, Filhol (J. Pharm. Chim. [iii.] 7, 267) adds 1 part of alcohol to a solution of 2 parts of crystallised sodium carbonate in 10 parts of water and raises the temperature to 60°–80°. 1 part of powdered iodine is then *gradually* added, and when the liquid has become colourless, iodoform slowly forms and sinks to the bottom and may be removed by filtration. The filtrate is heated as before, another portion of sodium carbonate and alcohol added, and chlorine is led into the mixture to liberate iodine which has combined with the alkali. Another deposit of iodoform occurs, and the process may be repeated until the product represents nearly half the iodine employed. Another plan, suggested by Rother (Pharm. J. [iii.] 4, 594), is to warm the following mixture until it becomes colourless: iodine 32 parts, potassium carbonate 32 parts, 95 p.c. alcohol 16 parts, water 80 parts. The iodoform which is deposited is removed, and to the clear solution a mixture of potassium dichromate 2 to 3 parts, and hydrochloric acid 16 to 24 parts, is added to liberate iodine. After neutralising the solution with potassium carbonate, 32 parts more of that salt are added, together with 6 parts of iodine and 16 parts of

alcohol, and the heat being maintained a second quantity of iodoform precipitates. This may be removed and the operation repeated several times (*cf.* Cornelius and Gille, *J. Pharm. Chim.* [iii.] 22, 196; Smith, *Pharm. J.* [iii.] 5, 211; Bell, *ibid.* [iii.] 12, 786; Günther, *Arch. Pharm.* [iii.] 25, 373). Iodoform can be prepared by the electrolysis of a solution of an iodide in the presence of alcohol, aldehyde, or acetone (Dingl. poly. *J.* 255, 88; *J. Soc. Chem. Ind.* 1885, 243; Foerster and Meves, *J. pr. Chem.* 1897, [ii.] 56, 353; Elbs and Herz, *Zeitsch. Elektrochem.* 4, 113; Abbot, *J. Phys. Chem.* 1903, 84; Teeple, *Amer. Chem. J.* 1904, 26, 170. The last-named claims an almost quantitative yield). According to Suilliot and Raynaud (*Bull. Soc. chim.* [iii.] 1, 3) almost the whole of the iodine employed is obtained as iodoform when acetone is acted upon by what is possibly nascent potassium hypiodite produced by treating potassium iodide with sodium hypochlorite. A slight excess of dilute solution of sodium hypochlorite is added to a mixture of potassium iodide 50 parts, acetone 6 parts, and sodium hydroxide 2 parts, dissolved in 1 to 2 parts of water. The reaction probably takes place thus:

This process has been applied to the working of kelp, and is said to produce iodoform of a very high degree of purity (*Pharm. J.* [iii.] 20, 423).

A novel method has been described by Chattaway and Baxter (*Chem. Soc. Trans.* 1913, 103, 1896), in which acetone reacts with finely divided nitrogen iodide, prepared from iodine monochloride and ammonia. Tri-iodo acetone is first formed, and this is decomposed by water and by ammonia into iodoform, with acetic acid and acetamide respectively. Four-fifths of the iodine can be obtained as iodoform in one operation.

Iodoform crystallises in lemon-yellow hexagonal plates (according to Bardach, *Chem. Zeit.* 1911, 35, 11, it also forms thin needles and is consequently dimorphic). They melt at 119°, volatilise when heated, or better in a current of steam. It has a persistent and disagreeable odour. It is nearly insoluble in water, benzene, or light petroleum; 1 gram dissolves in 60 c.c. of alcohol, 80 c.c. of glycerine, 10 c.c. of chloroform, 7·5 c.c. of ether, 2·8 c.c. of carbon disulphide, and 34 c.c. of olive oil at 25°; also in 16 c.c. of boiling alcohol (U.S.P.). In the dry state iodoform is not acted on by sunlight; but in solution, with access of oxygen, it rapidly liberates free iodine (Humbert, *J. Pharm. Chim.* [iii.] 29, 352; Hebel, *Pharm. J.* [iii.] 16, 1088; Dacomo, *Gazz. chim. ital.* 16, 247; Neuss and Schmidt, *Pharm. J.* [iii.] 19, 247; Fischer, *Pharm. Zeit.* 34, 31; Bougault, *J. Pharm. Chim.* [vi.] 8, 213). Its antiseptic properties have been attributed to the slow liberation of iodine. *In vitro* it is almost without effect; it would appear, however, that it acts differently in presence of pus at the temperature of the body. Iodine is, in this case, liberated which perhaps also attacks the toxins. Hamburger, de Haan, and Bubanovic (*Proc. K. Akad. Wetensch. Amsterdam*, 1911, 13, 982) state that even in excessively dilute solution it has a favourable effect on phagocytoses; the action is not due to

iodine antiseptis, but rather to a physical effect (surface tension?) of intact iodoform on leucocytes.

Heated in sealed tubes to 150°, or with sodium ethoxide or alcoholic potash, iodoform forms methylene iodide CH_2I_2 . The zinc-copper couple, finely divided silver, and other metals reduce it to acetylene.

Iodoform is best detected and isolated by steam distillation from slightly acid solution (Stortenbeker, *Rec. trav. chim.* 1905, 24, 66). The distillate is extracted with ether, which is allowed to evaporate in the dark. Better crystals, for microscopic examination, may then be obtained by recrystallisation from glacial acetic acid. The red precipitate, formed by heating an alcoholic iodoform solution with sodium phenoxide, is, according to Stortenbeker, not characteristic, for it is also given by chloroform and bromoform. The estimation of iodoform may be carried out by digesting with silver nitrate and weighing the silver iodide, or titrating the excess by Volhard's method. Detection of adulteration (Kremel, *Pharm. Post.* 21, 213). Picric acid has been used, and is separated by shaking the ethereal solution with alkali. Assay of iodoform (Meillière, *Chem. Zentr.* 1897, ii, 140).

Iodoform is not now used so much as in the early days of antiseptic wound treatment, but as a dry powder which can be scattered it has considerable advantages. During the recent war it was used extensively and very successfully as bismuth-iodoform-petroleum-paste ('B.I.P.P.') suggested by Morison (*Lancet*, 1916, ii, 268), and consisting of bismuth subnitrate or carbonate with 1-2 parts of iodoform and enough pure liquid paraffin to make a thick paste. The odour, and to some extent the poisonous properties, of iodoform have given rise to a host of substitutes, all apparently inferior. Attempts have been made to mask the odour by admixing of coumarin (2 p.c.) or of oil of peppermint (1 p.c.) + phenol (0·5 p.c.). Other attempts depend on its combination with hexamethylene tetramine or with protein to form non-volatile compounds. The oldest substitute is *iodole* or tetra-iodopyrrole, C_4HNI_4 , formed by the action of iodine on potassium pyrrole (Ciamician and Dennstedt, *Ber.* 15, 2582; Ciamician and Silber, *ibid.* 18, 1766; 19 Ref. 327; 20 Ref. 123). It crystallises from alcohol in light yellow needles, decomposing at 140°-150° and is odourless. Like iodoform it is practically insoluble in water, and liberates iodine in contact with the tissues. Gently warmed with sulphuric acid it gives an intense green solution, gradually changing to dull violet and brown.

Di-iodoform, tetra-iodo-ethylene, is obtained from calcium carbide and iodine, or from iodine and di-iodo-acetylene (Biltz, *Ber.* 1897, 30, 1200; Biltz and Küppers, *ibid.* 1904, 37, 4412), but is too unstable and too heavy to displace iodoform in wound treatment.

A number of aromatic iodine derivatives have been suggested but those with iodine in the benzene ring do not split it off in contact with the tissues and hence are only antiseptic like other aromatic compounds. Such are iodo-hydroxyquinoline sulphonic acid (*lorclin*), tetra-iodo-phenolphthalein (*nosophen*), tri-iodometacresol (*losophan*) and iodoparaphenol-sulphonic

acid (*sozajodol*); *p*-Iodo-anisol (*isoform*) seems to be the best of this group. When the iodine is attached to oxygen as in hypiodites of phenols, it is more readily split off, as in dithymoldiiodide (*aristol*)

and di-isobutyl-o-cresol iodide (*europen*).

The physical properties and therapeutic effects of iodoform also belong to certain bismuth compounds, *e.g.* bismuth tribromophenoxide (*xeroform*) and bismuth oxy-iodogallate (*airol*). Another class consists of inert powders with which iodine is loosely combined or merely mixed physically, *e.g.* *novojodin*, an addition product of iodine to hexamethylenetetramine containing 60 p.c. of iodine; '*Jod-salusil*' (Chem. Zentr. 1917, ii. 189) is finely divided silicic acid, prepared by electrosmosis, mixed, with 1 p.c. of free iodine. Iodide of starch has occasionally been recommended. See further, SYNTHETIC DRUGS.

iodoformal v. SYNTHETIC DRUGS.

iodoformin $C_6H_{12}N_4I_4$ is prepared by adding an alcoholic solution of iodine to ammonia and formaldehyde mixed in molecular proportions when iodoformin falls as a brown pulverulent precipitate (*v.* SYNTHETIC DRUGS).

iodoformogen v. SYNTHETIC DRUGS.

iodogliadin. A combination of iodine and gliadin, a protein contained in wheat.

iodoglobin. Syn. for Di-iodotyrosine.

iodohydrin (*iothion*), Syn. for di-iodoisopropyl alcohol.

iodokol v. SYNTHETIC DRUGS.

iodole v. IODOFORM.

iodolen, **iodolin**, **iodogallacin**, **iodophenin**, **iodozol**, *v.* SYNTHETIC DRUGS.

iodolysin. An additive compound of an alcoholic iodide with thiosinamine. Used in relaxing scar-tissue.

iodomenin v. SYNTHETIC DRUGS.

iodometry v. ANALYSIS, VOLUMETRIC.

iodophenin. Trade name for *p*-aceto-hydriotetraiodide ($C_{10}H_{13}O_2N_2HI_4$) (Emery).

iodopyrine. A pharmaceutical preparation made by adding a solution of iodine in potassium iodide to an aqueous solution of antipyrine containing sodium acetate.

iodotheobromin, **iodylin**, **iodyloform** *v.* SYNTHETIC DRUGS.

iodothion v. SYNTHETIC DRUGS.

iodothyryne v. THYROID GLAND.

iodozol. Trade name for di-iodo-phenol sulphonic acid.

iodyrite, or **Iodargyrite**. A mineral composed of silver iodide (AgI) crystallising in the rhombohedral system. Distinctly developed crystals are small and comparatively rare; they possess a perfect cleavage parallel to the basal plane, on which the lustre is pearly, and are very soft (*H.*=1) and readily distorted. Their pale sulphur-yellow is not darkened by exposure to sunlight. Sp.gr. 5.51. At a temperature of 146°, the material becomes optically isotropic and cubic, reverting on cooling into the birefringent rhombohedral form.

The mineral occurs in the upper oxidised Vol. III.—T.

zones of certain silver-bearing veins, and when found in quantity, as at Broken Hill in New South Wales, in Chile and Mexico, and at Tonopah in Nevada, it is an important ore of silver (Ag, 45.97 p.c.). Some of the silver-ore formerly mined at Broken Hill consisted of white kaolin enclosing films and specks of iodyrite.

Miersite is a rare cubic form of silver iodide with copper iodide ($4AgI \cdot CuI$) from Broken Hill, New South Wales (L. J. Spencer, Min. Mag. 1901, 13, 41; G. T. Prior, *l.c.* 188). L. J. S.

iolite, **diechroite** or **cordierite**. A silicate of aluminium and magnesium with some ferrous iron replacing magnesium $H_2(Mg, Fe)_4Al_2Si_1O_{37}$ or perhaps $Mg_2Al_2(AlO)_2Si_5O_{16}$ crystallised in the orthorhombic system. It occurs as a constituent of certain gneisses and granites, and is readily altered to mica, pseudomorphs being more common than the fresh mineral. In its physical characters it presents a close resemblance to quartz, namely, in the glassy conchoidal fracture, hardness (*H.* 7-7½), density (sp.gr. 2.60-2.66), refractive index (1.54) and double refraction. The mineral is of interest on account of its strongly marked pleochroism (except in thin sections); viewed in the three directions of the crystallographic axes it shows dark blue, light blue, and pale yellow colours. It is occasionally used as a gem-stone; and to show the pleochroism to advantage it is sometimes cut in a cuboidal form and mounted on a swivel. When cut as a faceted gem this should be so orientated that the front facet will be perpendicular to the direction in which the deep blue colour is seen: such stones are known to jewellers as 'lynx-sapphire' or 'water-sapphire.' Material of gem-quality comes from the gem-gravels of Ceylon, Orijärvi in Finland, Haddam in Connecticut, and Mt. Bity in Madagascar.

L. J. S.

IONIUM. Sym. Io. At.wt. 230? A radioactive element, discovered by Boltwood in uranium minerals (Boltwood, Amer. J. Sci. 1907, 24, 370; cf. Hahn, Ber. 1907, 40, 4415). The results obtained by Boltwood and Hahn were confirmed by Marckwald and Keetman (Ber. 1908, 41, 49), who were unable to separate ionium from thorium, an element which it closely resembles. Ionium occurs, however, associated with actinium, in many of the uranium group of minerals in the absence of thorium (Szilárd, Le Radium, 1909, 6, 80).

Highly active preparations of ionium may be obtained from carnotite as follows (Boltwood) Amer. J. Sci. 1908, 25, 365). The ore is dissolved in hydrochloric acid and several grams of the chlorides of the cerite earths added. The earths are separated as oxalates, converted into chlorides, and precipitated with sodium thio-sulphate. The latter procedure is repeated several times, when a product is obtained having a radioactivity several thousand times as great as that of an equal weight of pure uranium.

The residues obtained in working up uranium ores containing little thorium may be precipitated in strongly acid solution with hydrofluoric acid. The precipitated fluorides are converted into sulphates, and from the aqueous solution of these, ionium and thorium are quantitatively precipitated by adding zinc hydroxide. The precipitate is dissolved in hydrochloric acid and

the solution precipitated with oxalic acid. The oxalate thus obtained contains the ionium, and has an activity 200 times as large as that of metallic uranium (Keetman, *Jahrb. Radioaktiv. Elektronik*, 1909, 6, 265).

Ionium emits α -rays, which have a range in air of only 2.8 cms.; it also emits β -rays. It produces no emanation. The life of ionium is at least as long as that of radium (*cf.* Soddy, *Le Radium*, 1910, 7, 295).

According to Boltwood, ionium is the direct parent of radium, and according to Keetman (*l.c.*), does not change directly into actinium.

Thorium-ionium oxalate has a very high and constant activity, and may with advantage be utilised in testing the constancy of electrometers and for determining capacities (Keetman, *l.c.*).

IONONES *v.* KETONES.

IPCACUANHA. *Ipecacuanha* Root. *Racine d'Ipecacuanha*, Fr.; *Brechwurzel*, Ger. *Ipecacuanha* is the root of *Psychotria Ipecacuanha*, Stokes, also known as *Cephaelis Ipecacuanha*, A. Richard, and *Uragoga Ipecacuanha*, Baillon (N. O. Rubiaceae), a low soft-wooded shrub indigenous to Brazil. Three commercial varieties of this root are distinguished: (1) Rio or Matto Grosso, (2) Minas, which is derived from the same plant, cultivated in the province of Minas Geraes in Brazil, and (3) Indian or Johore, also derived from the same plant, cultivated in the Straits Settlements.

Rio *Ipecacuanha* occurs in commerce in reddish-brown or dark brown pieces seldom exceeding 15 cm. in length, and 6 mm. in thickness; it has a thick bark, transversely corrugated or ringed—the corrugations often penetrating to the woody interior—and minutely wrinkled longitudinally. The Minas variety resembles it closely, whilst the Johore drug is rather larger than the Brazilian root.

The B.P. 1914 recognises only *Psychotria Ipecacuanha* as the official source of *ipecacuanha*, but the U.S.P. 1916 authorises the use of the root of *Cephaelis acuminata*, Karsten, also. This is known commercially as Carthagena or Colombian *Ipecacuanha*, and is usually lighter in colour and rather larger than the Brazilian root.

For information on the *ipecacuanhas* of English commerce and others sometimes substituted for them, *cf.* E. M. Holmes, *Yearbk. Pharm.* 1893, 402.

The drug was first introduced into Europe from Brazil about the close of the seventeenth century as a remedy for dysentery, and since that period it has always retained a place in *materia medica*. It is employed as an expectorant, as an emetic, and in the treatment of dysentery. Applied locally the powdered root is an irritant, and in large doses it is poisonous. (*Cf.* Pereira, *Mat. Med.* 1853, 2, 1591; Flück. a. Hanb. 370.) It is administered in the state of powder—for instance, admixed with opium and potassium sulphate in the well-known Dover's Powder—made into pills, or in vinous solution. In recent years, however, the salts of emetine have been largely used in its place in the treatment of amoebic dysentery.

The most important constituent of *ipecacuanha* is the alkaloid *emetine*, which is associated with several other bases closely related to it in

structure. The term *emetine* was first applied by Pelletier and Magendie (*Ann. Chim.* 1817, [ii.] 4, 172) to a crude preparation of the total alkaloids of *ipecacuanha*, and was used subsequently by numerous authors to designate various purified preparations of the alkaloids. The earlier researches may be traced by reference to the papers of Paul and Cownley, and only one need be mentioned here, namely, that of Glénard (*Ann. Chim.* 1876, [v.] 8, 233), who succeeded in preparing *emetine hydrochloride* in a crystalline state by a fortunate choice of procedure. The first real advance in the study of these alkaloids was made by Paul and Cownley (*Pharm. J.* 1894, [iii.] 25, 111), who showed that the portion soluble in ether could be separated into two fractions by extraction with aqueous sodium hydroxide, when the ethereal solution contained a nonphenolic alkaloid for which the name *emetine* was retained, whilst the alkaline liquor contained a crystalline alkaloid which was termed *cephaeline*. Subsequently (*Pharm. J.* 1894, [iii.] 25, 690) they isolated a third alkaloid, *psychotrine*, from the root. Many years later O. Hesse (*Annalen*, 1914, 405, 1) described two more alkaloids of *ipecacuanha*, *ipecamine* and *hydroipecamine*, but these are probably not homogenous substances (*cf.* Pyman, *Chem. Soc. Trans.* 1917, 111, 49). More recently Pyman (*l.c.*) isolated two new alkaloids of *ipecacuanha*, one being the *o*-methyl ether of *psychotrine*, whilst the other was termed *emetamine*.

Neglecting publications previous to those of Paul and Cownley, the chemistry of these alkaloids has been studied by Paul and Cownley, *Pharm. J.* 1893, [iii.] 24, 61; 1894, [iii.] 25, 111, 373, 641, 690; 1895, [iv.] 1, 1, 321; the same with Hesse, *Pharm. J.* 1898, [iv.] 7, 98; Frerichs and de Fuentes Tapis, *Arch. Pharm.* 1902, 240, 390; Keller, *Arch. Pharm.* 1911, 249, 512; 1913, 251, 701; 1917, 255, 75; Carr and Pyman, *Chem. Soc. Proc.* 1913, 29, 226; *Chem. Soc. Trans.* 1914, 105, 1591; Hesse, *Annalen*, 1914, 405, 1; Windaus and Hermanns, *Ber.* 1914, 47, 1470; Pyman, *Chem. Soc. Trans.* 1917, 111, 419; 1918, 113, 222; and Karrer, *Ber.* 1916, 49, 2057; 1917, 50, 582. Patents have been taken out by W. G. Whiffen, D. R. P. 99090 (1897) for the purification of *emetine* by crystallisation of the hydrobromide; by Chem. Werke vorm. Dr. Heinr. Byk., D. R. P. 267219 (1912) for the extraction of the alkaloids from the root by means of chloroform mixed with alcoholic hydrogen chloride; by H. S. Wellcome, F. H. Carr and F. L. Pyman, *Eng. Pats.* 14677 and 17483 (1913) for the preparation of *emetine* by the methylation of *cephaeline* by means of dimethyl sulphate and sodium methyl sulphate respectively; by Farbw. vorm. Meister, Lucius and Brüning, D. R. P. 298678 (1916) for the preparation of *emetine* by the methylation of *cephaeline* by means of diazomethane; by J. W. Meader, *Eng. Pats.* 11717, 11718, 11719 (1915); 103881, 104652, 105722 (1916); U.S. Pat. 1209575 (1917), and by Farbw. vorm. Meister, Lucius und Brüning, D. R. P. 301498 (1915) for the preparation of homologues of *emetine* by the alkylation of *cephaeline* with derivatives of alcohols other than methyl alcohol.

Isolation of the alkaloids.—The total alkaloids extracted from the powdered root by means of

alcohol, amyl alcohol (Paul and Cownley), or a mixture of benzene with light petroleum (Hesse) are dissolved in dilute hydrochloric acid, basified with ammonia, and extracted with ether which removes all the known alkaloids except psychotrine; this is extracted from the mother liquor by chloroform and crystallised from moist acetone. The ethereal solution is extracted with dilute aqueous sodium hydroxide, from which cephaeline can be extracted by means of ether after the addition of ammonium chloride; on concentrating this ethereal solution cephaeline separates in long colourless needles. The ethereal solution containing the nonphenolic alkaloids is concentrated and the residue converted into the hydrochloride (Paul and Cownley), hydrobromide (Whiffen), or hydriodide (Karrer), when the emetine salt separates in a crystalline form. After removing the emetine, the remaining alkaloids are converted into acid oxalates in alcoholic solution, when the crystalline acid oxalates of *O*-methylpsychotrine and emetamine are deposited; these are separated by fractional extraction from their chloroform solutions by dilute acids.

Properties.—Emetine has the formula

(Carr and Pyman; Karrer) being the mono-methyl ether of cephaeline, for which the formula $C_{28}H_{38}O_4N_2$ is accepted. Other formulæ proposed for emetine are $C_{30}H_{44}O_4N_2$ (Paul and Cownley), which is employed in the U.S.P. 1916, $C_{30}H_{42}O_4N_2$ (Hesse, 1898) and $C_{30}H_{40}O_5N_2$ (Hesse, 1914). It contains four methoxyl groups, one tertiary nitrogen atom common to two rings, and one secondary nitrogen atom contained in a ring. The largest fragment of the molecule so far obtained on oxidation is 6:7-dimethoxyisoquinoline-1-carboxylic acid, the formation of which shows that emetine is a derivative of *iso*quinoline.

Emetine is amorphous and colourless, but turns yellow on warming or keeping. It melts at 74° (corr.) and has $[\alpha]_D -50^\circ$ in chloroform ($c=2$). It is sparingly soluble in water or light petroleum, but readily so in alcohol, ether, or chloroform. It is a diacidic base forming neutral salts with two equivalents of acids. The hydrochloride, hydrobromide, and the double iodide of emetine and bismuth are employed in medicine.

The hydrochloride $B,2HCl$ contains water of crystallisation varying from 3 to $8H_2O$. It forms colourless woolly needles, which after drying at 100° , melt indefinitely at $235^\circ-255^\circ$ (corr.). Its specific rotatory power in aqueous solution varies with the concentration from $[\alpha]_D +11^\circ$ ($c=1$) to $[\alpha]_D +21^\circ$ ($c=8$), calculated for the anhydrous salt. It is readily soluble in warm water (about 1 in 4 at $37^\circ C.$), but more sparingly so in cold water (about 1 in 7 at $25^\circ C.$, and 1 in 11 at $15^\circ C.$), giving solutions which are neutral to litmus. It is official in the U.S.P. 1916. This salt and also the hydrobromide are given by the mouth or hypodermically in doses up to 1 grain in the treatment of amœbic dysentery.

The hydrobromide $B,2HBr,4H_2O$ forms colourless needles, which melt indefinitely at $245^\circ-265^\circ$ (corr.). It is readily soluble in hot, sparingly so in cold water (1:50).

Emetine bismuthous iodide, prepared by the addition of Dragendorff's reagent (potassium bismuthous iodide) to an aqueous solution of an emetine salt, is a dull scarlet powder, almost insoluble in water, approximating in composition to $B,2HI,2BiI_3$. It is given orally in amœbic dysentery, and is stated to cause less nausea than the soluble salts, since it is almost insoluble in the acid contents of the stomach, exerting its full effect only in contact with the alkaline juices of the intestines.

The sulphate, nitrate and hydriodide are also crystalline, the last two being sparingly soluble in water.

Cephaeline $C_{28}H_{38}O_4N_2$ forms colourless needles from ether, melting at $115^\circ-116^\circ$ (corr.), $[\alpha]_D -43^\circ$ in chloroform ($c=2$). Sparingly soluble in water, ether, or light petroleum; easily so in alcohol or chloroform. The hydrochloride, $B,2HCl$, 5 to 7 H_2O forms colourless prisms, easily soluble in water, melts at $245^\circ-270^\circ$ (corr.) when anhydrous, and is dextrorotatory. The hydrobromide is also crystalline.

Psychotrine $C_{28}H_{36}O_4N_2,4H_2O$ crystallises from moist acetone in yellow prisms having a blue fluorescence. M.p. (anhydrous) $124^\circ-126^\circ$ (corr.) $[\alpha]_D +69^\circ$ in 99 p.c. alcohol ($c=2$). Forms crystalline dextrorotatory salts with H_2SO_4 , HI and HNO_3 . Yields cephaeline and an isomeride on reduction.

***O*-Methylpsychotrine** $C_{28}H_{38}O_4N_2$ is amorphous and has $[\alpha]_D +46^\circ$ in chloroform ($c=2$). Forms crystalline dextrorotatory salts with H_2SO_4 , HBr and oxalic acid. Yields emetine and an isomeride on reduction.

Emetamine $C_{28}H_{36}O_4N_2$ (or $C_{30}H_{36}O_4N_2$) forms colourless needles from ethyl acetate. M.p. $155^\circ-156^\circ$ (corr.) $[\alpha]_D +10^\circ$ in chloroform ($c=4$). Forms crystalline levorotatory salts with HBr, and oxalic acid.

Detection and estimation. A characteristic reaction of the alkaloids is the yellow or orange colour produced by the action of bleaching powder and acetic acid (Power, Pharm. J. 1877, [iii.] 8, 344). Froehde's reagent gives a grass-green colour with emetine, and a purple colour with cephaeline; this distinction is utilised in a test devised to detect the presence of cephaeline in commercial emetine hydrochloride (U.S.P. 1916).

The official methods of assay of ipecacuanha consist in the estimation of the total ether-soluble alkaloids. The B.P. 1914 requires a content of 2 p.c. estimated gravimetrically, whilst the U.S.P. 1916 requires a content of 1.75 p.c. estimated by titration with standard acid. The nonphenolic and phenolic portions of the ether-soluble alkaloids may be separated and estimated similarly. For a review of the methods of assay, see Frerichs and Tapis (Arch. Pharm. 1902, 240, 390).

The root contains 1.5-2.5 p.c. of total alkaloids, consisting mainly of emetine and cephaeline, with 0.04-0.06 p.c. of psychotrine, 0.015-0.033 p.c. of methylpsychotrine, and 0.002-0.006 p.c. of emetamine; the proportions of emetine and cephaeline in the different commercial varieties are given by Paul and Cownley, Pharm. J. 1896, [iv.] 2, 321; 1903 [iv.] 15, 256; Umney and Swinton, Yearbk. Pharm. 1899,

348; Carr and Reynolds, Pharm. J. 1908, [iv.] 26, 542, and Hesse, Annalen, 1914, 405, 1.

Non-alkaloidal constituents.—Besides the alkaloids, few definite compounds have been isolated from the root. A crystalline yellow colouring matter, *erythrocephalein*, forming purple-red compounds with alkalis was isolated by Podwysotzky, Pharm. J. 1880, [iii.] 10, 642. The presence of *choline* was detected by H. Kunz, Arch. Pharm. 1887, [iii.] 25, 461. A colourless glucoside, *ipeacuanhin*, was isolated by Finne-more and Braithwaite, Pharm. J. 1912, [iv.] 35, 136, and a *phytosterol*, m.p. 160°–162° (corr.) by Carr and Pymn. The root contains a large amount of starch and up to 5 p.c. of ash.

IPOMEA v. SCAMMONY, art. GUM RESINS.

IRETOL v. PHENOL AND ITS HOMOLOGUES.

IRIDIN v. GLUCOSIDES.

IRIDIUM. Sym. Ir. At.wt. 193·04.

The occurrence of this metal and the properties of its principal alloys with platinum will be described under PLATINUM. Its principal source is the osmiridium which is left after treatment of crude platinum with *aqua regia*.

The cleaning and methods of attack of the insoluble osmiridium are also given under PLATINUM. Briefly, iridium is freed from ruthenium and osmium by distilling in chlorine after an alkaline fusion, and from rhodium and palladium by the difference of solubility of the double chlorides with potassium or ammonium. It may be freed from platinum either by melting the metal with ten times its weight of lead, parting in nitric acid and boiling the residue in *aqua regia*, or by reducing the acidified chloride solution with H_2S , SO_2 , ferrous salts, nitrites, oxalic acid or other suitable reagent, precipitating the unattacked $PtCl_4$ with ammonium or potassium chloride and either re-oxidising the solution to precipitate the chloroiridate or crystallising the chloroiridite by evaporation. The ammonium salt has the advantage over the potassium salt that it may be decomposed to leave a base-free solution by boiling with *aqua regia*, or it may be calcined in a closed vessel to leave the metal as sponge. If calcined in an open vessel the residue may subsequently be reduced to metal by hydrogen at a gentle heat.

The metal is best converted into the soluble chloride by heating in chlorine with salt or dehydrated barium chloride. In the latter case the barium may be removed from the solution by sulphuric acid.

Iridium sponge is oxidised but not dissolved by fused bisulphate. Traces of osmium in iridium sponge may be detected by bringing some of it on a piece of platinum foil into a Bunsen burner flame alternately in the reducing and oxidising zones, when bright flashes or sparks are observed; but the characteristic smell of OsO_4 on heating in air is reliable and sensitive.

On account of their extreme hardness, the native grains of osmiridium are employed as such for tipping the points of gold nibs, but only a small proportion even of the few grains which occur with ordinary crude platinum are suitable for the purpose. A small quantity of osmiridium is used for pivots, &c., of watches

and scientific instruments, but practically the whole is worked up for the production of iridium, which is mainly employed in alloy with platinum, as described under PLATINUM.

Melted iridium may be cast in a lime mould, and the ingot forged or rolled at a bright red heat. Sheets suitable for dishes or crucibles may thus be prepared, but the metal, even if pure, is very hard and brittle when cold. Thin foil may, however, be rolled out, and has found an application in an electric meter as an electrode in a solution of a mercury salt. The forged metal becomes superficially oxidised at a red heat in air or oxygen, but the blue tint, not so pronounced as the 'temper' colours of steel, disappears on further heating. Acids, however, have no action on it, nor have certain fused base metals. For further details see Crookes, Proc. Roy. Soc. 1908, A. 80, 535.

Iridium is a white metal as bright as steel, having a sp.gr. of 22·39 (G. Matthey), and melting at about 1950°; 2150°–2250° (J. Ind. Eng. Chem. 1911, 3, 354).

The compact metal, like osmiridium, may be broken down by melting with excess of zinc, in which, of course, it sinks, and then boiling away the whole of the zinc. Or the zinc may be kept as long as is necessary just below its boiling-point (918°), and then dissolved away by acid (Deville and Debray, Ann. de Ch. et de Ph. 1859, [3] 56, 439).

At a dull red heat iridium combines with fluorine, chlorine, or oxygen. It also combines with sulphur when heated, and gives a readily fusible compound with phosphorus, which is decomposed at a white heat.

Colloidal iridium may be obtained by mixing iridium chloride with lysalbic acid and concentrated soda, and subsequently dialysing the mixture (Paal and Amberger, Ber. 1904, 37, 124); or by reducing iridium chloride with hydrazine hydrate in the presence of gum arabic solution (Gutbier and Hoffmeier, J. pr. Chem. 1905, [ii.] 71, 452). It is a catalyst, but is not as powerful as colloidal platinum. See Paal, Biehler & Steyer, Ber. 1917, 50, 722.

For its action in inducing the catalytic oxidation of carbon monoxide by oxygen, see Paal, Ber. 1916, 49, 548. *

Iridium black is a complex mixture containing varying proportions of the metal and its oxides, obtained by reducing iridium salts with alcohol, formic acid, or formaldehyde. The black powder thus formed is washed with water and dried *in vacuo* (Böttger, J. pr. Chem. 1834, 3, 276). It has properties similar to, but more powerful than, those of platinum black. It absorbs gases and has the property of inducing chemical action, as, for instance, the combustion of hydrogen and of alcohol, the transformation of chlorine, iodine, or bromine water into halogen acid and oxygen, the decomposition of hypochlorites, and so forth (Schönbein, Ann. Chim. 1866, [iv.] 7, 103, 113).

Although the black iridium oxide is a valued pigment for china, the commercial use of iridium for that or other purposes other than as metal or in alloys, is practically *nil*, as the demand for the metal as such exceeds the supply. For the same reason, none of the large variety of salts which iridium forms, is of technological interest.

IRIDIUM COMPOUNDS.

According to Wöhler and Witzmann (Zeitsch. anorg. Chem. 1908, 57, 323; see also Zeitsch. Elektrochem. 1908, 14, 97), the oxide IrO does not exist under ordinary conditions, and all the known oxides are unstable at 800° – 1000° .

Iridium dioxide IrO_2 is best prepared by the action of alkali on a hot solution of sodium iridichloride Na_2IrCl_6 , the sesquioxide first formed being oxidised to dioxide by a current of oxygen. The oxide is then dried in a current of carbon dioxide at 200° , after which it is boiled with alkali and then with sulphuric acid. The anhydrous dioxide and also the one containing 2 mols. H_2O is black. When freshly precipitated it is more readily soluble in acids and alkalis than when dried.

The solution obtained by the action of potash or sodium iridichloride in the cold, ultimately becomes violet in colour and contains the dioxide in colloidal form; after a time a violet modification of the dioxide separates, and on boiling, the solution becomes blue. The blue and green solutions of the dioxide in hydrochloric acid also contain the dioxide in colloidal solution.

Iridium sesquioxide Ir_2O_3 is obtained by mixing air-free hot solutions of sodium iridium trichloride $\text{Na}_3\text{IrCl}_6 \cdot 12\text{H}_2\text{O}$, and potash in a current of carbon dioxide. The mixture is evaporated to dryness and heated to redness in a current of the same gas, after which it is purified in the same way as the dioxide. With hydrochloric acid this oxide also gives a colloidal solution. Like the dioxide, its properties depend on the proportion of water it contains. The sesquioxide imparts a fine black colour to porcelain after firing, and when mixed with zinc oxide it yields a grey tint.

Iridium trioxide is so unstable that it has not been obtained pure.

Iridium trihydroxide $\text{Ir}(\text{OH})_3$ is a yellowish-green substance which dissolves in alkalis and oxidises rapidly in the air, forming

Iridium tetrahydroxide $\text{Ir}(\text{OH})_4$, a heavy indigo-blue powder, which becomes green, then brown on heating (Joly and Leidié, Compt. rend. 1895, 120, 1341; Gutbier and Riess, Ber. 1909, 42, 3905).

Iridous chloride IrCl_2 is a green, insoluble mass, formed when chlorine is passed over spongy iridium or when the tetrachloride is heated.

Iridium trichloride IrCl_3 is a light, insoluble, olive-green powder prepared by heating one of its double salts with sulphuric acid, and also by other methods (Antony, Gazz. chim. ital. 1893, 23, i. 184). It forms complex compounds with the chlorides of phosphorus and arsenic (Geisenheimer, Compt. rend. 1890, 110, 1004, 1336), and double salts with metallic chlorides.

The most important of these are the potassium salt, $\text{K}_3\text{IrCl}_6 \cdot 3\text{H}_2\text{O}$, big rhombic prisms, efflorescent in air and losing 9.45 p.c. at 18° ; the ammonium salt $2(\text{NH}_4)_3\text{IrCl}_6 \cdot 3\text{H}_2\text{O}$ and the sodium salt $\text{Na}_3\text{IrCl}_6 \cdot 12\text{H}_2\text{O}$, large dark olive prisms, soluble in alcohol and melting at 50° .

Iridium tetrachloride IrCl_4 may be obtained by heating ammonium iridichloride in chlorine, or by dissolving the finely divided metal in *aqua regia*, or the blue hydroxide in hydrochloric acid. It loses chlorine at 50° and is

readily converted by heat into IrCl_3 . It forms double chlorides of the type M_2IrCl_6 with the alkali metal chlorides and with alkylamines. The potassium salt K_3IrCl_6 and the ammonium salt $(\text{NH}_4)_3\text{IrCl}_6$ both form small black octahedra, slightly soluble in water and almost insoluble in potassium or ammonium chloride solutions, like the corresponding platinum salts. The sodium salt $\text{Na}_3\text{IrCl}_6 \cdot 6\text{H}_2\text{O}$ is also similar to the platinum salt, except in colour, and is freely soluble, as also is the barium salt (Rimbach and Korten, Zeitsch. anorg. Chem. 1907, 52, 406; Delépine, Compt. rend. 1909, 149, 1072; *ibid.* 1908, 146, 1267; Vézès, *ibid.* 1392; Gutbier, Zeitsch. physikal. Chem. 1909, 69, 304; Gutbier and Riess, *l.c.*). The iridichlorides, when reduced, yield the iridichlorides. Similar bromides and iodides of iridium also exist. See also Delépine, Bull. Soc. chim. 1914, [iv.] 15, 231, 267, 438, 505.

Iridium forms ammonium or ammine derivatives similar in constitution to the platinum compounds and corresponding to the chlorides IrCl_2 , IrCl_3 ; also a series of compounds corresponding to IrCl_3 , and analogous to the cobaltic, chromic, and rhodic compounds.

When iridium chloride is treated with ammonia, double salts $\text{Ir}(\text{NH}_3)_3\text{Cl}_3$,

and $\text{Ir}(\text{NH}_3)_5\text{Cl}_3 \cdot \text{H}_2\text{O}$ are formed. Iridium ammonia chlorohydroxide, sulphate, thionate, oxalate, nitrate, and a number of halide derivatives are also known (Palmer, Zeitsch. anorg. Chem. 1895, 10, 320; *ibid.* 1896, 13, 211; see also Mylius and Dietz, Ber. 1898, 31, 3187).

Complex iridium nitrites and their chloro and oxalic acid derivatives have been prepared (Joly and Leidié, Compt. rend. 1895, 120, 1341; Leidié, *ibid.* 1902, 134, 1582; Bull. Soc. chim. 1902, [iii.] 27, 936; Vézès and Duffour, *ibid.* 1910, [iv.] 7, 507, 512; Miolati and Gialdini, Atti. R. Accad. Lincei, 1902, [v.] 11, i. 151; Werner and Vries, Annalen, 1908, 364, 77).

Iridicyanides resemble the ferricyanides and are described by Martius (*ibid.* 1861, 117, 357; see also Rimbach and Korten, Zeitsch. anorg. Chem. 1907, 52, 406).

Iridium sulphides IrS , Ir_2S_3 , IrS_2 (Antony, Gazz. chim. ital. 1893, 23, i. 184, 190), and the ammonium pentadecasulphide $(\text{NH}_4)_3\text{IrS}_{15}$ (Hofmann and Höchtlein, Ber. 1904, 37, 245) are known.

Iridium sulphate $\text{Ir}(\text{SO}_4)_2$ is a yellow-brown mass which when warmed with sulphuric acid is reduced, giving a green solution of the sesquisulphate $\text{Ir}_2(\text{SO}_4)_3 \cdot 6\text{H}_2\text{O}$ (Rimbach and Korten, *l.c.*; also Lecoq de Boisbaudran, Compt. rend. 1883, 96, 1406 and 1551).

Iridium sesquisulphate forms alums with ammonium, thallium, and the alkali metals, of the type $\text{Ir}_2(\text{SO}_4)_3 \cdot \text{M}_2\text{SO}_4 \cdot 24\text{H}_2\text{O}$ (Marino, Zeitsch. anorg. Chem. 1904, 42, 213; Rimbach and Korten, *l.c.*; Delépine, Compt. rend. 1906, 142, 631). It also forms sulphates of the type

$\text{Ir}(\text{SO}_4\text{M}')_3 \cdot \text{H}_2\text{O}$ (?) or $\text{Ir}_2(\text{SO}_4)_3 \cdot 3\text{M}_2\text{SO}_4 \cdot \text{H}_2\text{O}$ which are bluish-green in colour, and are decomposed by ammonia and alkali hydroxides with precipitation of a violet oxide of iridium. The contained sulphuric acid is not precipitated by barium (Delépine, Compt. rend. 1906, 142, 1525).

According to Delépine iridium forms two series of disulphates: (1) green salts, generally acidic, derived from the acid

(2) reddish-brown basic salts derived from the acid $\text{H}_3[\text{Ir}(\text{SO}_4)_2(\text{OH})_2]$ (Compt. rend. 1909, 149, 785). He has also obtained green, pyridine derivatives (*ibid.* 1910, 151, 878).

Double salts of *iridosulphite* have been described by Seubert (Ber. 1898, 11, 1761).

Iridium selenide (Chabrie and Bouchonnet, Compt. rend. 1903, 137, 1059); *oxalates* (Gialdini, Atti. R. Accad. Lincei, 1907, [v.] 16, ii. 551, 648; Vézès and Duffour, Bull. Soc. chim. 1907, [iv.] 5, 869, 872); *phosphor halides* (Strecker and Schurigin, Ber. 1909, 42, 1768); and *mercaptide* (Hofmann and Rabe, Zeitsch. anorg. Chem. 1897, 14, 293) are known. A. J. W.

IRIDOSMINE or **OSMIRIDIUM**. A native alloy of iridium and osmium crystallised in the rhombohedral system. Analyses show the following range in composition: Ir 10.0–77.2, Os 17.2–80.0, Pt 0–10.1, Rh 0–17.2, Ru 0–8.9, Fe 0–1.5, Cu 0–0.9 p.c., Pd traces. Iridium and osmium replace one another isomorphously, the former usually predominating, and the names *nevanskite* (osmiridium) and *sysertskite* or *sisserskite* (iridosmium) are applied to members towards the two ends of the series respectively. Crystals have the form of hexagonal plates, which possess a perfect basal cleavage; but more often the mineral is found as small flattened grains of irregular outline. Nuggets consisting of an aggregate of scales, and weighing up to 60 grams, have been found in Tasmania. The material is tin-white to lead-grey with bright metallic lustre, the colour being lighter in nevanskite and darker in sysertskite. It is somewhat brittle or only slightly malleable, H. 6½–7; sp.gr. 18.6–21.6. It is unattacked by aqua regia; and in the treatment of crude platinum (with which iridosmine is often associated) it remains in the residues. At a high temperature sysertskite give the characteristic odour of osmium, but nevanskite is not decomposed. Decomposition can be effected by fusion with nitre, the product being soluble in water. The mineral is found sparingly in certain platinum and gold washings, especially in those on rivers draining regions of peridotite and serpentine rocks. Its occurrence in situ has been recorded from Nizhni-Tagilsk in the Urals and at Bald Hill in Tasmania. Localities are in the Urals, Siberia, and Caucasus, particularly in Govt. Perm, e.g. at Nevjansk and Syserts (on Russian localities, see V. I. Vernadsky's descriptive mineralogy, vol. 1, St. Petersburg, 1908–1914; translation, in part, in Mining Jour. London, 1912, 98, 851); Japan, Borneo, New South Wales, Victoria, Tasmania, New Zealand, British Columbia, Quebec, Oregon, and northern California (here rather abundantly in the auriferous beach sands), San Domingo in the West Indies, Colombia, and Brazil. In South Africa it has been detected in the heavy concentrates from the auriferous blanket of the Witwatersrand. The most profitable occurrence is that in the Savage river and other tributary streams of the Pieman river in north-west Tasmania, which rise in the district of Bald Hill where peridotites (harzburgite) and pyroxenites

(enstatite-rock) with secondary serpentine rocks are exposed. In this material osmium predominates and very little platinum is present; analysis gave: Ir and Rh 33.80, Pt 0.37, Ru 8.19, Pd 0.21, Au 0.04, Fe 0.30, Cu trace, Os (diff.) 57.09=100 p.c. sp.gr. 18.87 and 19.5.

On account of its hardness and resistance to corrosion, the mineral is used directly for tipping the gold nibs of reservoir-pens, for surgical needles, watch pivots, and compass bearings. Selected grains free from flakiness are soldered with silver on the gold nibs, which are then split by a rotating metal disc charged with diamond powder, and finally ground down to shape. Other material is used for hardening platinum (for use as standard weights, jewellery, &c.), and as a source of iridium and osmium.

IRON. Sym. Fe. At.wt. 55.84. *History*.—Iron has been known and prized from the very earliest historical period, articles of the metal having been found among the contents of the Great Pyramid of Egypt, where they are believed to have remained for 5000 years. Iron was also used in Nineveh in considerable quantities, and in the British Museum are picks, hammers, and saws made of iron, found by Layard in the ruins of Nineveh, and which are believed to be of a date not later than 880 B.C. Iron is frequently mentioned in the earlier books of the Bible; it was much prized by the Greeks, and was discovered by Schliemann in the ruins of Mycenæ, which was destroyed B.C. 561. The Chinese were acquainted with the use of iron at a very early period, and it was also highly valued and much worked by the Romans. The metal employed in all the above instances was obtained by direct reduction from the ore, by methods very closely resembling those still in use by semi-barbarous peoples in various parts of the world. In England iron was largely worked by the Romans, and in the Forest of Dean there are still to be seen remains of these old Roman workings, whilst the partly reduced slags left by the Romans were in more modern times employed for many years in the blast furnaces of that district as a source of iron. At the Norman invasion Gloucester possessed a considerable trade in iron, but until the introduction of coal Sussex was the chief seat of the manufacture in this country. The exact date at which the blast furnace was introduced is not known, and it was probably the result of a gradual development of the more primitive hearths formerly in use. Cast iron was, however, known to Agricola, who died in 1555, and it was employed for cannon in this country in the year 1516. At this period small blast furnaces were employed which were capable of producing about 7–10 tons of metal per week, the fuel used being charcoal. The resulting pig iron was afterwards converted

into wrought iron in a finery, or small hearth, not unlike the smith's fire. The large quantities of wood employed for the production of charcoal for this manufacture led to the introduction of various Acts of Parliament during the 16th century, which had for their object the restriction of the industry to certain districts, and a diminution of the waste of valuable timber. In the early part of the 17th century Dud Dudley succeeded in 'charring' coal or producing a coke suitable for use in the blast furnace, but the use of coal did not become general until after Abraham Darby had again succeeded in the manufacture of coke at Colebrook Dale about 1730. The introduction of the steam engine by Watt led to the use of more powerful blowing machinery, and gave increased yields, which again were much improved upon by the application of hot blast in 1829, by subsequent alteration in the shape of the interior, and by the considerable increase in the size and the capacity of the furnaces. Various other improvements have from time to time been adopted, such as improved methods of calcining the ore, and of charging the materials into the furnace; and the utilisation of the gases from the furnace for heating the blast, and for the blowing engines, so that the present output of the best furnaces is about 400 times that of the blast furnaces of 200 years ago, whilst the consumption of fuel has been reduced to about one-fifth of that formerly employed. In connection with the manufacture of steel, the cementation process is in various forms of very great antiquity, but a notable improvement was effected by Huntsman, about 1740, by the introduction of cast steel, while a further advance was made in 1839, when Heath introduced the use of manganese in steel melting. Wrought iron, as before mentioned, was originally prepared directly from the ore, and at a subsequent date was obtained from cast iron by the use of the open-hearth finery. In 1784 Cort patented the puddling process, and in so doing laid the foundation of much of the prosperity of England during the century that followed. But in recent years the whole system of the manufacture of wrought iron has been revolutionised by the magnificent inventions of Bessemer and Siemens, by which the decarburised iron is obtained in the fluid condition. The metal then is commonly known as 'mild steel,' and has met with such a variety of applications that for rails, girders, guns, ship-building, bridge construction, and many other uses, it has gradually replaced the iron obtained by the puddling process.

Of later inventions reference may be made to the introduction of the basic process, by Thomas, which rendered phosphatic ores available for steel making; the production of manganese steel by Hadfield thus laying the foundation of the important series of alloy steels; and the invention of the continuous process of steel making by Talbot.

Chief iron ores. Iron is occasionally found native, either in the form of meteorites also containing nickel, or as metal which, by the action of heat and reducing agents, has been naturally separated from the ore. These sources are, however, unimportant, except for savage tribes, who are in some instances largely dependent upon such methods of supply. Iron is very

widely distributed throughout the crust of the earth in various forms. On account of its cheapness, and the readiness with which it combines with various elements, such as sulphur, phosphorus, or arsenic, which, if present in the metal, would injuriously affect its mechanical properties, comparatively few ferruginous compounds are practically available as sources of iron. It is necessary if an iron ore is to be profitably employed that the working expenses and carriage should be small, that the ore should be rich and readily reduced, and that it should be free from sulphur, phosphorus, arsenic, or other impurities which seriously deteriorate the quality of the iron. Such ores are practically either oxides or carbonates.

Oxides of iron. These may be divided into three classes.

1. *Magnetites.* Magnetic oxide of iron (Fe_3O_4) is the richest oxide of iron which occurs in nature; if pure, it would contain 72.4 p.c. of metallic iron. Its colour varies from brownish-grey to iron-black; it is brittle, magnetic, and produces a black streak. It crystallises in the cubic system, but is generally found massive. It occurs in remarkable purity in Sweden, also in India, and in immense quantities in the region of Lake Superior. The Swedish iron, which has so long been famed, is made from this ore. *Ilmenite* is an impure magnetite containing titanium, which occurs in Norway. *Franklinite*, which occurs in New Jersey, may be regarded as a magnetite in which the ferrous oxide is more or less replaced by oxide of zinc; and *Chrome Iron Ore* is a magnetite in which the ferric oxide is replaced by oxide of chromium. Magnetic iron sands occur on the shores of Java and New Zealand.

2. *Red hæmatites.* Ferric oxide (Fe_2O_3) occurs in a number of forms which possess different physical characters, such as *Micaceous iron ore*, *Specular iron ore*, *Kidney iron stone*, &c. These forms differ in hardness, density, and colour, but gives each a red streak. Red hæmatite is generally very free from phosphorus, and is found in Cumberland, where it is employed in the preparation of a pig iron low in phosphorus, suitable for the ordinary, or acid, steel making process. Many of the ores of Spain and of the Lake Superior district, such as those of Vermillion, are red hæmatites. Hematites are also obtained from Algiers, and from Cuba, while very large deposits occur in Brazil. These are all low in phosphorus.

In the United States a deposit of phosphoric red fossil (hæmatite) ore runs from Clinton in the State of New York to Birmingham in Alabama.

3. *Brown hæmatites.* Ferric oxide occurs associated with a variable amount of combined water in the different varieties of brown hæmatites. In colour these vary from light to dark brown, and they give a brown streak. A specially rich, pure, and easily reducible variety is now imported in large quantities from Spain, and a pure variety was formerly worked in the Forest of Dean. In Northamptonshire and Oxfordshire, a brown hæmatite is employed which contains about 10 p.c. of silica and over 0.5 p.c. of phosphorus. In Lincolnshire large deposits of a similar character occur, but the silica is replaced by calcium carbonate. The *minette* ores of

France and Lorraine, in the vicinity of the Rhine, although phosphoric, and containing only about 30 p.c. of iron, are of this class, and are among the most important iron ore deposits of the world. Brown ores are also met with in considerable quantities in the United States. *Limonite*, *Bog iron ores*, and *Lake ores* are other examples of hydrated oxides of iron occurring in various localities. *Laterite* is found in India and other tropical countries. It is formed by a curious replacement of silica by hydrated oxide of iron. It is usually poor in iron, but in some localities is rich and important.

Carbonates. These consist essentially of ferrous carbonate (FeCO_3), the notable differences in character observed in various ores depending chiefly upon the amount and character of the impurities present. These ores are widely distributed and of great importance.

Spathic iron ore is the purest form in which ferrous carbonate occurs; it has a pearly lustre, and is generally light brown in colour. There are very extensive deposits of this ore in various parts of Europe, notably at Erzberg in Styria; the ore is usually free from phosphorus, but contains much manganese.

Clay iron stone is a less pure variety of ferrous carbonate which contains clayey matter, and was for many years the most important ore of this country; it usually occurs in the coal-measures. The ore is generally dark in colour, and contains from 30 to 40 p.c. of metallic iron, associated with less manganese and more phosphorus than in the purer spathic ores.

Cleveland iron stone is a variety of clay iron stone met with in the North Riding of Yorkshire. It is generally uniform in character and contains about 30 p.c. of metallic iron; it contains little manganese, but the percentage of phosphorus is

higher than in any of the ores previously mentioned, except, perhaps, in the case of the impure brown hæmatites.

Black band iron stone is an ore which occurs chiefly in Scotland and North Staffordshire. It contains a variable amount of bituminous matter which imparts a characteristic black colour, and which frequently enables the ore to be calcined without the addition of any extra fuel. In other respects black band very closely resembles clay iron stone.

In addition to the ores previously enumerated, several other materials are employed for the production of iron, such as 'tap-cinder,' which is essentially ferrous silicate, and is produced in the puddling process. It was formerly used for making a cheap phosphoric iron known as 'cinder pig,' but is now in demand for basic pig iron for steel making. Tap-cinder is only met with in quantities suitable for the requirements of blast furnaces in those districts where puddling has been conducted for a considerable period. 'Flue cinder' is a richer and purer silicate of iron obtained from furnaces in which iron or steel is reheated previous to rolling. The residue from Spanish pyrites, after the extraction of sulphur and copper, is commonly known as 'purple ore,' and has been made into bricks and used in the blast furnace. It is often used as a fettling in the puddling process.

The following table will illustrate the approximate composition of the various ores of iron. It will be understood, of course, that such materials are subject to considerable variations in character, and it has been thought better to give approximate values deduced from a number of analyses, than to introduce a mass of figures detailing actual results obtained.

APPROXIMATE COMPOSITION OF IRON ORES.

	Magne- tite	Red hæ- matite	Brown hæmatite		Carbonate ores

A full account of the occurrence, properties, and supplies of the chief iron ores of the world has been prepared by the Imperial Mineral Resources Bureau, and is now in course of publication (1921).

Preparation of iron ores.—The greater part of the iron ores now raised are charged into the blast furnace without any special preparation. Anhydrous oxides, such as Lake Superior ores, do not require calcination, except in some cases, to remove sulphur. The chief European ores

are, however, treated before smelting. The mechanical preparation of iron ores is very simple, and consists of a rough assortment of the size of the materials to be employed. In some cases the larger pieces are broken by hand or suitable crushing machinery, whilst in other instances the very fine ore is separated by riddles, and briquetted, or sintered, or used for other purposes, as it would be apt to choke up the blast furnace. Poor ores, such as those of Cleveland, are charged in larger pieces than the

richer hæmatites or magnetites. Non-calcareous ores, which contain iron pyrites, are frequently weathered for a few months, and the sulphur, becoming oxidised, passes away in solution as ferrous sulphate. Shale is also removed by weathering.

Magnetic Concentration is employed for the separation of gangue, pyrites, or calcium phosphate. The magnetic ore, such as that from Scandinavia, is crushed and passed either when dry on a revolving drum or belt in front of powerful electro-magnets; or the crushed ore is mixed with water and caused to flow in front of the magnets. In other cases the finely crushed dry ore is allowed to fall past terminals charged with electricity of high potential. The richer and purer particles become charged differently from the gangue, and may be deflected into separate bins. Ores which are not originally magnetic often become so on roasting, and may be successfully treated provided that the impurities are mechanically separable and not intimately mixed.

Calcination.—Many iron ores are calcined before being used in the blast furnace, the object being to remove volatile substances such as sulphur, water, carbon dioxide, arsenic, &c., and to concentrate the iron in the residue. Two other important objects are also gained by calcination; in the first place the iron is oxidised from the ferrous to the ferric condition, which prevents the formation of scouring slags, rich in ferrous silicate, during reduction in the blast furnace; and further, the material is rendered much more porous so that it is more readily acted upon by the gases of the furnace. From the above remarks it will be evident that some ores, such as red hæmatites, do not require calcination. Ores which are in a state of fine division, such as much of the ore from the Lake Superior district, are not calcined. Fine ores are frequently briquetted, and the briquettes are generally calcined before use in the blast furnace. When calcining, it is necessary to regulate the temperature as carefully as possible; with low temperatures the ore is insufficiently calcined, whilst if the heat be too great, or too much fuel is employed, the materials clot together and much of the benefit otherwise obtained is thus lost. Calcination is often conducted in open heaps, or between rectangular walls, exactly as in the case of many ores of other metals; but these methods are costly in fuel, space, and labour, and are apt to give irregular results, so are chiefly used for roasting tapcinder in Staffordshire, or the black bands of North Staffordshire and Scotland, in which latter case the ore itself contains the necessary fuel. Kilns are now very generally employed for calcining, and in the Cleveland district the use of large circular kilns, constructed of iron lined with fire brick, is almost universal. In such kilns the ore and fuel are charged in at the top, and the calcined material removed from the bottom, the operation being continuous; in such kilns calcination is well under control, fuel is economised, and labour is saved. Rectangular kilns, fired with surplus gas from the blast furnace, have been introduced both in the United Kingdom and elsewhere.

Production of pig iron.—The ore, having if necessary been prepared as before described, is

now *smelted* in the *blast furnace* to produce pig iron. For this purpose it is introduced at the top of the furnace together with the *flux* necessary to form a fluid slag (or 'cinder') with the gangue of the ore; *fuel* is also added in sufficient quantity to melt the materials and to reduce the iron. The air necessary for combustion is introduced near the bottom of the furnace, having been blown, and usually also heated, by suitable appliances. The operation is continuous, a furnace frequently working without any important stoppage for a number of years. The whole of the materials introduced into the furnace have either to be melted and flow off from the bottom as iron and cinder, or to be converted into vapour and pass off as 'waste gases' from the top.

The blast furnace.—The earliest type of blast furnace is shown in Fig. 1, which represents

FIG. 1.

a form employed on the Continent for the production of wrought iron about 500 years ago. After the furnace had been heated, ore and fuel were introduced at the top, and blast from below; the result was the production of a bloom of wrought iron, which, owing to the low temperatures of such furnaces, was never melted, but was removed by taking down the brickwork at the front of the furnace. Doubtless in some of the larger furnaces of this description cast iron would sometimes be accidentally obtained, and as the value of this material for castings, and for the direct production of wrought iron by means of the finery came to be recognised, cast iron would be regularly made. This change was probably introduced early in the 16th century, and the furnaces gradually increased in size until they were capable of producing about 20 tons of pig iron per week, using charcoal for fuel. About two centuries ago coke was introduced as fuel in the blast furnace, and the size and production were slightly increased. Since this period enormous changes have been introduced, commencing with the use of coke about 1735; of hot blast in Scotland in 1829; the adoption of round and larger hearths in South Staffordshire about 1835; the utilisation of

the waste gases; the largely increased height and capacity adopted in the Cleveland district shortly after 1860, and the use of hot blast stoves on the regenerative principle. A remarkable development took place in West Pennsylvania about 1890, and as a result of easily reducible ores, smaller and steeper furnaces, higher blast pressure, and increased engine power, a weekly production of nearly 5000 tons of pig iron per furnace has been attained. Fig. 2 represents a

important source of potash in the United Kingdom. The furnace itself is very light in construction for so large an erection, which is intended to contain a great weight and to resist a very high temperature. The outer casing is of iron plates riveted together, and the furnace is lined with refractory firebrick. The blast is delivered into the furnace by about six tuyers, which are connected with the hot blast main, and which are water-jacketed where they enter the furnace to prevent them being rapidly destroyed by the high temperature. The following summary will illustrate the nature of the products, and the approximate weight of the charges employed for the production of 1 ton of No. 3 Ormesby (Cleveland) hot blast pig iron:

Charge	cwt.	Products	cwt.
Calced iron stone	48	Iron . . .	20
Limestone . .	12	Slag . . .	30
Hard Durham coke	20		
Blast . . .	100	Waste gases . .	130
9 tons		9 tons	

In working richer ores, such as hæmatites, the amount of limestone and ore employed would be less than the quantities required in the Cleveland district, and the weight of slag would be proportionately diminished. To prepare a No. 1 pig iron the quantity of fuel used would be somewhat greater, whilst with a No. 4, or a white iron, rather less fuel would be required; the weight of the blast and of the waste gases would vary correspondingly. Usually the only material added as a flux is limestone, which is sometimes burnt before being charged into the furnace. Other fluxes are often indirectly added in the form of iron ores rich in argillaceous or aluminous matter, as mixtures of ore are frequently made to obtain a more fusible cinder. The fuel most generally used is hard coke, free from sulphur, and with as little ash as possible. Raw bituminous coal is used in Scotland and North Staffordshire and in parts of the United States, though lower furnaces are necessary as the fuel is more friable. Mixtures of coal and coke are not uncommon, and anthracite is employed in Eastern Pennsylvania. Charcoal is still used on the Continent in Sweden and in some parts of America (particularly Michigan) for the production of a superior class of iron where coal is scarce.

Any moisture which is present in the blast is decomposed in the furnace hearth, with the formation of hydrogen and carbon monoxide, and absorption of heat. Hence blast furnaces work better and more economically in cold dry weather. Gayley has successfully introduced a method of drying the blast, by refrigeration, before it is passed into the hot blast stoves. With large installations this leads to greater regularity of composition, increased output, and lower fuel consumption.

The chief changes which take place in the blast furnace may be briefly summarised as follows. The ore in the first part of its descent is rapidly heated to low redness, at which temperature the carbon monoxide, which at this point forms about 36 p.c. of the furnace gases, reduces the ferric oxide to metallic iron; thus—

The iron is not melted at this low temperature,

FIG. 2.

Cleveland blast furnace, the height of which would be about 80 feet, its capacity about 25,500 cub. ft., and the weekly production of pig iron varying from 500 to about 1000 tons, according to the character of the ore used, the temperature and pressure of the blast, and other circumstances. Such a furnace is closed at the top by means of the 'cup and cone' arrangement, into which the materials are charged, and delivered into the furnace at suitable intervals by lowering the moveable cone. The combustible gases are conducted by means of suitable pipes to the regenerative stoves employed for heating the blast, or to the boilers required for raising steam for the works. A portion of the gases is carefully cleaned from dust and used for power purposes in gas engines. The dust recovered from the cleaning of the gases is rich in potash salts, and has become an

but remains as a metallic sponge, which if brought in contact with the air would rapidly burn, and so reproduce ferric oxide. At a part of the furnace slightly lower than that at which reduction is chiefly accomplished the limestone is decomposed, carbon dioxide being evolved and lime produced; thus $\text{CaCO}_3 = \text{CaO} + \text{CO}_2$. During the next stage of the process, which occupies more time than either of the others, the materials gradually descend to the boshes of the furnace, and in so doing absorb heat from the ascending gases. Carbon in a state of minute subdivision produced by the reduction of carbon monoxide, is also deposited in the pores of the spongy iron, which becomes more and more carburised as it descends to the hotter parts of the furnace where fusion takes place. In passing from the boshes to the hearth the temperature is sufficiently high to cause the combination of the silica in the gangue with the lime, alumina, and other bases in the charge, and thus to form a fluid cinder, which separates from the now molten iron, the latter sinking to the bottom of the hearth, while the slag, on account of its relative lightness, floats on the top. The cinder is either tapped off at intervals, or is allowed to flow regularly off through what is known as the 'slagging hole.' The iron is allowed to accumulate, and is then tapped off from a lower point, usually at

intervals of about 12 hours, into moulds roughly made in sand. The product is cast iron, but on account of its being cast in long pieces of D section, which are called 'pigs,' and which generally weigh about 1 cwt. each, this variety of cast iron is commercially known as pig iron.

For steel making the iron is usually tapped

FIG. 3.—MODERN AMERICAN BLAST FURNACE WITH MECHANICAL CHARGING.

off more frequently, and conveyed while still fluid, in ladles holding, say, 20 tons of metal, to the steel works.

Shaft furnaces are also employed for producing cast iron by heating with the electric current, in countries such as Sweden, where electric energy is cheap. The reduction is accomplished by means of charcoal, and the fuel consumption is only about one-fourth of that required in the coke blast furnace. This branch of the iron industry is as yet conducted only on a relatively small scale, but considerable progress has already been made. The gases

from such furnaces are small in volume, and of low calorific value.

CHEMICAL PROPERTIES OF CAST IRON.

The metal obtained as just described is by no means pure metallic iron, but usually contains at least 5 p.c. of other materials, such as carbon, silicon, sulphur, phosphorus, manganese, chromium, &c., &c. The element which imparts the characteristic properties to cast iron is *carbon*, which is present to the extent of at least 1.5 p.c. Under ordinary conditions the maximum amount of carbon found in pig iron is 4.25 p.c., but in

the presence of much manganese this amount may be considerably exceeded. The carbon is present in cast iron in two distinct conditions, known respectively as 'graphitic' and 'combined.'

Iron and carbon unite to form a definite carbide Fe_3C , and it is probable that in molten cast iron the carbon exists in solution in this form. This carbide is retained in solution if the metal is rapidly cooled, but on slow cooling, or conversely by long heating to a temperature of 900° , the carbide decomposes into the more stable condition of iron and graphite. Silicon assists the decomposition of the carbide. The graphite is of two kinds, primary and secondary. Primary graphite is formed at about 1050° , and occurs in relatively large flakes; it causes the iron to be soft and weak. Secondary graphite or 'temper carbon' is produced by decomposition of the residue of the carbide at a lower temperature (700° - 800°). It is smaller, more evenly distributed, and the metal is soft but strong. The carbide may exist in solid cast iron in two forms, one of which separates at about 680° (the recalescence point), and can be seen by the microscope. The other is retained in solution at the ordinary temperature, and hence cannot be seen in micro-sections. The latter is sometimes called 'missing' carbon, as it is not determined in the ordinary Eggertz colour test.

Graphitic carbon renders the iron *grey* in fracture, soft to the tool, and capable of taking a sharp impression of a mould. Combined carbon gives a *white* fracture, the metal is very hard, it melts at a lower temperature, but is never so fluid as in the case of grey iron. Graphitic carbon may be separated from the metal either by mechanical or chemical processes, and may be obtained in either of these ways in a state of great purity. Combined carbon, on the other hand, cannot be mechanically separated from cast iron; whilst if white iron be treated with an acid, such as hydrochloric or sulphuric, the carbon passes off in the gaseous condition, with the hydrogen evolved, in the form of badly smelling hydrocarbons. The graphitic carbon, on the other hand, would in a similar case be left behind in the insoluble residue. Iron which contains combined and graphitic carbon in nearly equal proportions has a characteristic fracture, and on this account is called 'mottled' iron. Slow cooling produces grey iron, while rapid cooling, or 'chilling,' produces white iron.

Silicon is always present in cast iron, the amount varying from about 0.2 p.c. in specially pure Swedish iron, to upwards of 18 p.c. in some varieties of 'silicon pig,' which are specially prepared for certain purposes. Still richer 'ferro-silicons,' containing up to 50 or even 90 p.c. of silicon, are prepared in the electric furnace. In ordinary pig iron the usual limits are from about 1 to 4 p.c. The melting-point of pure iron (*circa* 1515°) is reduced to 1445° when the silicon content is 1.5 p.c. As the silicon content is measured the m.p. is raised to 1516° (3 p.c. Si) and then falls again to 1410° (6 p.c. Si). A 7 p.c. Si alloy melts at 1257° and the fusion point falls regularly to 1256° (14.3 p.c. Si). When present in large proportions silicon renders the pig hard, weak, and brittle; it is also quite unsuitable for use

in the puddling furnace on account of the waste of time and the injury to the lining of the furnace. Silicon, however, renders cast iron soft, strong, and grey when present in suitable proportions; and silicious irons have been largely used in the foundry on this account, as they allow of the use of larger quantities of foundry scrap, which is white and hard. They also allow in many cases of the employment of cheaper irons in foundry mixtures (Turner Chem. Soc. Trans. 1885, 577, 902; 1886, 130). For such purposes the amount of silicon should vary from about 0.8 to 3.5 p.c., according to the size and character of the work; the lower value would be employed for chilled rolls or other purposes where crushing strength is desired, whilst the higher value would be preferred where fluidity and softness are necessary. With higher silicon acid-resisting alloys are obtained. Usually between 15 and 20 p.c. of silicon is added for this purpose. With more silicon the alloy is less fusible, and more difficult to cast. In the blast furnace high temperatures and silicious slags favour the absorption of silicon.

Sulphur is generally present only in very small quantities in good cast iron. With much sulphur the metal is white, hard, and unsound in the foundry; and if converted into wrought iron or steel the product is red-short, and useless. In the blast furnace hot working, a slag rich in lime, and the presence of either silicon or manganese in the metal, prevents the absorption of sulphur.

Manganese is always present in pig iron; its reduction is favoured by hot working and basic slags. *Spiegel-eisen* is a white iron, containing upwards of 5 p.c. of manganese. With 20 p.c. of manganese or upwards, the metal is known as *ferro-manganese*; it frequently contains as much as 86 p.c. of metallic manganese. Both *spiegel eisen* and *ferro-manganese* are used in steel making, as additions at the end of the operation, the object being to add a little manganese to the bath of metal to prevent red-shortness.

Pig iron, which contains manganese, is generally low in sulphur; this fact has been applied to the production of a special pig for use in the basic process, where both sulphur and silicon are required to be present in small quantity.

Sulphur is removed from fluid cast iron for steel making by the use of 'metal mixers,' which are large vessels or furnaces capable of holding about 250 tons of fluid metal. If the iron does not already contain sufficient manganese that element is added, and manganese sulphide separates and passes into the slag. The desulphurised metal is drawn off as required and fresh iron added, so that the process is simple and continuous. Metal mixers also equalise the content of silicon, and this element may be considerably reduced in quantity by adding oxides of iron to the mixer slag.

Phosphorus varies from 0.02 in best Swedish or hæmatite iron to upwards of 3 p.c. in common cinder pig. In the case of each of the elements previously considered only a portion of that which is present in the blast furnace charge passes into the metal, but with phosphorus practically the whole of that which is present in the materials used passes into the pig iron.

For foundry and forge purposes probably a little phosphorus is actually beneficial in cast iron; but in the case of wrought iron or steel its presence is highly prejudicial, as it produces remarkable brittleness in the metal when cold. Hence in the manufacture by the ordinary or 'acid' process, of either Bessemer or Siemens steel, only such pig iron as is free from phosphorus may be employed, since by the acid process no phosphorus is removed. For irons containing phosphorus the 'basic' process must be employed if they are to be converted into steel (*v. infra*, p. 673). A selection of representative analyses of cast iron will be found in Tables at the end of this article.

Grades of pig iron.—For a great number of uses pig iron is sold by the appearance on fracture. A pig which is very grey, with large crystals, is called No. 1; if the fracture shows smaller crystals it is called No. 2; with still closer grain it would be sold as No. 3 or 4. If white and grey are mixed it is called mottled; when graphitic carbon almost entirely disappears it is called white. On account of their softness and fluidity Nos. 1, 2, and 3 are chiefly employed for foundry purposes, and usually command a somewhat higher price. No. 4 is largely used in the puddling process, and would be called a forge or 'strong' iron. No. 4 is also employed in mixtures in the foundry when heavy castings are required, or when the metal is to be chilled—*i.e.* when the surface is to be rendered white and hard by cooling in contact with a mass of metal, technically known as a 'chill.' Mottled and white irons are chiefly used in mixtures of pig iron to give hardness, strength, or density.

Foundry practice.—The ironfounder commonly employs a mixture of irons, and it is the custom to mix not merely different grades of iron, but also metal from different localities. This originated at first from the results of practical experience, but it has since been shown in many cases to be in accordance with scientific knowledge, as the best foundry iron for any particular purpose contains a certain proportion of combined and graphitic carbon, silicon, phosphorus, &c. (Turner, Journ. Iron and Steel Inst. 1886), and these constituents can usually be best regulated by mixing together the irons obtained from different localities. If special strength is required the silicon should not exceed about 2 p.c., and the phosphorus should be somewhat less than half that quantity. But if softness and fluidity are specially desired, these amounts may frequently be nearly doubled without serious injury. The metal is melted in a small blast furnace called a cupola, which is constructed of iron plates, lined with firebrick or ganister; it is circular in section, and is driven with a low-pressure cold blast, introduced through twyers near the bottom. The metal is charged from the top, the fuel used being hard coke free from sulphur; the weight of coke varies from about 5 to 15 p.c. of the metal used, being higher with smaller outputs. A small quantity of limestone is added to act as a flux. The metal on melting runs down, accumulating in the bottom of the cupola below the twyers, and is then tapped off at intervals into suitable ladles. For special qualities of castings, melting is sometimes performed in a reverberatory furnace; this is more expensive, but gives

a cleaner and more uniform metal, which can, if necessary, be tested before use. For the majority of purposes 'green sand moulding' is adopted, a pattern being first prepared and an impression obtained in fine sand, which has been previously mixed with a small proportion of carbonaceous matter, such as coke dust. For special work, or intricate forms, other varieties of moulds are prepared, which are often of loam; these are supported by masonry, and braced with tie rods, &c., as may be found necessary. Such moulds are carefully dried before being used; in some cases drying is performed in stoves at a low red heat, in other instances by means of a fire which is placed inside the mould. In the latter case gaseous fuel is commonly employed. Green sand moulds are not dried before use; where they can be employed they have the advantages of rapidity and economy.

Iron, when remelted in the foundry, becomes harder, owing to the elimination of silicon and the absorption of sulphur. Hence in some cases, when the metal is originally too soft, a great improvement is noticed on remelting several times; but in other cases no improvement is observed, and frequently deterioration results. Many observers, among them Sir W. Fairbairn (Brit. Assoc. Report, 1853, 87), have stated that iron is improved by remelting a certain number of times, and that afterwards by further melting it again deteriorates. But the experiments of various observers gave very conflicting results in this direction, some recommending very few meltings, others a larger number. It has been shown by Turner (Chem. Soc. Trans. 1886, 493) that the effect formerly attributed to the operation of remelting is really due to the chemical changes which take place during that operation, and that the chemical composition of the product, when rightly understood, gives an indication of its mechanical properties.

Production of wrought iron.—It has already been mentioned that by the earlier processes wrought iron was produced directly from the ore. Similar processes are still carried on by semi-civilised races in various parts of the world, and in an improved form direct reduction is still practised in parts of America where charcoal is cheap, and where no ready means of transit exist. Many attempts in the same direction have also been made in various parts of Europe. In several instances great expectations have been raised in connection with these suggested improvements, but none of them has met with much commercial success. In these methods of reducing the iron ore the temperature employed is usually not sufficiently high to melt the metal obtained; the phosphorus present in the ore remains in a great measure in the slag, which is rich in oxide of iron, and the wrought iron obtained even from moderately phosphoric ores, is still sufficiently pure to be useful. The direct method is usually extravagant both in fuel and labour, whilst the slags produced frequently contain sufficient iron to make them valuable for use in the blast furnace.

Wrought iron is now generally prepared by an indirect process, cast iron being produced as an intermediate product between the ore and the finished metal. The impurities of the crude pig iron are then removed by oxidation, and pass

away either in the form of gas, as with carbon, or, like phosphorus, silicon, and manganese, remain in the slag. This purification was originally performed in small hearths called 'fineries,' and for the production of specially selected metal these have survived in isolated places to the present day. But a most important change was introduced in 1784, when Cort patented the puddling process, in which the operation of purification is conducted in a reverberatory furnace. In Cort's original furnace the working bottom was made of sand, and white pig iron was employed; the iron never became perfectly fluid, and from the pasty character of the metal the 'puddling' process derived its name. This original form of the process has now almost entirely given way to what is known

fettling, the operation is conducted more rapidly, and larger charges can be employed; whilst, as grey iron is used, the metal is perfectly fluid when melted, and 'boils' vigorously during the elimination of the carbon. A sketch of the furnace is given in Fig. 4.

The operation is conducted as follows. The furnace being at a red heat from the previous charge, the fettling is repaired, as necessary, by the addition of 'bull-dog,' pottery mine, hematite, or other forms of oxide of iron. About 4 or 4½ cwt. of pig iron are then charged on to the bed of the furnace, the door being closed and the temperature raised while melting proceeds. After about 30 minutes the iron is generally melted, and is then kept fluid and well rabbled for about 10 minutes, the length of time depending very much on the composition of the metal employed. By this time practically the whole of the silicon will have been removed, and much of the manganese. The temperature is then lowered somewhat, by regulating the damper, and a violent reaction ensues between the oxygen of the fettling and the carbon in the metal. The iron boils vigorously owing to the escape of carbon monoxide, which burns in jets at the surface, and a quantity of slag, called tap cinder, is removed, part of this being allowed to boil over the fore plate of the furnace, and the remainder being tapped out at the end of the operation. The phosphorus gradually passes

out during the process, being eliminated most rapidly at this stage, and passing into the tap cinder. After the boiling stage is over the metal 'drops' and 'comes to nature'—i.e. granules of malleable iron gradually separate, and the whole becomes quite pasty. In this condition it is 'balled up' by the puddler into blooms, each of which is somewhat under 100 lbs. in weight. These are then hammered and rolled, forming puddled bar, which is not yet fit to be sent into commerce. The whole operation of puddling usually occupies about 70 minutes. Analyses of forge irons, puddled bar, &c., are given in Tables at the end of this article. The puddled bar is cut up into lengths and made into suitable bundles

called 'piles,' which are reheated in a furnace, which is larger but otherwise very similar in construction to that in which the puddling operation is conducted. The piles are withdrawn at a welding heat, and hammered or rolled to produce merchant iron, best iron, best best iron, &c., according to the quality and the amount of work expended on the material. A number of attempts have been made to introduce mechanical contrivances to replace the laborious process of puddling; but, after numerous trials, these have been almost entirely abandoned in this country, though a revolving furnace invented by Danks was successfully used in America. Wrought iron was formerly used for ship building, bridge construction, rails, armour plates, and similar purposes, for which it has since been replaced by steel. Wrought iron is now chiefly employed for purposes which require a reliable metal which can be easily welded or otherwise worked by the

FIG. 4.—THE PUDDLING FURNACE.

as 'pig boiling,' in distinction from the earlier 'dry process.' Pig boiling was introduced by Joseph Hall, of Tipton, Staffordshire, about 1820. In principle the operation is exactly the same in either case; in practice the chief differences are in the construction of the furnace, the materials forming the bottom, and the kind of cast iron employed. In the more modern process (which, however, is gradually being replaced by the use of 'mild steel') the furnace bottom is constructed of cast-iron plates, and the bridge is internally cooled either by air or water; the cast-iron bottom plates are covered with a layer of oxide of iron about 3 inches thick, which forms the working bottom of the furnace; the sides are formed of fettling, also consisting essentially of oxide of iron; the metal used is a grey iron, usually what is known as a No. 4 forge quality. The result of these changes is that the furnace works with fewer repairs; that, owing to the use of oxidising

smith. It is also used for tubes, wire, sheets, and fittings which are exposed to atmospheric oxidation.

Steel. Steel was formerly defined as a variety of iron which contained from 0.5 to 1.5 p.c. of carbon, and which was capable of being hardened and tempered. This definition however, has now to be extended so as to include various forms of 'mild steel' which contain under 0.5 p.c. of carbon, and which cannot be hardened. We therefore include under the designation of 'steel' all metal which, though containing under 0.5 p.c. of carbon, has been produced in the molten condition. In such a classification wrought iron is obviously excluded, as it is produced in a pasty form. The characters of steel depend largely on the proportion of carbon and other elements which enter into its composition. With low percentages of carbon the metal possesses great ductility, moderate tenacity, and very slight power of hardening. With 0.45 p.c. of carbon the ductility is somewhat less, the tenacity greater, whilst its hardening power is quite appreciable. Such a metal would be employed in the manufacture of rails and for similar purposes. With from 0.6 to 1 p.c. of carbon the ductility is still lower, whilst the tenacity reaches upwards of 40 tons per square inch of section, and a metal is obtained which can be readily hardened and tempered. This class of steel is largely used for cutting tools, drills, dies, &c., and for best purposes is still usually produced in crucibles. The use of the electric furnace is rapidly extending for the production of tool steels, especially for such as contain other elements in addition to carbon. With carbon from 1 to 1.5 p.c. a steel is obtained which is suitable for the hardest tools, and which requires to be very skilfully hardened and tempered. As the proportion of carbon increases, the steel requires to be worked at a somewhat lower temperature. With upwards of 1.5 p.c. of carbon the metal is brittle, is no longer capable of being hardened, it is more fusible, and thus gradually passes into cast iron. Hardening increases the tenacity of steel, but diminishes its ductility. The tenacity of steel, like that of wrought iron, is also increased by the amount of work done in rolling or in drawing out the metal into wire, and certain varieties of steel wire are prepared which have a tensile strength of upwards of 150 tons per square inch. The presence of manganese in steel increases its tenacity; in suitable proportions it also very materially improves the working properties of the metal, and on this account is employed both in crucible steel making and in the Bessemer and Siemens processes. In large quantities manganese renders steel permanently harder, and also causes it to be unmagnetisable (Hadfield). 'Manganese steel' contains about 10 p.c. of manganese. It is permanently hard, and is used chiefly in the form of castings for tramway points, stamp batteries, and many similar purposes (*cf.* Hall, J. Soc. Chem. Ind. 1915, 57). Phosphorus renders steel cold-short, and should on this account not exceed 0.1 p.c., whilst crucible steel of special quality usually contains not more than 0.04 p.c. of phosphorus. Sulphur renders steel red-short, and should never exceed a few hundredths per cent. Silicon in the absence of any reducing agent forms silica,

which renders mild steel red-short and brittle, although the presence of manganese very much modifies these effects, so that with about 0.5 p.c. of manganese several tenths per cent. of silicon may be present without injury. In steel castings about 0.3 p.c. of silicon is frequently added to promote soundness. A special steel, containing about 3.5 p.c. of silicon, is used for the production of sheet steel for armatures, as it shows remarkably low hysteresis losses. Arsenic renders steel both hot- and cold-short; practically the whole of the arsenic present in the blast furnace charge passes into the pig iron, and is not removed during conversion into steel (*v.* Stead, also Harbord and Tucker, Jour. Iron & Steel Inst. 1888, part 1). Chromium in small quantities gives increased tenacity, and on this account is frequently added to basic or other very mild steel so as to impart greater strength. With considerable proportions of chromium the welding power of steel is much reduced. Chromium is added to steel shells as the penetrating power is thereby greatly increased. It is also employed in the production of rustless or stainless steel for cutlery. Aluminium is frequently used for addition to fluid steel for deoxidising purposes. It assists in the production of solid ingots, and prevents segregation of the impurities. The amount of aluminium left in the steel is, however, so small as to be with difficulty estimated by analysis. Nickel is added to mild steel for shipbuilding and constructional purposes, usually to about the extent of 3.5 p.c., as it imparts increased tenacity with unusual ductility. With higher proportions of nickel hard non-magnetic alloys are obtained, which are only used for certain special purposes. Chrome-nickel steels, containing about 1 p.c. of chromium and 3.5 p.c. nickel, are used for tools and in automobile construction. In recent years tungsten has been used on a very considerable scale for the production of self-hardening and other 'special' steels. Usually about 6 or 7 p.c. of tungsten is added; the steels are made in crucibles, and contain from 1 to 2 p.c. of carbon. High-speed steels contain still more tungsten, and retain their cutting properties even at a red heat. Vanadium is also added to mild steels with marked advantage, a very small percentage giving improved physical properties. Much attention is now being devoted to the production of special alloy steels for a variety of purposes. They generally contain from 0.6 to 1 p.c. of carbon, with varying proportions of manganese, chromium, nickel, cobalt, tungsten, molybdenum, vanadium, &c. Such alloy steels are now generally melted in the electric furnace in charges varying from about 2 to 10 tons.

Manufacture of steel.—A variety of steel, or more correctly steely iron, was obtained by the earlier processes used for the production of wrought iron directly from the ore, when the process was modified by altering the amount of blast used, and the angle at which it was introduced, together with a slight increase in the quantity of fuel employed. By these means the metal prepared contained sufficient carbon to impart steely properties, although when obtained by such methods the steel is never of uniform quality. A steely iron was also frequently prepared in the puddling furnace when the process was carried on in such a manner as

to remove the metal before the carbon was completely eliminated. But for some centuries at least the best varieties of steel have been prepared by what is known as the 'cementation' process. For this purpose, bar iron of the best quality is cut up in suitable lengths and placed in charcoal in the cementation furnace. This furnace consists essentially of two rectangular chambers which are constructed of firebrick, and are arranged to contain the iron and charcoal. The charge of iron used in one operation is generally about 15 tons. A fireplace under the chambers supplies the necessary heat, whilst the whole is contained in the base of a large conical chimney stack. The iron is carefully arranged and surrounded with charcoal, the rectangular chests, which are open at the top, being covered with 'swarf' to protect the contents, as far as possible, from oxidation. The heat is continued for about 7 days, although the time will vary somewhat with the temper required and other circumstances. The progress of the operation is judged by the appearance of the fracture of trial bars, which are removed and examined from time to time. The product is known as 'blister' steel, the name being derived from the characteristic appearance of the surface. Percy has shown that this is probably due to carbon monoxide evolved at a high temperature by the action of carbon on the oxygen of the intermingled slag. In good blister steel the protuberances should be as evenly distributed as possible. When fractured, the blister steel is generally found to consist of an outer crystalline layer of steel surrounding an inner portion of less altered iron. The exact theory of cementation has not been made out with certainty, although Roberts-Austen showed that pure iron became carburised when heated with a diamond *in vacuo*; but under usual conditions carbon monoxide is known to play an important part in the process. The result is that the metal, when heated in contact with solid carbon, becomes gradually carburised on the outside, and if the heating be continued for a sufficient length of time, carburisation gradually extends throughout the whole of the mass. Blister steel, when piled and reheated, is known as 'shear' steel, and gains considerably in uniformity by the treatment. The name is derived from the fact that shears used for cutting woollen cloth were formerly made of this variety of steel. But for best steel for tools and other purposes it is usual to employ 'cast steel,' the best qualities of which are prepared by melting blister steel in clay or plumbago crucibles. The charges usually weigh somewhat less than 100 lbs., a little glass or other flux is employed, and the crucible is kept covered while melting proceeds. Heating is conducted usually in wind furnaces, using coke as fuel, though gaseous fuel has also been employed. It is contended that gaseous fuel has the advantage of being more under control; it is also economical in working, and enables the process to be carried on continuously, whilst the wind furnace 'clinkers' up and has to be stopped for cleaning. Cast steel is also prepared in crucibles from materials other than blister steel, but the product is usually of an inferior character. It is found advantageous (especially with cheaper mixtures) to introduce a little

manganese in the production of crucible steel, as the metal then possesses better working qualities. The 'body,' which is so characteristic of good steel, appears to be closely connected with its chemical composition, and is associated with special freedom from phosphorus and similar impurities. Crucible steel contains a few hundredths per cent. of silicon, which is reduced from the silicious material of the crucible during the melting, and which appears to play an important part in producing solid castings. For special purposes, in recent years, considerable quantities of manganese, nickel, chromium, tungsten, and of other elements have been added to steel produced in the crucible, and the 'special' steel industry has become important both in this country and abroad. But, as before stated, the electric furnace has been introduced on a very considerable scale, for the production of such special steels.

Bessemer steel. The method of producing steel with which the name of Bessemer will always be connected, and which has done so much to revolutionise the iron trade of the world, was described and patented in 1856. At first great incredulity was manifested by ironmasters, and the product was inferior; but when it came to be recognised that only iron free from phosphorus could be employed in this process, and that the red-shortness which at first had been so difficult to overcome could be removed by the addition of manganese before tapping the metal, the success of the process was assured. The iron now used in the ordinary, or as it has come to be called the 'acid' Bessemer process, is of special quality, and is made from ores of hæmatite quality. It should contain only a few hundredths p.c. of phosphorus, and about 1-3 p.c. of silicon. With rapid working, as in the large American works, the silicon is about 1 p.c. lower than is the custom where fewer charges are run in the same time as in England. The metal is either remelted in a cupola or is run in the fluid state from the blast furnace, or the metal mixer, according to circumstances, but in any case is introduced in the molten condition into an egg-shaped vessel known as a 'converter,' and which has been heated either by a previous charge or by lighting a fire inside. The converter is constructed externally of iron plates, and is arranged so as to rotate on trunnions which are fixed on either side a little below the middle of the vessel. By this arrangement the converter can be readily manipulated as required during the process. At the lower part of the vessel is a moveable bottom, fitted with a blast box into which air is admitted during the 'blow' at a pressure of about 20 lbs. to the square inch. From the blast box the air enters the vessel through a number of holes passing through a firelay or ganister bottom lining. The sides of the converter are generally lined by means of ganister (a silicious or 'acid' material) which is generally rammed into position. At the top of the converter, a little on one side, is an opening which serves for the introduction of the metal in the first place, then for the escape of waste gases during the blow, and lastly for the tapping of the metal and slag when the operation is concluded. The charge of pig iron, which weighs from about 8 to 12 tons, is introduced while the

vessel is in a horizontal position, in order to avoid closing the twyers at the bottom; the blast is then turned on and the vessel rotated so as to cause the blast to rise through the bath of metal. The silicon present is rapidly oxidised and passes into the slag, at the same time producing sufficient heat, not merely to maintain the fluidity of the metal, but actually to very much increase its temperature. After the silicon has in this manner been removed, which generally occupies about 10 minutes, the carbon is attacked, and this is rendered evident by a marked increase in the size and luminosity of the flame produced. This flame continues for rather more than 10 minutes, and then, when the carbon has been burned out, suddenly 'drops,' *i.e.* becomes much smaller and less luminous, showing that the operation is concluded. During the whole of the blow the metal remains molten, and the temperature produced by the combustion of the carbon and silicon is so great that the resulting decarburised

metal can be readily poured into suitable ingot moulds. But if used in this form, when it is almost perfectly freed from carbon and manganese, the metal would be red-short, and would also be too soft for many purposes. It is usual, therefore, after the flame has dropped, to add a quantity of spiegeleisen or ferro-manganese in order to counteract this red-shortness and to introduce the required amount of carbon. After the requisite addition has been made the metal is allowed to stand a few minutes so as to some extent to mix the constituents; it is then 'teemed' into the ladle and thence cast into ingots.

The basic Bessemer process.—It will be noticed that in the original Bessemer process the vessel is lined with silicious or acid materials, and only cast iron free from phosphorus can be employed, as practically none of this element is removed during the blow. But a modification of the process was introduced by Messrs. Thomas and Gilchrist, which most successfully solved

FIG. 5.

the problem of the treatment of phosphoric iron. Fig. 5 (after A. Holley) shows the general arrangement of a basic Bessemer works. The mechanical arrangements of the plant and general principles involved in the two processes are exactly alike, with the exception that the lining used in the basic process is a mixture of lime and magnesia, obtained by calcining dolomite. This is mixed with dry tar in suitable proportions so as to make it bind, and is then either rammed into shape with hot tools, or pressed into bricks and baked as may be most convenient. The cast iron used should be as low in silicon as possible, on account of the injurious action of a silicious slag on the basic material of which the lining is composed. The phosphorus, on the other hand, may be as high as 3 p.c. without exerting any injurious effect on the finished product. To ensure low sulphur while the silicon is also low, about 1.5 p.c. of manganese is usually introduced into the iron. In modern works the proportions both of silicon and of sulphur are reduced and rendered more uniform by the use of a metal mixer. The 'blow' is conducted in the early stages just as in the acid Bessemer process, silicon being removed first while carbon afterwards passes out, and the flame 'drops' as before. Lime is then added, and an after-blow is given, which lasts some 5 minutes, depend-

ing on the amount of phosphorus present; during this stage the phosphorus is almost completely removed and passes into the slag. The progress of the operation is judged by means of small samples which are withdrawn and examined at intervals during the after-blow. When ready, the metal is tapped as usual, and the product is a specially mild and soft metal. The slag is used, when ground to fine powder, as a phosphatic manure; it has also been used as a material for the construction of the bottoms of reheating furnaces (Harbord and Tucker's patent). The basic Bessemer process is applied on a large scale in this country, but is used still more extensively on the Continent, especially in the large steel works in the district around Düsseldorf on the Rhine.

Where metal of special purity is required, the fluid steel, instead of being cast into ingots, may be transferred to an electric furnace, where with high temperatures and very basic slags the phosphorus may be reduced to a mere trace. After the phosphorus has thus been transferred to the basic oxidising slag, this slag is removed, and a slag is made of lime and fluor spar; carbon is also added and this reducing slag removes the sulphur. Hence by working with two slags in succession, one oxidising, and the other reducing, both phosphorus and sulphur can be removed, and a steel of special purity obtained. This

method of working is employed at a number of American steel works.

In Bessemer's earlier experiments small converters were employed; some of which were moveable, whilst others were fixed. Both of these forms have been recently reintroduced, and small converters have met with considerable favour for special purposes, particularly for the production of steel castings.

Siemens steel. Numerous attempts have been made to prepare steel by decarburising cast iron by some method other than that previously described; but the only successful rival to the Bessemer process was originated by the late Sir William Siemens. The invention of the Siemens furnace, with the accompanying gas producers and regenerators, placed in the hands of the practical man the successful application of a beautiful scientific principle which has been largely used in many branches of manufacture, such as the production of glass, porcelain, and pottery; for the reheating of iron and steel, and for numerous other purposes. Space will not here allow of the description of the apparatus, and it will only be necessary to mention that by this means a temperature can be easily and economically obtained, which is amply sufficient to melt wrought iron, and to enable it to be readily poured when melted. Apart from the method used in heating the furnace, the Siemens-Martin process (which was invented by Siemens, and rendered commercially successful by Martin) closely resembles in principle the original puddling process. The furnace is of the same general shape as the puddling furnace, but is capable of working a charge of from 5 to upwards of 50 tons. The external portions are of cast iron lined with very refractory silicious firebrick, while the working bottom is of refractory sand. The pig iron to be used is charged first, and the malleable iron and iron ores which are added to decarburise the pig iron are introduced at suitable intervals during the operation, which generally lasts about 8-10 hours. Several modifications of the process have been introduced, it being convenient sometimes to omit either the malleable iron or the ore, whilst in some cases malleable iron or steel scrap only has been used (Martin's process). In any case, so long as a silicious lining is employed, the materials used must be as free as possible from phosphorus. The *basic process* is also conducted in the Siemens furnace, phosphoric pig iron, or similar metal from a mixer, being used, together with the necessary steel scrap and ore or other ferruginous oxidising materials. In larger establishments hand charging has now generally been replaced by mechanical appliances. For basic working the chief modification introduced is the substitution, for the ordinary silicious bed, of a working bottom of basic material, similar to that used in the basic Bessemer process. Quicklime is also added to the charge during the working of the heat so as to ensure a basic slag and the removal of the phosphorus. The open hearth process differs from the Bessemer basic process in that while in the latter the phosphorus remains in the fluid metal until practically all the carbon has been eliminated, in the open hearth process, on the other hand, much of the phosphorus is removed during the earlier stages of the opera-

tion. If the acid Siemens furnace may be regarded as a large puddling furnace with gaseous fuel, working on Cort's original lines, except that the temperature used is sufficiently high to melt the resulting malleable iron and so produce mild steel, then we may consider the basic Siemens process as closely resembling the 'pig boiling' of more recent times, except that, as in the previous case, the operation is on a much larger scale and the product is in a molten condition.

As compared with the Bessemer process the Siemens, or as it is frequently called, the 'open hearth' process, possesses the advantage that it is more under control, and for this reason is frequently preferred when work of a specially uniform character is required; it is also more in favour for steel castings. Further, it permits of the use of considerable quantities of scrap, which is relatively cheap, and would otherwise be a drug on the market. It also gives a greater yield per ton of metal used. This extra yield often more than pays for the cost of fuel used. The Bessemer plant, on the other hand, gives more rapid working, and hence is preferred for large outputs. There is little doubt that equally good steel may be produced by either of the processes, though the pneumatic method requires very careful attention when special uniformity is desired. In the United Kingdom the acid Siemens process is most important; in Germany the basic Bessemer is chiefly used; in America the two processes employed are the acid Bessemer for rails, &c., and the basic open hearth for structural materials. From the metal which is slightly too phosphoric to be used in the acid process an excellent steel is made in the basic open hearth furnace.

The tendency in recent years has been to replace the Bessemer process by the open hearth, and to develop the basic method of working.

The Talbot process. In this important modification of the open hearth basic process a large tilting furnace of cylindrical form is heated at either end by gaseous fuel and regenerators. The vessel, which holds 150 tons or more of fluid metal, is basic lined and a slag rich in molten oxides of iron is maintained. The charge of fluid cast iron is first worked till steel of the required composition is obtained; about 20 tons of this fluid steel is then tapped out of the furnace. Some 20 tons of metal is added to the contents of the furnace and a reaction is set up as a result of which silicon, carbon, and phosphorus are removed, and fluid steel remains. Metal is run off into the ladle as required for the rolling mills, and fresh iron poured in from time to time. The process is thus continuous, and the furnace works from week to week without stopping. The fuel consumption is low, the yield good, repairs are diminished, whilst steel of excellent quality can be produced from phosphoric ores.

Malleable cast iron. For many purposes where a complex form is necessary, and only moderate strength is required, the articles are cast in green sand in the ordinary way, but a special variety of pig iron is used, low in phosphorus, and manganese, and containing about 0.65 p.c. of silicon. The castings so prepared are white, hard, and brittle; but when heated, in

contact with oxide of iron, in covered cast-iron boxes, to about 900° for several days, they become grey and soft. The softness so developed is accompanied with considerable malleability, so that the articles can be readily worked under the tool and punched, planed, &c., as required. Malleable cast iron, however, will not weld like ordinary malleable iron. This process is chiefly conducted in this country in the Midlands, particularly at Walsall and Birmingham, and the heating in contact with oxide of iron is known technically as 'annealing.' A portion of the graphite is removed by oxidation, and the rest, having been thrown out of solution at about 900°, exists as secondary graphite, or 'temper' carbon. In recent years the malleable cast iron industry has reached very large proportions in the United States, the output being now about ten times as great as that of the United Kingdom. The castings are generally produced from metal low in sulphur, but slightly higher in silicon than is usual with the European or 'Reaumur' process; it is melted in a coal-fired reverberatory, or in an acid Siemens furnace. The annealing is conducted at a temperature of about 750° and occupies a shorter time. Hence less graphite is removed by oxidation, and the product is known as 'black heart' castings.

Tin plates. In order to protect iron from oxidation it is frequently covered with a thin layer of metallic tin. This is chiefly applied to the protection of thin plates of steel, which are first rolled in the ordinary way, and, after a preparation (including 'pickling' in dilute sulphuric acid, annealing, and cold rolling) in order to obtain a suitable surface, the plates are immersed in a bath of molten tin which is kept

covered with grease. In this way a thin coating of tin adheres to the surface of the iron and protects it from oxidation so long as the iron is completely covered. In case the tin is removed from any part of the surface, however, oxidation takes place more readily than in the original metal. For this reason galvanised iron is to be preferred for purposes where iron has to be exposed to atmospheric action, and where there is no chance of articles of food coming in contact with the zinc. Tin plates are largely manufactured in South Wales, and were formerly made from an iron possessing special malleability, and which was prepared in the old-fashioned open hearth. At present tin plates are prepared from mild steel, chiefly that produced by the Siemens process. (For details of preparation *v.* TIN PLATES.)

Galvanised iron. Iron which has to be exposed to the weather or other oxidising agencies is frequently galvanised, *i.e.* covered with a thin coating of metallic zinc. In this case the metal is previously cleaned from scale, &c., by being 'pickled' in hydrochloric acid, and after cleansing the article is immersed for a few moments in a bath of molten zinc, which is kept covered with a little ammonium chloride. By this means a uniform covering of zinc is obtained, which protects the iron underneath, not merely so long as the coating is perfect, but also when the zinc has been partly removed. Galvanised iron, however, cannot be used in contact with either mineral or vegetable acids, and hence is not employed for cooking utensils, nor for the cans in which food is preserved. Iron can also be coated with zinc by electro-deposition; or by heating at a moderate

Iron as produced by the reduction of its oxides by carbon always contains more or less of the latter element. Wrought iron is the purest form of commercial iron, but in addition to carbon it usually contains small quantities of sulphur, phosphorus, silicon, &c. Chemically pure iron may be obtained as a black powder devoid of metallic lustre by reducing the oxide or oxalate in a current of hydrogen which is pyrophoric if the reduction is effected at a low temperature.

Pure iron finds a limited use in transformer cores and for experimental work. It is usually prepared by electrolysis, the electrolyte consisting of a solution of ferrous chloride and calcium chloride, or a mixture of ferrous ammonium sulphate, magnesium, and sodium hydrogen carbonate, the working temperature being 90° and current density 10 amps. per dm.².

Pure iron has a silver-white lustre and is capable of a high polish. It is highly ductile and malleable, becomes soft at a red heat, and may be welded at a white heat; m.p. 1530° (Dana and Foote). It may be distilled in the electric furnace. It is attracted by the magnet but is not permanently magnetic. It seems to exist in three allotropic forms, distinguished as α -, β -, and γ -ferrite, depending on temperature (Osmond and Cartaud). Sp.gr. 7.86; mean sp.h. 6.1098 (15°-100°) increasing rapidly up to 850°, when it decreases.

COMPOUNDS OF IRON.

Oxides. Three oxides of iron are known:—

Ferrous oxide or iron monoxide FeO;

Ferric oxide or iron sesquioxide Fe₂O₃;

Ferroso-ferric oxide or magnetic oxide of iron Fe₃O₄.

The trioxide FeO₃, which may be considered to exist in the ferrates, has not been isolated.

Iron monoxide or ferrous oxide FeO is a strong base. It may be prepared by the reduction of the sesquioxide in a current of hydrogen at 300°. On exposure to air it oxidises with incandescence, but loses this property when allowed to remain for 12 hours in an atmosphere of hydrogen. It is also obtained as a black, velvety powder by adding ferrous oxalate to boiling caustic potash solution; when washed with water in air it takes up oxygen. Ferrous oxide is also formed by the action of nitrous oxide on metallic iron at 200° (Sabatier and Senderens, Compt. rend. 1892, 114, 1429).

The hydrated oxide Fe(OH)₂ is precipitated on addition of caustic soda to a ferrous salt in absence of air. When absolutely pure the precipitate is white, but it rapidly absorbs oxygen, acquiring a greenish hue and becoming ultimately converted into the red sesquioxide. It crystallises from a strong caustic soda solution in flat, pale green prisms (de Schulten, Compt. rend. 1889, 109, 266).

Ferrous oxide absorbs carbon dioxide with avidity. It dissolves in about 150,000 parts of water. It is used to impart a green colour to glass, which at the same time becomes athermanous, transmitting but little heat (Zsigmondy, Dingl. poly. J. 287, 17 *et seq.*).

Ferroso-ferric oxide, Magnetic oxide, Black oxide (FeO·Fe₂O₃ or Fe₃O₄, occurs in nature as *magnetite* (magnetic iron ore or lodestone (q.v.)) in

most parts of the world, and constitutes one of the most important ores of iron. It is always attracted by the magnet, but does not always possess the property of attracting iron. It may be prepared by passing steam or carbon dioxide over red-hot iron, but the primary product in the case of water vapour is FeO. It is probably a coating of Fe₃O₄ which renders iron 'passive,' or unacted upon by concentrated nitric acid or water. This property is taken advantage of in the Bower-Barff process for preventing the rusting of iron, in which the metal is heated to redness and subjected to the action of steam.

When pure this oxide is an iron-black substance having a sub-metallic lustre. Its sp.gr. is 5.18, and its melting-point is 1527° (Kohlmeyer, Metallurgie, 1909, 6, 323).

The oxide is soluble in strong acids, the solutions containing a mixture of ferrous and ferric salts. By adding caustic alkali to such a solution or to a mixture of ferrous and ferric chlorides in proper proportions, a black precipitate of *ferroso-ferric hydroxide* is obtained, which, on drying in air, yields a brown-black, brittle mass, stable in air, which is magnetic, and may thus be separated from admixed ferrous and ferric oxides. It has the composition Fe(OH)₂·Fe₂O₃.

Iron-scale is a compound of ferrous and ferric oxides in varying proportions. The inner layers are not magnetic, and approximate in composition to 6FeO·Fe₂O₃; the outer layers of the scale are magnetic, and contain a larger proportion of ferrous oxide.

Iron sesquioxide or ferric oxide Fe₂O₃ occurs anhydrous as *hematite*, sp.gr. 5.19-5.25, *specular iron ore*, *kidney ore*, and *micaceous iron ore*, and, in the hydrated condition, as the yellow or brownish *limonite* 2Fe₂O₃·3H₂O, of which *bog iron ore*, *pea iron ore*, and certain *clay iron stones* are earthy varieties. *Göthite* Fe₂O₃·H₂O and *turgite* 2Fe₂O₃·H₂O are other forms in which the hydrated oxide occurs. The earthy varieties of hematite are known as *redde* or *raddle*, and as *red ochre*, and are used as pigments; the earthy varieties of limonite being similarly used under the names *yellow* and *brown ochre*.

The anhydrous oxide may be obtained by heating the hydrated oxide or a ferrous or ferric salt containing a volatile acid. The latter method is the one principally used for the preparation of the commercial oxide, the salts most used being the sulphate or the chloride obtained from the 'pickling' of iron in the process of galvanising.

It may be prepared in small crystals by passing the vapour of ferric chloride over heated lime. The ignited or native oxide is slowly soluble in acids, the best solvent being a mixture of 8 parts sulphuric acid and 3 parts water.

Ferric oxide crystallises in tabular rhombohedral scales of sp.gr. 5.17, having a steely lustre. At the edges the crystals transmit light of a ruby-red colour. The solidifying-point of the molten oxide is 1562°-1565° (Kohlmeyer, Metallurgie, 1909, 6, 323).

Heated in the electric furnace or in the oxyhydrogen flame it yields the magnetic oxide (Moissan, Compt. rend. 1892, 115, 1034; Read, Chem. Soc. Trans. 1894, 314). Usually it is very slightly paramagnetic, but it is more strongly magnetic if prepared by the oxidation

of ferrous hydroxide (Malaguti, Compt. rend. 1862, 55, 350). Walden states that at 1350° the dissociation pressure of the oxide is about equal to that of the oxygen in the air (J. Amer. Chem. Soc. 1908, 39, 1350).

The residue obtained in the manufacture of Nordhausen sulphuric acid by distillation of ferrous sulphate consists of this oxide, and is known as *colcothar*, and is largely used as a pigment. On account of the absence of grit it is used as polishing *rouge*; the parts which are of a scarlet colour—i.e. which have not been strongly heated—being preferred for glass polishing and for jewellery, &c., whilst the more strongly heated parts, which possess a bluish tint, are employed under the term *crocus* for polishing metals. It has been shown that these variations in colour are due to the varying size of the grains (Wöhler and Condrea, Zeitsch. angew. Chem. 1908, 21, 481).

Ferric oxide acts as a catalyst in promoting the combination of sulphur dioxide and oxygen, and a process for the preparation of sulphuric acid has been based upon this reaction (Lunge and Reinhardt, Zeitsch. angew. Chem. 1904, 17, 1041; see also Keppeler, d'Ans, Sundell, and Kaiser, *ibid.* 1908, 21, 532, 577; Keppeler and d'Ans, Zeitsch. physikal. Chem. 1908, 62, 89). This oxide is also used in some forms of accumulator (see e.g. D. R. PP. 180672 and 190236; also Peters, Chem. Zentr. 1908, i. 213).

The use of ferric oxide for standardising solutions of permanganate has been proposed by Brandt, who describes a method for the preparation of the pure substance (Chem. Zeit. 1908, 32, 812 *et seq.*).

Ferric oxide is invariably present in considerable quantities in *copper paint* (v. COPPER OXIDES).

This oxide may be combined with the monoxides of calcium, magnesium, zinc, copper, and other metals. The resultant oxides, which are prepared usually by fusing the mixed oxides, are always magnetic, and correspond in composition with the magnetic iron oxide. The oxide containing magnesium $\text{Fe}_2\text{O}_3 \cdot \text{MgO}$ occurs naturally as *magnoferrite*, and that containing zinc and manganese is found as *Franklinite* (see Percy, Phil. Mag. 1873, [iv.] 45, 455; and List, Ber. 1878, 11, 1512).

Solutions of alkali ferrites are obtained by boiling solutions of the ferrates or by boiling ferric hydroxide in strong caustic alkali solution (Haber and Pick, Zeitsch. Elektrochem. 1900, 7, 215; 1901, 7, 724).

The hydrated oxide is best prepared by precipitating a solution of ferric chloride with excess of ammonia. It forms a bulky, brown, slimy precipitate, which shrinks considerably in drying. It slowly gives up its water at 320°, and if heated to dull redness when anhydrous, suddenly contracts and glows brightly, becoming much less soluble in acids; this is probably due to an allotropic change which is known to take place at 640° (Keppeler and d'Ans, Zeitsch. physikal. Chem. 1908, 62, 89; see also *ibid.* 641).

Freshly precipitated ferric hydroxide when heated with water under a pressure of 5000 atmospheres gives the following products:—

At 30°–42.5° limonite,

At 42.5°–62.5° goëthite,

And above 62.5° targite or hydrohæmatite (Ruff. Ber. 1901, 34, 3417).

A 'yellow hydrate,' which, under these conditions is unchanged between 40° and 70°, can be obtained by the oxidation of moist ferrous hydroxide or carbonate (Muck, Zeitsch. Chem. 1868, [ii.] 4, 41; Tommasi, Ber. 1879, 12, 1299, 2334).

When the hydrated oxide is merely allowed to remain for some months under water, a crystalline powder containing $\text{Fe}_2\text{O}_3(\text{OH})_2$ is obtained which corresponds to the native limonite. This hydrate is the colouring ingredient of yellow clays, &c., and constitutes the precipitate from chalybeate streams. It may also be obtained by precipitation from a cold solution of a ferric salt and drying, without the aid of heat, over sulphuric acid.

The freshly precipitated oxide is readily soluble in acids and in concentrated solutions of ferric salts. The solution in ferric chloride, when containing excess of oxide, may be slowly dialysed with separation of a dark red liquid in which the ratio of chlorine to iron corresponds to the composition $82\text{Fe}(\text{OH})_3 : \text{FeCl}_3$ (Linder and Picton, Chem. Soc. Trans. 1905, 1920). A similar solution containing a small amount of acetate is prepared by dialysing ferric acetate, and is used medicinally as *dialysed iron* or *liquor ferri dialysati*.

A colloidal solution of pure ferric hydroxide may be obtained from the dialysed solution containing chlorine by electrolysis under special conditions (Tribot and Chretien, Compt. rend. 1905, 140, 144). The solution is gelatinised by alkalis and by many acids and salts, even in very small amounts (see also Gilotti, Gazz. chim. ital. 1908, 38, ii. 252).

Soluble metaferric hydroxide $\text{Fe}_2\text{O}_4\text{H}_2$ is obtained by heating a solution of ferric nitrate to 100° for 3 days, and then adding a few drops of hydrochloric acid. The hydroxide is thus precipitated, and when dried on a porous tile forms black scales, which dissolve in water to a tasteless red liquid (Péan de St. Gilles, Ann. Chim. Phys. 1856, [iii.] 46, 47; Scheurer-Kestner, *ibid.* 1859, [iii.] 57, 23; Debray, Compt. rend. 1869, 68, 913).

A similar solution can be prepared by boiling a solution of ferric nitrate with copper filings or zinc-dust (Cohen, J. Amer. Chem. Soc. 1914, 36, 19).

The hydrated oxide combines with sugar, forming a soluble compound, thus lowering the percentage of crystalline sugar obtained from the pans and raising the proportion of molasses. On this account raw sugar is soon injured by contact with iron vessels, and even the clearing 'char' should be as free as possible from iron. According to Schachtrupp and Spunt (Pharm. Centralhalle, 1893, 11, 148) the hydroxide is soluble only in solutions of invert sugar, and cannot itself cause inversion, though this may be brought about by anhydrous ferric oxide.

The hydrated oxide is largely used for removing sulphuretted hydrogen from coal gas. A hydrated sulphide is thus produced with evolution of water. When the oxide ceases to absorb the gas, it is exposed to a current of air, care being taken to prevent great rise of temperature, and the oxide is reproduced with separation of free sulphur. The large quantity

of Prussian blue contained in the spent 'oxide' is now used for the production of cyanides (*q.v.*).

A yellowish-brown hydrated sesquioxide, precipitated on calico by the action of caustic soda on ferrous sulphate, is known as *chamois* or *rouille*.

Iron rust when completely oxidised has a composition approximating to that of limonite, but when freshly formed contains much hydrated ferrous oxide and carbonate.

In pure water, free from air, the rusting of iron is purely electrolytic and does not proceed beyond a concentration of Fe equal to 1.2×10^{-6} gram-mol. per litre. The presence of oxygen gives rise to a new e.m.f.; carbon dioxide plays a secondary part, affecting the very variable composition of the rust and its presence is not essential; hydrogen peroxide need not be formed. The corrosion is most rapid when both air and water are in direct contact with the metal. Caustic soda and sodium carbonate stop corrosion; ammonium salts accelerate it. *Cf. art. CORROSION OF METALS.*

Ferric acid H_2FeO_4 is only known in combination. The potassium salt is produced with evolution of considerable heat by heating the sesquioxide with potassium nitrate or hydroxide, or with a mixture of the two substances (Fremy, J. Pharm. Chim. 1841, 27, 97; Hofmann, Ber. 1869, 2, 239).

It may be prepared by the electrolytic oxidation of iron in caustic potash solution (Haber and Pick, Zeitsch. Elektrochem. 1900, 7, 215), or by passing chlorine through a suspension of ferric hydroxide in caustic potash.

Barium ferrate is the most stable salt of ferric acid, and is obtained as a dark red powder by precipitating a solution of sodium ferrate with barium chloride (Baschieri, Gazz. chim. ital. 1906, 36, ii. 282).

Ferrous sulphide FeS is found in certain meteorites. It may be considered to exist in combination with the sesquisulphide in *pyrrhotine* or *magnetic pyrites*, and in combination with other sulphides in other minerals. It is found in considerable quantities in the black deposit in cesspools, &c., being produced by the action of organic matter on ferruginous bodies or iron oxide in presence of sulphates. In meteorites it occurs as the mineral *troilite*.

It may be prepared by heating a mixture of iron filings and sulphur, or of ferrous sulphate and charcoal; by stirring a white-hot rod of wrought iron in melted sulphur; by heating other iron sulphides to bright redness in hydrogen, or by precipitating ferrous salts with alkaline sulphides or sulphuretted hydrogen. In the compact state, ferrous sulphide is a very hard, metallic-looking black, or nearly black crystalline solid of sp.gr. 4.69. It has a metallic lustre with a yellowish reflex, and sometimes occurs in hexagonal prisms. It is not magnetic, is permanent in air, and fusible at a full red heat. The precipitated sulphide, however, is readily oxidised to sulphate in air, especially when moist.

It is decomposed by acids with evolution of sulphuretted hydrogen, and is usually employed for the preparation of that gas.

Ferrous sulphide forms the main constituent of *iron lute* (*v. LUTES*).

Ferroso-ferric sulphide $\text{FeS} \cdot \text{Fe}_2\text{S}_3$ forms one

of the varieties of *pyrrhotine*: it is obtained when iron pyrites is heated out of contact with air for the production of sulphur. *Magnetic pyrites* $5\text{FeS} \cdot \text{Fe}_2\text{S}_3$ or $6\text{FeS} \cdot \text{Fe}_2\text{S}_3$ occurs in hexagonal plates of a brassy colour. It is attracted by the magnet and has sp.gr. 4.4-4.7.

Ferric sulphide Fe_2S_3 is obtained by gently heating a mixture of iron and sulphur or by the action of sulphuretted hydrogen on the sesquioxide below 100° , and may be prepared by pouring a solution of ferric salt into excess of ammonium sulphide. By the latter reaction it is formed in the purification of coal gas (Gedel, J. Gasbel. 1905, 48, 400; Stokes, J. Amer. Chem. Soc. 1907, 29, 304). It combines with other sulphides of iron, and with the sulphides of silver, potassium, and sodium. The hydrated sulphide is rapidly decomposed by air, and in absence of air undergoes spontaneous decomposition into ferrous sulphide and iron disulphide. The anhydrous sulphide is pyrophoric if suddenly brought into contact with air.

Potassium ferric sulphide $\text{K}_2\text{Fe}_2\text{S}_4$ is obtained when iron filings, potassium carbonate, and sulphur are heated together and the mass extracted with water. It is thus obtained in purple-coloured, needle-shaped crystals of sp.gr. 2.863, which burn when heated in air.

Sodium ferric sulphide $\text{Na}_2\text{Fe}_2\text{S}_4 \cdot 4\text{H}_2\text{O}$ is obtained in a similar way and forms brown microscopic needles. It occurs in the 'black-ash liquors' of the Leblanc process.

Cuprous ferric sulphide $\text{Cu}_2\text{S} \cdot \text{Fe}_2\text{S}_3$ occurs native as 'copper pyrites.'

Iron disulphide FeS_2 occurs in immense quantities as *iron pyrites* or *muncie* in hard, yellow, brassy cubes, sp.gr. 5.185; or in other forms of the regular system, and in masses of various shapes, frequently known as 'thunderbolts.' This mineral, as well as *marcasite* or *white iron pyrites* (sp.gr. 4.68-4.85), and other minerals of the same composition, but crystallising in the rhombic system, is produced in nature by the reduction of ferrous sulphate by organic matter, and is therefore often found forming fossils in peat, chalk, &c., and in clay, containing much organic matter. *Marcasite* may be prepared artificially by heating ferrous sulphide with sulphur; by passing hydrogen sulphide over the oxides or chlorides of iron at a red heat; by the action of carbon disulphide vapour on heated ferric oxide or by heating ferric chloride with phosphorus pentasulphide (Glatzel, Ber. 1890, 23, 37).

Pyrites is quite permanent in air, but *marcasite* slowly becomes oxidised and disintegrated on exposure. Iron pyrites is largely employed as a source of sulphur in the manufacture of sulphuric acid, ferrous sulphate, &c. (*v. SULPHURIC ACID; SULPHUR*).

By heating iron disulphide with aluminium powder in a stream of hydrogen sulphide the compound Al_2FeS_4 is obtained (Houdard, Compt. rend. 1907, 144, 801; see also Ditz, Metallurgie, 1907, 4, 786).

Iron sub-sulphide Fe_4S_7 is obtained when iron is heated in the vapour of carbon disulphide. It forms a crystalline mass of sp.gr. 6.957, and dissolves in dilute acids with evolution of hydrogen and hydrogen sulphide (Gautier and Hallepeau, Compt. rend. 1889, 108, 806).

Ferric arsenide occurs in nature as *lollingite*

FeAs_2 , and with sulphur as *mispickel* or *arsenical pyrites* Fe_3AsS , from which the greater part of the arsenic of commerce is obtained (*v. ARSENIC*). Arsenic combines directly with iron.

Compounds of carbon, phosphorus, silicon, and nitrogen with iron are also known. The effects produced on the properties of iron and steel by the three first-named elements are described under the manufacture of iron.

Iron nitride Fe_2N (Stahlschmidt, Pogg. Analen, 1864, 125, 37) is obtained by the action of excess of ammonia at 420° on ferrous chloride or bromide, reduced iron, or iron amalgam, as a dull grey powder (Fowler, Chem. Soc. Trans. 1901, 285).

It may be prepared in the compact state by heating iron wire or rod to a bright red heat in a large excess of ammonia. The product is so brittle that it can be powdered, and has sp.gr. 6.0–6.5. When heated in air it is oxidised, and it ignites when warmed in chlorine. Dilute acids dissolve it with the formation of ferrous and ammonium salts (Beilby and Henderson, Chem. Soc. Trans. 1901, 1249; Guntz, Compt. rend. 1902, 135, 738).

Phosphides of iron. A phosphide Fe_2P is produced by heating a mixture of ferrous or ferric phosphate under common salt or by heating iron filings with cuprous phosphide in the electric furnace. It forms lustrous grey crystals, probably hexagonal in form; sp.gr. 6.56; m.p. 1290° (Maronneau, Compt. rend. 1900, 130, 656; Le Chatelier and Wologdine, *ibid.* 1909, 149, 709). Heated in air it forms the basic phosphate $2\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5$.

When iron is heated in phosphorus vapour, or the monosulphide is heated in hydrogen phosphide gas, the phosphide FeP is formed. It is a dark grey powder of sp.gr. 5.76.

Another phosphide Fe_2P_3 is formed by strongly heating phosphorus and ferric chloride vapours in a current of carbon dioxide (Granger, Compt. rend. 1896, 122, 936); or by the action of the vapour of phosphorus iodide on finely divided iron. It forms hard, non-magnetic, steel-grey crystals; sp.gr. 4.5.

A phosphide Fe_3P of sp.gr. 7.74 and m.p. 1110° has also been described (Le Chatelier and Wologdine, *l.c.*).

Iron borides. Two borides of iron have been described:

Fe_2B forms steel-grey prisms; sp.gr. 7.37 at 18° . It is oxidised by dry air at a red heat and by moist air at the ordinary temperature.

FeB_2 has not been obtained pure, but has sp.gr. *circa* 5, and is extremely hard (Binet du Jassonneix, Compt. rend. 1907, 145, 121).

Iron silicide SiFe_3 (ferro-silicon) is produced by heating iron with silicon, or with silica and carbon, in the electric furnace (Moissan, Compt. rend. 1895, 121, 621; Bertolus, Fr. Pat. 393, 818, 1908). It forms grey magnetic prisms of sp.gr. 7, and is readily attacked by acids.

Several iron-silicon compounds are known, viz. Fe_2Si , FeSi , and FeSi_2 . Two eutectics are known, the first containing 21.6 p.c. Si and composed of Fe_2Si and FeSi , the second containing 60 p.c. Si and composed of FeSi and Si.

Under certain circumstances commercial ferro-silicon may evolve the gaseous hydrides of arsenic and phosphorus (present as impurities)

with very bad effect on human beings (*e.g.* see J. Soc. Chem. Ind. 1909, 25; Pellew, *ibid.* 1914, 774). The tendency to decomposition is not so marked in alloys containing less than 30 p.c. Si; the richer alloys over 65 p.c. Si are also less liable to spontaneous disintegration (Anderson, Eng. and Min. J. 1917, 103, 1095).

Iron carbide (see CEMENTITE and STEEL).

FERROUS SALTS.

Anhydrous ferrous salts are usually colourless; the hydrated salts are greenish or blue. The solutions are sweet and astringent and ink-like in taste, and form powerful reducing agents.

Ferrous chloride FeCl_2 may be prepared by passing dry hydrogen chloride over red-hot iron or by reducing ferric chloride in a current of hydrogen, when the anhydrous salt is deposited in colourless shining scales, sp.gr. 2.528, which are very deliquescent and easily soluble in water and alcohol. It fuses at a red heat, and volatilises at a yellow heat, the V.D. being 6.4–6.6 (V. Meyer, Ber. 1884, 17, 1335). At 1300° – 1500° the V.D. is normal = 4.3 (Nilson and Pettersson, Chem. Soc. Trans. 1888, 827).

In solution it is obtained by dissolving iron in hydrochloric acid. It crystallises in deliquescent, bluish-green, monoclinic crystals, sp.gr. 1.93, containing 4 molecules of water.

Solutions of ferrous chloride in strong hydrochloric acid are partially converted into ferric chloride by sulphur dioxide. The reaction is reversible:

(Wardlaw and Clews, Chem. Soc. Trans. 1920, 117, 1093).

The anhydrous salt absorbs ammonia to form the compound $\text{FeCl}_2 \cdot 6\text{NH}_3$, which gives off ammonia at 100° , and at higher temperatures yields ammonium chloride, nitrogen, and iron nitride (Fowler, Chem. Soc. Trans. 1901, 288). It combines with bromine to form the unstable compound FeCl_2Br (Lenormand, Compt. rend. 1893, 116, 820).

Ferrous bromide FeBr_2 is obtained as a yellowish crystalline solid by the union of its elements. The hydrated bromide crystallises in bluish-green rhombic tablets with 6 molecules of water.

Ferrous iodide FeI_2 is obtained by heating iron with iodine as a grey lamino-crystalline mass; m.p. 177° (Carius and Wanklyn, Annalen, 1861, 120, 69).

Ferrous sulphite FeSO_3 . Iron dissolves in aqueous sulphurous acid in absence of air, with formation of ferrous sulphite and thiosulphate. The latter salt is very soluble, but the sulphite is deposited in greenish crystals.

Ferrous sulphate, green vitriol, or copperas. $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, occurs as *melanterite*, being derived from the decomposition of the native sulphide, especially of marcasite, and is manufactured by the oxidation of pyrites by air and rain.

The pure salt is prepared by heating an excess of iron wire or $1\frac{1}{2}$ parts of precipitated ferrous sulphide in $1\frac{1}{2}$ parts of sulphuric acid diluted with four times its weight of water. The solution is acidified if necessary, and is filtered quickly. Bluish-green monoclinic crystals containing $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, and having a

sp.gr. of 1.889 at 4° (Joule and Playfair), are thus produced.

It is prepared on the large scale by dissolving scrap iron in warm sulphuric acid of 1.150 sp.gr., and concentrating the nearly neutral solution. The liquid is settled, quickly drawn off, allowed to clear for 24 hours, and run into crystallising tanks, in which strings, straws, or wooden laths are suspended to induce crystallisation. The crystals are washed with a minimum quantity of water and dried.

When sulphur is distilled from iron pyrites, the residue, known as *sulphur waste*, is laid upon inclined shelves in contact with air to oxidise. The weathered mass is levigated, and the ferrous sulphate is crystallised out.

Large quantities of this sulphate are obtained in the manufacture of copper sulphate (*v. COPPER*), and small quantities in the preparation of sulphuretted hydrogen for precipitating arsenic from sulphuric acid.

Ferrous sulphate is obtained at Fahln during the extraction of copper sulphate from mine water, and also from the runnings of other mines.

The *Salzburg vitriol* prepared at Buxweiler contains ferrous and copper sulphates (*v. COPPER*). The copper may be separated as metal and any excess of acid converted into sulphate by the addition of scrap iron to the liquid.

Crude ferrous sulphate always contains ferric sulphate, which gives the crystals a more decided green colour; they are frequently coated with a yellow deposit due to oxidation. By washing with absolute alcohol, this deposit, being soluble, is removed, and the crystals are rendered more permanent.

The pure salt may be obtained in the most permanent condition by precipitating a concentrated aqueous solution by addition of excess of alcohol and washing the precipitated crystals with nearly absolute alcohol. It can be obtained perfectly pure and dry, by powdering an ordinary sample and repeatedly pressing it between filter paper. It is quite stable in air at 15°, and neither oxidises nor effloresces, or deliquesces (De Forcrand, *Compt. rend.* 1914, 158, 20). The presence of even a trace of ferric salt increases the liability of the crystals to oxidation. The crystals contain 7 molecules of water and are monoclinic, of sp.gr. 1.889 at 4°. Another hydrate contains 5H₂O and crystallises in the triclinic system, being isomorphous with CuSO₄.5H₂O. Ferrous sulphate may be obtained in rhombic prisms containing 4 molecules of water, isomorphous with zinc sulphate. Crystals may also be produced containing 3 and 2 molecules of water. The monohydrate is obtained when the heptahydrate is allowed to effloresce over conc. sulphuric acid, or when it is melted in its water of crystallisation and allowed to solidify (Etard, *Compt. rend.* 1878, 87, 502; Scott, *Chem. Soc. Trans.* 1897, 564).

When gradually heated to 140° *in vacuo* it loses 6 molecules of water and becomes colourless, but the remaining molecule is not removed at 260°, and, except when heated in small quantities, it is impossible to render the salt anhydrous without loss of acid. At a red heat a basic sulphate is produced, with evolution of sulphur trioxide, and, at higher temperatures, ferric oxide is left. A complete investigation

of the dissociation of ferrous sulphate has been made by L. Wöhler, Plüddemann, and P. Wöhler (*Ber.* 1908, 41, 793).

Ferrous sulphate is insoluble in absolute alcohol. Its solubility in 100 parts of water is

10°	15°	25°	32.5°	46°	60°	90°	100°
61	70	115	151	227	263	370	333

The reduced solubility at 100° may be attributed to partial dehydration or dissociation.

The aqueous solution slowly oxidises on exposure to air, and deposits a yellowish, highly basic ferric sulphate, leaving the normal ferric sulphate in solution. The acid finally becomes divided between the precipitated salt and that in solution, rendering the former less basic but still insoluble, and converting the normal salt into a soluble basic sulphate. Ferrous sulphate, like the chloride, absorbs nitric oxide in solution. The gas is given off in a vacuum, or when the solution is heated, but it probably forms the compound FeSO₄.NO. When such a solution is mixed with sulphuric acid and cooled a purple-red colour is produced, which is used in the well-known ring test for nitrates (*see also* Machot and Zechentmacher, *Annalen*, 1906, 350, 368).

On account of its reducing power, ferrous sulphate precipitates gold and palladium from solution, and reduces indigo to the leuco compound.

Ferrous sulphate is largely used in dyeing and tanning, and in the manufacture of inks (*v. INK*), Prussian blue, red oxide of iron, and other pigments. In weak solution it is said to promote the growth of certain plants, especially of roots. When added to excremental matters it absorbs ammonia and other volatile substances, and renders the matter almost odourless. It is used for the treatment of sewage (*see e.g.* Pochin and Richardson, *Eng. Pats.* 15239 and 17976, 1908).

In dyeing textiles, leather, wood, &c., it is largely used for the production of various shades of black, grey, lilac, and brown. It is used as a mordant for the production of Prussian blue in calico-printing, and is the raw material from which acetates, nitrosulphates, and other iron mordants are prepared.

Ferrous disulphate FeS₂O₇ is separated as a white powder on addition of excess of concentrated sulphuric acid to a concentrated aqueous solution of the normal sulphate. On addition of water, it is decomposed into the normal salt and free acid (Bolas, *Chem. Soc. Trans.* 1874, 812).

With ammonium and potassium sulphates, ferrous sulphate produces double salts containing 6 molecules of water and of great stability and fine crystalline form.

Ferrous ammonium sulphate

is prepared by dissolving molecular proportions of the two sulphates in the minimum quantity of hot water, filtering hot, and crystallising. It forms fine bluish-green monoclinic crystals of sp.gr. 1.813, of which 100 parts of water dissolves 21.6 parts at 20° and 56.7 parts at 75°.

The double salt is permanent in air, particularly when precipitated by addition of alcohol to the concentrated aqueous solution and washed with absolute alcohol, and is used by chemists in place of ferrous sulphate, especially for standardising solutions.

Ferrous phosphate $\text{Fe}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$ occurs as *Vivianite* or *blue iron earth*, sometimes mixed with clay and peat or associated with bog iron ore. It may be produced by addition of sodium phosphate to ferrous sulphate. The fresh precipitate is used medicinally. When quite pure it is colourless, but it rapidly becomes bluish or green from oxidation. When iron is dissolved in phosphoric acid the solution deposits colourless needles of $\text{Fe}(\text{H}_2\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$, which rapidly alter in air (Erlenmeyer, *Annalen*, 1878, 194, 182).

Ferrous arsenate prepared from ferrous sulphate and sodium arsenate has been proposed for use as an insecticide, for which purpose it has many advantages over Scheele's green (Vermorel and Dantony, *Compt. rend.* 1909, 148, 302).

Ferrous carbonate FeCO_3 occurs as *spathic iron ore*, together with the carbonates of lime, magnesia, and manganese. *Clay iron stone* is an argillaceous ferrous carbonate.

Ferrous carbonate dissolves in water containing free carbonic acid, the acid salt so produced being the essential constituent of chalybeate waters. The solution is decomposed rapidly on boiling and slowly on exposure to air, with precipitation of an ochreous deposit of the hydrated oxide, which, in the case of mineral waters, frequently contains organic matter and ferric arsenate, and is occasionally found to contain antimony.

Spathic iron ore can be obtained artificially in microscopic rhombohedra by precipitating ferrous sulphate with sodium hydrogen carbonate and heating the solution for 12-36 hours at 150° . When sodium carbonate solution is added to ferrous sulphate solution a flocculent white precipitate is obtained which rapidly becomes green, and is ultimately completely converted into ferric hydroxide.

Ferrous nitrate $\text{Fe}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ is prepared by dissolving ferrous sulphide in dilute nitric acid, or, preferably, by addition of barium nitrate to ferrous sulphate solution.

The solid salt is very soluble in water and very unstable, changing to ferric nitrate. The action between iron and dilute nitric acid does not result in the formation of ferrous nitrate, and is extremely complicated (Montemartini, *Chem. Soc. Abstr.* 1892, 1278).

Cyanogen compounds of iron (see CYANIDES).

FERRIC SALTS.

Are usually of yellowish or reddish brown colour. In solution they are reduced to the ferrous condition by zinc, or, with precipitation of sulphur, by sulphuretted hydrogen. Potassium or other soluble thiocyanate imparts an intense blood-red colour to a neutral or acid solution of a ferric salt.

Ferric fluoride $\text{FeF}_3 \cdot 6\text{H}_2\text{O}$ *v.* Recoura (*Compt. rend.* 1912, 154, 655).

Ferric chloride FeCl_3 or Fe_2Cl_6 may be obtained in the anhydrous condition by passing excess of chlorine gas over red-hot iron or by passing hydrogen chloride over the heated sesquioxide, and thus occurs not infrequently in the craters of volcanos. Thus prepared, it forms iridescent iron-black scales which are dichroic, appearing red by transmitted and green by reflected light.

In solution it may be prepared by dissolving

the precipitated sesquioxide in hydrochloric acid, and driving off the excess of acid by heat; or, preferably, by dissolving iron in hydrochloric acid and passing chlorine through the liquid until saturated with that gas, finally entirely removing the chlorine by passage of a current of carbon dioxide through the warm liquid. A commercial method for the preparation of ferric chloride from native phosphate of iron and aluminium has been described by Schröder (*D. R. P.* 192591).

Ferric chloride readily volatilises at 448° , and the V.D. is then less than that required for Fe_2Cl_6 . It is, therefore, probable that the molecular formula is FeCl_3 (Grünwald and V. Meyer, *Ber.* 1888, 21, 687). In boiling alcohol or ether it also appears to have the molecular formula FeCl_3 (Müller, *Compt. rend.* 1894, 118, 641). At the ordinary temperature it forms unstable compounds with nitric oxide, but at higher temperatures it is reduced by that gas to ferrous chloride (Besson, *Compt. rend.* 1889, 108, 1012; Thomas, *ibid.* 1895, 120, 447; 121, 128).

Ferric chloride is very deliquescent, and dissolves in alcohol and ether. The concentrated aqueous solution is dark brown and oily; if diluted it becomes of a pale yellow colour. In dilute solution the salt may exist as $\text{Fe}_2\text{Cl}_4 \cdot \text{Cl}_2$ (Tufereff, *Zeitsch. anorg. Chem.* 1908, 59, 82).

There are four hydrates of ferric chloride, $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, m.p. 37° ; $2\text{FeCl}_3 \cdot 7\text{H}_2\text{O}$, m.p. 32.5° ; $2\text{FeCl}_3 \cdot 5\text{H}_2\text{O}$, m.p. 56° ; and $\text{FeCl}_3 \cdot 2\text{H}_2\text{O}$, m.p. 73.5° . Solutions which contain more of the chloride than corresponds with the composition $\text{FeCl}_3 \cdot 2\text{H}_2\text{O}$ deposit the anhydrous salt when heated above 66° (Roozeboom, *Zeitsch. physikal. Chem.* 1892, 10, 477).

Compounds of the formulæ $\text{FeCl}_3 \cdot \text{HCl} \cdot 2\text{H}_2\text{O}$, $\text{FeCl}_3 \cdot \text{HCl} \cdot 4\text{H}_2\text{O}$, and $\text{FeCl}_3 \cdot \text{HCl} \cdot 6\text{H}_2\text{O}$ are known (Sabatier, *Bull. Soc. chim.* 1881, [ii.] 36, 197; Roozeboom and Schreinemaker, *Zeitsch. physikal. Chem.* 1894, 15, 588).

Ferric chloride is partly hydrolysed by water with the formation of many complex colloid bodies (Malfitano and Michel, *Compt. rend.* 1907, 145, 185, and 1275; Michel, *ibid.* 1908, 147, 1052, and 1288; Kratz, *J. Phys. Chem.* 1912, 16, 126).

Ferric chloride forms compounds with alkaloids, most of which have definite melting-points. The use of these substances has been suggested for the identification of the alkaloids (Scholtz, *Chem. Soc. Abstr.* 1908, i. 202, from *Ber. Deut. pharm. Ges.* 1908, 18, 44).

Solutions of ferric chloride in methyl alcohol are reduced by light, which acts, not as a catalyst, but as the source of the energy required to bring about the reaction (Benrath, *J. pr. Chem.* 1909, [ii.] 80, 283).

Ferric chloride is sometimes used as a disinfectant. It deodorises sewage with partial reduction to ferrous chloride.

With potassium chloride it produces a finely crystallised garnet-coloured double chloride $\text{Fe}_2\text{Cl}_6 \cdot 4\text{KCl} \cdot 2\text{H}_2\text{O}$ decomposed by water. A similar garnet-coloured salt crystallising in cubes is formed with ammonium chloride and is used medicinally as *ammonio-chloride of iron*. The salt used, however, does not correspond to the potassium salt, but usually contains less than 2 p.c. of iron. It is very deliquescent and

may be considered as formed by the combination of the normal salt $Fe_2Cl_3 \cdot 4NH_4Cl \cdot 2H_2O$ with variable proportions of ammonium chloride.

Soluble and insoluble *oxychlorides* of iron are known, but are unimportant.

Ferric sulphate $Fe_2(SO_4)_3$ occurs in Chile as *coquimbite* in white silky pyramids containing $Fe_2(SO_4)_3 \cdot 9H_2O$. It is usually prepared by mixing one equivalent of concentrated sulphuric acid with a solution of two equivalents of ferrous sulphate, concentrated nitric acid being added in portions to the hot solution until red fumes cease to be evolved. On concentrating the solution to a syrup colourless crystals are obtained.

Several hydrated basic sulphates are prepared artificially, or occur in nature.

Ferric sulphate, obtained by dehydrating the hexahydrate at 108° , dissolves in ethyl alcohol to form a solution in which barium chloride forms no precipitate of barium sulphate. This fact is explained by Recoura (Compt. rend. 1911, 153, 1223) by assuming that the trihydrate has the constitution $Fe_2(SO_4)_3(OH)_3$ analogous to the green pentahydrate of chromic sulphate.

Ferric sulphate is used to a slight extent in dyeing cotton, but not in printing. The basic sulphates are used for dyeing cotton, for the production of buffs, or, in combination with logwood and sumach, for blacks. The iron mordant prepared by treating ferrous sulphate with nitric acid is sold as *nitrosulphate* or *nitrate of iron*, and is used in dyeing, but not in printing cotton.

With alkaline sulphates ferric sulphate forms double salts, resembling and corresponding in composition to alum.

The potassium salt, *potassium iron alum* $Fe_2(SO_4)_3 \cdot K_2SO_4 \cdot 24H_2O$, is prepared by mixing molecular proportions of ferric and potassium sulphates and concentrating the solution spontaneously. It forms fine violet octahedra very liable to decompose into a brown, gummy, deliquescent mass. This alum is used to a limited extent in dyeing and calico-printing. If caustic potash is added to a solution of iron alum, and the brown liquid allowed to evaporate, yellowish-brown crystals separate of the composition $5K_2SO_4 \cdot 2Fe(SO_4)_2(OH)_2 \cdot 16H_2O$. These crystals have the peculiar optical properties of tourmaline (*see* Lachaud and Lepierre, Compt. rend. 1892, 114, 915).

The corresponding ammonium alum is more permanent, and has been proposed as a standard in titrations (de Coninck, Bull. Soc. chim. 1909, 23, 222).

Ferric nitrate $Fe_2(NO_3)_6$ may be obtained in several states of hydration by crystallising the solution obtained by the action of concentrated nitric acid on scrap iron or iron oxide. The hydrate $Fe_2(NO_3)_6 \cdot 6H_2O$ crystallises in cubes and the hydrate $Fe_2(NO_3)_6 \cdot 9H_2O$ in colourless monoclinic crystals. It is usually prepared by the first method for use as a mordant for producing buffs and blacks in dyeing. An alkaline mordant is prepared for dyeing and calico-printing by treating a ferric salt with caustic soda, with addition preferably of glycerol, or sometimes of glucose, to prevent precipitation of the oxide.

Nitroso-compounds of Iron. Anhydrous ferric chloride absorbs nitric oxide, forming the compounds $2FeCl_3 \cdot NO$ and $4FeCl_3 \cdot NO$ as reddish-brown, hygroscopic powders. The action

of nitric oxide on an ethereal solution of ferric chloride gives nitrosyl chloride and a solution which, when evaporated over sulphuric acid, deposits black needles of the composition $FeCl_3 \cdot NO \cdot 2H_2O$; or at 60° gives the anhydrous salt $FeCl_3 \cdot NO$, crystallising in yellow needles (Thomas, Compt. rend. 1895, 120, 447).

The stable nitroso compounds were discovered by Roussin (Compt. rend. 1858, 46, 224), and are formed by the action of ferrous sulphate on alkali nitrites and sulphides. They are salts of complex acids, containing iron and the monovalent group NO' in the acid radicle (Cambi, Atti. R. Accad. Lincei. 1908, [v.] 17, i. 202), and fall into two classes:

(1) *Ferrodinitroso* derivatives.

(2) *Ferroheptanitroso* derivatives.

Potassium ferrodinitroso sulphide

is formed by the action of caustic potash on the heptanitrososulphide (*v. infra*). It forms dark red crystals, insoluble in water, and decomposes violently when heated, yielding potassium and ammonium sulphates and other products.

The free acid $H[Fe(NO)_2S]$ is obtained by the action of sulphuric acid on the potassium salt and slowly decomposes into hydrogen sulphide, nitrogen, nitrous oxide, and the heptanitroso acid. The ethyl and phenyl derivatives have been prepared: $C_2H_5[Fe(NO)_2S]$, and

Potassium ferrodinitrosothiosulphate

is prepared by passing nitric oxide into a solution of ferrous sulphate and potassium thiosulphate for 10 hours. It forms reddish-brown crystals with a bronze lustre which are but slightly soluble in water. The ammonium and sodium salts are similar, but the latter is the more soluble.

Potassium ferroheptanitrososulphide

is the most stable of these salts and is formed by the action of ferrous sulphate on potassium nitrite and sulphide in solution, or by boiling a solution of the ferrodinitrosothiosulphate. It forms dark-coloured monoclinic crystals having an adamantine lustre and is only sparingly soluble in water.

The free acid is obtained as an amorphous brown mass by the action of sulphuric acid on the potassium salt.

The ammonium salt may be prepared by the action of nitric oxide on freshly precipitated ferrous sulphide suspended in water.

(For details as to these compounds *see*: Procizinsky, Annalen, 1863, 125, 302; Rosenberg, Ber. 1879, 3, 312; Pavel, *ibid.* 1882, 15, 2600; Marchlewski and Sachs, Zeitsch. anorg. Chem. 1892, 2, 175; Marié and Marquis, Compt. rend. 1896, 122, 137; Hofmann and Wiede, Zeitsch. anorg. Chem. 1895, 8, 318; 1895, 9, 295; 1895, 11, 281; *see* also Atti. R. Accad. Lincei, 1906, [v.] 15, ii. 467; 1907, [v.] 16, i. 654.)

Ferric phosphates occur native as *beraunite*

formed by the oxidation of *vivianite*, and as *dufrenite* $Fe_4(OH)_3PO_4$.

The normal phosphate, FePO_4 , is produced as a yellowish-white precipitate by adding sodium hydrogen phosphate to ferric chloride solution; it is soluble in dilute acids (except acetic acid) and is slowly decomposed by water.

When ferric hydroxide is dissolved in orthophosphoric acid and the solution rapidly evaporated, the di-acid salt $\text{Fe}(\text{H}_2\text{PO}_4)_3$ is obtained as a pink crystalline powder, decomposed by moist air, with formation of the monacid salt $2\text{FeH}_3(\text{PO}_4)_2 \cdot 5\text{H}_2\text{O}$.

Ferric metaphosphate is deposited in pink plates when the hydroxide is digested with glacial phosphoric acid at 100° (Hautefeuille and Margotte, *Compt. rend.* 1888, 106, 138; *Johns.* Ber. 1889, 22, 976).

Pascal has described (*Compt. rend.* 1908, 146, 231, 279) certain complex salts of iron with phosphoric acid in which the iron exists in the acid radicle.

Sodium ferripyrophosphate $\text{Na}_6\text{Fe}_2(\text{P}_2\text{O}_7)_3$ is precipitated as a pale violet, micro-crystalline powder from a saturated solution of ferric pyrophosphate in 15 p.c. sodium pyrophosphate solution maintained at 30° . The silver and copper salts and the free acid have been prepared.

Ferric arsenite $\text{Fe}_2(\text{AsO}_3)_2$ is of interest as being the salt produced when freshly precipitated hydrated oxide of iron is taken as an antidote in cases of arsenical poisoning. It may be obtained as a brown precipitate by addition of arsenious acid or an arsenite to a solution of ferric acetate.

Ferric acetate *v.* ACETATES.

Ferric ferrocyanide *v.* CYANIDES.

Ferric tannate or *gallo-tannate* forms the basis of black inks (*v.* INK). The sponges, sand, pumice-stone, &c., of Gerson's filters are impregnated with the tannate, which is said to completely remove all organic matter from water (*v.* Steiger, *J. Soc. Chem. Ind.* 1886, 416).

Ferric citrate $\text{Fe}(\text{C}_6\text{H}_5\text{O}_7)$ is prepared by dissolving the hydrated oxide in citric acid, and evaporating the solution in thin layers. It forms permanent, transparent, garnet-coloured scales, which dissolve slowly in water, but are insoluble in alcohol.

Ferric ammonium citrate is prepared as above, with addition of ammonia. It forms thin, transparent, deep-red scales, which dissolve readily in water, but not in absolute alcohol.

It is used in medicine as is also the double citrate of iron and quinine.

IRON CARBONYLS. Three carbonyls of iron are known, viz.: Iron pentacarbonyl $\text{Fe}(\text{CO})_5$, iron tetracarbonyl $\text{Fe}(\text{CO})_4$, and diferrononacarbonyl $\text{Fe}_2(\text{CO})_9$.

Iron pentacarbonyl. This compound was discovered by Mond, Langer, and Quincke, who prepared it by treating finely divided iron, obtained by reducing ferrous oxalate by hydrogen, with carbon monoxide. On heating to 120° , the carbonyl distilled over and was collected in a cooled tube. The yield is about 1 gram per 100 grams of iron (*Chem. Soc. Trans.* 1891, 604 and 1090).

Iron pentacarbonyl is a viscid yellow liquid of sp.gr. 1.466 at 18° ; b.p. 102.8° at 749 mm. At -21° yellow crystals are formed, which become white at the temperature of liquid air.

It is not acted upon by dilute acids, but concentrated acids form the corresponding salt with evolution of carbon monoxide and hydrogen. Upon exposure to air, it is converted into ferrous hydroxide and eventually into the red ferric hydroxide. The pentacarbonyl is soluble in most organic solvents and in nickel tetracarbonyl, forming $\text{FeNi}(\text{CO})_9$ (?), insoluble in water.

Light decomposes the pentacarbonyl, giving the diferrononacarbonyl and carbon monoxide: $2\text{Fe}(\text{CO})_5 = \text{Fe}_2(\text{CO})_9 + \text{CO}$ (Dewar and Jones, *Proc. Roy. Soc.* 1905, A. 76, 588; 1907, A. 79, 66).

The decomposition of the pentacarbonyl is most rapid in blue light and least of all in red, green and yellow being intermediate in their effects; in fact, a solution exposed to blue light will deposit about ten times as much solid as a similar solution exposed for the same period to red light.

The action of light on the pentacarbonyl is reversible, as the substance in sealed tubes, after exposure to light, when left in the dark, gradually become colourless.

Diferrononacarbonyl crystallises in lustrous hexagonal golden or orange-coloured crystals of sp.gr. 2.085 at 18° , which are perfectly stable in dry air. They are decomposed at 100° yielding the pentacarbonyl, carbon monoxide, and iron: $\text{Fe}_2(\text{CO})_9 = \text{Fe}(\text{CO})_5 + 4\text{CO} + \text{Fe}$. It is insoluble in water and nearly so in benzene, but is slightly soluble in alcohol or acetone and very soluble in pyridine. The nonacarbonyl in solution heated to 95° becomes green and then contains the tetracarbonyl $\text{Fe}(\text{CO})_4$. At a higher temperature it forms the pentacarbonyl together with iron and carbon monoxide, the reaction taking place in two stages:

When strongly heated the action is:

Iron tetracarbonyl. The method of preparation of the tetracarbonyl is as follows: a solution of the diferrononacarbonyl in toluene (1 gram to 20 c.c.) is gradually heated to 95° in an atmosphere of carbon dioxide until the reddish-yellow solid has disappeared. On cooling, green crystals of the tetracarbonyl are formed:

The yield is 20 p.c.

The tetracarbonyl forms dark green lustrous crystals of sp.gr. 1.996 at 18° , stable at ordinary temperatures: on heating at 140° – 150° , iron and carbon monoxide are formed. The empirical formula is $\text{Fe}(\text{CO})_4$, but the molecular formula in benzene appears to be $[\text{Fe}(\text{CO})_4]_{20}$.

The substance is insoluble in water but soluble in most organic solvents giving green solutions. In pyridine, the solutions are first green, but soon become red, especially on warming. The change in colour is probably due to molecular dissociation. The green solutions lose their colour upon exposure to light, iron being deposited, but the red ones are unaffected by light.

IRON CEMENT *v.* LUTES.

IRON LIQUOR. *Ferrous acetate* (*v.* ACETIC ACID).

IRON PYRITES. *Ferric sulphide* (v. PYRITES; IRON).

IRONE v. KETONES.

IRVINGIA BUTTER v. WAXES.

ISATIN v. BONE-OIL; INDIGO, NATURAL; INDIGO, ARTIFICIAL.

ISATIN BLUE v. BONE-OIL.

ISETHIONIC ACID $\text{CH}_2\text{OH}\cdot\text{CH}_2\text{SO}_3\text{H}$, an isomeride of ethyl sulphuric acid obtained by the action of sulphur trioxide on ethylene, or ethyl alcohol. Has the dual function of a sulphonic acid and alcohol. With phosphorus pentachloride forms the chloro-acid chloride $\text{CH}_2\text{Cl}\cdot\text{CH}_2\text{SO}_3\text{Cl}$, which on hydrolysis yields *chloroethyl sulphonic acid* $\text{CH}_2\text{Cl}\cdot\text{CH}_2\text{SO}_3\text{H}$. This heated with ammonia solution forms amino ethyl sulphonic acid $\text{CH}_2\text{NH}_2\cdot\text{CH}_2\text{SO}_3\text{H}$, which is the *taurine* of bile. (V. art. TAURINE.)

ISINGLASS (Fr. *Colle de poisson*; Ger. *Huascenblase*) consists of the dried swimming-bladders of various fishes. These bladders differ in shape and size, according to their origin, and are prepared either by simply drying them whilst slightly distended, which process forms 'pipe isinglass,' or by splitting them open, pressing, and drying them in the form of 'leaf isinglass.' That form, again, which is known as 'purse isinglass,' consists of such bladders as contain a natural opening.

The chief supply of isinglass is derived from Russia and Hudson's Bay; some portion also being obtained from Brazil, West Indies, Penang, Bombay, and Manilla; the finest kind, the 'Beluga leaf,' coming from the first-named of these countries, and being the produce of a species of sturgeon. Other Russian or Siberian varieties are 'Astrakhan leaf,' 'Saliensky leaf,' and 'Samovy leaf.'

The following are the principal species of fish from which Russian isinglass is obtained: *Acipenser huso*, or the Hausen; *A. Güldenstedtii*, or the Osseter; *A. ruthenus*, or the Sterlet; *A. stellatus*, or the Sewruga; *Silurus glanis* and *Cyprinus carpio*. The isinglass of New York is derived from *Labrus squeteague*; that of New England—the 'ribbon isinglass'—from the common Cod, *Gadus Morrhua*. In Brazil, it is taken from a species of *Silurus*; and in Iceland, from *Gadus* and *Molva vulgaris*, or the Ling.

The chief emporium for Russian isinglass was the great fair of Nijni-Novgorod, whence the largest part of the merchandise found its way to London, through the agency of Petrograd traders. It arrived here about the end of June. Those supplies which reach us from Brazil and other countries are received at all seasons.

The fish being taken, the bladders are immediately removed, sufficient care in the cleansing of them from mucus and blood-stains being often purposely neglected, since a loss of weight results in the process when properly performed. In consequence of this neglect, the value of the material is diminished in proportion to the impurities which it contains.

On its arrival here isinglass is a hard, tough substance, and for many purposes it is necessary to 'cut' it. The operations of 'cutting' consist, first, in soaking the flakes until somewhat pliable, trimming the edges, and scraping off the dark spots; next, in putting them through

two sets of rollers, under great pressure, by which they are flattened to the thickness of writing-paper; and, finally, in cutting them into fibres of extreme fineness, a process now almost always effected by a machine constructed for that purpose.

The uses for which isinglass is employed are the 'fining' or clarifying of fermented beverages, as ale and wine, and various culinary preparations. For the former purpose, the properties of isinglass are remarkable; for, whilst possessing the exact chemical composition of gelatin, it has the power, which is wanting in gelatin, of entangling in the film or web which it forms as it dissolves, all the suspended impurities contained in the liquids which it is sought to clarify. The lower grades of isinglass are used either in the natural or the manufactured condition by brewers and the manufacturers of cider, and the better classes of the Russian material by wine merchants. For the purpose of the brewer it is usual to dissolve the isinglass in sulphurous acid which has a tendency to preserve the ale.

The choicest descriptions are used by the cook and the confectioner for the thickening of soups, jellies, &c., but as for these purposes the fining properties of isinglass are not of any account, gelatin serves equally well, and has, under the name of patent isinglass, been so employed (v. GLUE).

ISOCETIC ACID $\text{C}_{14}\text{H}_{25}\text{COOH}$, m.p. 55°, is obtained from the oil extracted from the seeds of *Jatropha Curcas* (Linn.) (Bouis, J. 1854, 462).

ISOFORM v. SYNTHETIC DRUGS AND IODOFORM.

ISOPRAL. *Trichloroisopropyl alcohol*

m.p. 49°. Obtained by the action of methyl magnesium bromide on chloral. Used as a hypnotic (v. SYNTHETIC DRUGS).

ISOPRENE. *β-Methyldivinyl*

Discovered by Greville Williams among the products obtained by the destructive distillation of rubber (Phil. Trans. 1860, 241). Tilden obtained it among the more volatile compounds obtained by the action of heat on oil of turpentine and other terpenes (Chem. Soc. Trans. 1879, 417; 1884, 415), and Gladstone from refraction and dispersion measurements came to the same conclusion as Tilden, viz. that the so-called *pentene* obtained from turpentine was identical with isoprene from rubber (Chem. Soc. Trans. 1896, 619). Mokiewski (J. Russ. Phys. Chem. Soc. 1898, 30, 885) found that isoprene obtained from turpentine contains some trimethylethylene, for on treatment with one molecule of bromine in a cooled ethereal solution, isoprene dibromide and any amylene derivative were obtained. Ipatiew and Wittorf (J. pr. Chem. 1897, [ii.] 55, 1) proved the presence of trimethylethylene in isoprene obtained from rubber. By treating isoprene dibromide with zinc-dust, pure isoprene is obtained. Staudinger and Klever (Ber. 1911, 44, 2212), using Tilden's method, have shown that a better yield of isoprene can be obtained by working under reduced pressure. A 60 p.c. yield of isoprene can be obtained by passing

the vapours of dipentene or limonene under very greatly reduced pressure over an electrically heated platinum spiral; the isoprene so obtained is almost pure, containing very little trimethyl-ethylene. Terpineol, terpinene and camphene do not yield isoprene under these conditions.

FIG. 1.

Harries and Gottlob (Annalen, 1911, 383, 228) have described an 'isoprene lamp' (Fig. 1) for the production of the hydrocarbon from turpentine and limonene by this process (Harries, D. R. PP. 243075, 243076).

A platinum wire (120 cm. long, resistance at medium red heat 9 ohms, taking 5 amps. at 220 volts) is heated to redness above the surface of the boiling liquid. A reflux condenser, through which circulates water at 50°, is attached to the flask. The isoprene is collected by a side tube leading to a vessel cooled in a freezing mixture. The product is rectified through a column and the fraction 35°-37° is separated. Commercial pinene in this way gives about 1 p.c. of isoprene, whilst carvone gives 30-

50 p.c. according to the amount of limonene present.

Methylisopropenyl carbinol

heated to 130°-150° with anhydrous oxalic acid, zinc chloride, hydrogen potassium sulphate, or other similar dehydrating agent, yields isoprene (Bayer & Co., D. R. P. 246241). *as*-Dimethylallene (b.p. 39°-41°), dropped on to strongly heated alumina under a pressure of about 20-30 mm. is converted into isoprene (Badische Anilin- & Soda-Fabrik, D. R. P. 251216). See also D. R. P. 231806 for the exhaustive methylation of $\alpha\delta$ -diaminobutane and its derivatives.

Euler (Ber. 1897, 30, 1989) has obtained isoprene by the exhaustive methylation of β -methyl pyrrolidine, a reaction which establishes its structure, as does Ipatiew's synthesis from dimethylallene (J. pr. Chem. 1897, [iii.] 55, 1, 4). The latter hydrocarbon by the addition of hydrogen bromide yields β -methyl- $\beta\delta$ -dibromobutane, which on treatment with alcoholic potash is converted into isoprene.

Harries (Ann. 1911, 383, 157) has also prepared the hydrocarbon from acetone. In this series of reactions the ketone is converted by the action of magnesium ethyl iodide into dimethyl ethyl carbinol, elimination of water from this alcohol transforming it into trimethyl-ethylene. Addition of bromine to the ethylene hydrocarbon yields β -methyl- $\beta\gamma$ -dibromobutane,

which when passed over hot soda lime decomposes into hydrogen bromide and isoprene.

W. H. Perkin and his collaborators (J. Soc. Chem. Ind. 1912, 31, 616) have devised a method for the preparation of isoprene from commercial fusel oil. The fraction of fusel oil, boiling at 128°-130°C. (consisting mainly of isoamyl alcohol, together with some active amyl alcohol), is subjected to the action of dry hydrogen chloride and then further chlorinated in a specially constructed apparatus. On distillation the product was found to consist of $\gamma\delta$ -dichloro-, $\beta\gamma$ -dichloro-, and $\alpha\delta$ -dichloro- β -methyl butanes. These products were not separated, but the combined fraction (b.p. 140°-180°) was passed over soda lime at 470° and the vapour condensed. On fractionation of the product a 40 p.c. yield of isoprene was obtained. It would seem that in this process the $\gamma\delta$ -dichloro- β -methyl butane must first yield an isopropyl acetylene which then undergoes molecular rearrangement into isoprene.

Isoprene is a colourless liquid, b.p. 33.5° (Mokiewski; Ipatiew, *l.c.*); sp.gr. 0°/0° 0.6989 (M. *l.c.*); magnetic rotation, 7.529; sp.gr. 15°/15°, (from turpentine) 0.6768, (from rubber) 0.6748 (Perkin, Chem. Soc. Trans. 1895, 258); thermal expansion (Thorpe and Jones, *ibid.* 1893, 277). For a redetermination of the physical constants, see Harries, Ber. 1914, 47, 1999. By heating isoprene to 300°, only a little dipentene is formed, but a quantity of another hydrocarbon (b.p. 64°-66° (12 mm.)), possibly diisoprene, and also di- and polymers (v. RUBBER) (Harries, Ber. 1902, 3265; Tilden, Chem. News, 46, 120; Bouchardt, Compt. rend. 87, 654; 89, 361). According to Bouchardt (*l.c.*) and Tilden (Chem. News, 1892, 65, 265), strong acids, such as hydrochloric acid, convert isoprene into a tough elastic substance resembling rubber. Bouchardt (Gummi-Zeit, 1901, 16, [viii.] 133) finds that when isoprene (1 part) and hydrochloric acid (12-15 parts) saturated at 0° are sealed in a tube and placed in a freezing mixture, much heat is evolved on shaking. After leaving for 2 or 3 weeks, the contents were diluted and distilled until oily drops ceased coming over. The residue was purified by boiling with water, had all the properties of rubber and gave similar distillation products. Analysis gave the following figures: C=87.1; H=11.7; Cl=1.7. Tilden found that on standing for some months, isoprene is slowly polymerised into a rubber-like substance. Harries (Chem. Zeit. 1910, 34, 315) converted isoprene into rubber by means of acetic acid, but could not effect the change with hydrochloric acid. Chromic acid oxidises isoprene into carbon dioxide, formic, and acetic acids; nitric acid yields oxalic acid. Isoprene dibromide $\text{CH}_2 : \text{C}(\text{CH}_3)\text{CHBr} \cdot \text{CH}_2\text{Br}$ is formed when isoprene is treated with bromine in carbon disulphide solution at 0° (Blaise and Courtot, Bull. Soc. chim. [iii.] 35, 989); b.p. 101° (19 mm.).

On treatment with sodium ethoxide and ethyl malonate, it yields an ethyl ester $C_{12}H_{18}O_4$, which on hydrolysis yields isoprenic acid (isopropyltrimethylenedicarboxylic acid)

m.p. 115° (Ipatiew, J. Russ. Phys. Chem. Soc. 1901, 33, 540). Ostromisslenski and Koscheler (J. Russ. Phys. Chem. Soc. 1913, 47, 1928) have shown that isoprene undergoes auto-condensation when preserved at 80°–90°, yielding the open chain dimerile β -myrcene

ISOTONIC SOLUTIONS. Solutions having the same osmotic pressure.

ISPAGHULA (B.P.). The dried seeds of *Plantago ovata* (Forsk.).

ISTIZIN. Trade name for 1:8-dihydro-oxyanthraquinone.

ITROL v. SYNTHETIC DRUGS.

IVORY is essentially *dentine*, the main constituent of all teeth, but usage restricts the term to the dentine of those teeth which are available for industrial purposes; chiefly those of the elephant, hippopotamus, walrus, narwhal, and sperm-whale.

Ivory contains 57–60 p.c. of calcium salts, chiefly the phosphate, with 40–43 p.c. of an organic matrix and 0.24–0.34 p.c. of fat. It differs from other dentines chiefly in the large amount of organic matter it contains (*cp.* human dentine containing 25 p.c. of organic matter), and in its structure (*v. infra*) and from bone in its greater elasticity and the absence of the larger canals conveying blood vessels.

The substance of ivory is permeated by an immense number of fine canals, about $\frac{1}{1500}$ inch in diameter and strongly curved, to which are due its fineness of grain and probably much of its elasticity. That obtained from the tusks of *Proboscidea* exhibits, on a transverse section, a characteristic pattern of curved decussating lines. The cross-section shows a central spot, the residue of the pulp-centre (*v. infra*), surrounded by concentric circular 'contour lines,' due to a number of minute, irregular 'interglobular spaces.' These spaces and the canals are probably filled with protoplasmic matter in the living tooth. The exterior of the tooth is covered with cementum, usually of a brown colour.

Most of the ivory now used is obtained from the upper incisor teeth of the elephant. The tusks of the African elephant are 9–10 feet long and weigh up to 160 lbs., and are possessed by both males and females. Of Indian elephants, none of the females and not all the males have tusks, and those of the latter are usually less than 8 feet in length and 90 lbs. weight. Captive elephants have their tusks shortened and the ends bound with metal. The tusks grow continuously, and if cut at intervals of ten years yield a useful amount of ivory, although that from wild elephants, especially African elephants, is more highly valued.

The tusks are implanted to the extent of about half their length in curved bony sockets which run nearly vertically upwards to the level

of the eyes. The part within the socket has a conical centre of pulp by the conversion of which into dentine growth takes place, fresh pulp being continually formed at the base of the tooth. The pulp is not easily injured and sometimes foreign bodies, such as bullets and spear-heads, have been found embedded in solid ivory, their presence in the pulp having failed to inhibit its conversion into dentine.

In Russia the tusks of mammoths from North Siberia are much used; they have been preserved unchanged from prehistoric times by the low temperatures of that region.

The canine teeth of the hippopotamus yield an ivory harder and whiter than that of the elephant, and less prone to turn yellow.

Among Northern nations, the upper canine teeth of the walrus are used as a source of ivory. They consist of dentine covered with cementum and have an axis of secondary dentine which is nodular in appearance but usually dense and uniform. The spiral tusk of the narwhal is similarly employed.

Ivory is largely used for making billiard balls, graduated scales, knife-handles, piano-keys, combs, fans, &c., and a considerable quantity is imported into China for the manufacture of ornamented articles. Dieppe is the principal centre for ivory-working in Europe.

As ivory shrinks when dried it is usually cut roughly to shape first, then dried spontaneously or by heat, and finally finished. Because of its high price, great care is taken to cut it up economically and all chips, cuttings, &c., are used for making *ivory-black* or for the preparation of a very pure gelatin.

Ivory can be made flexible by treatment with phosphoric acid and re-hardened by washing and drying, but not without injury to its quality. It takes dyes well and it may be bleached by exposure to sunlight and moisture, by the action of hydrogen peroxide, or by washing alternately with solutions of potassium permanganate and of oxalic acid (Textile Colourist, 1901, 23, 285; *v.* also Livache, J. Soc. Chem. Ind. 1903, 307).

IVY. The leaves, berries, and wood of the common ivy, *Hedera Helix* (L.) have been used in medicine; they contain a mixture of glucosides, soluble and insoluble in water. One of the latter is crystalline, and has been repeatedly examined, last and most thoroughly by van der Haar (Pharm. Weekblad, 1913, 50, 1350, 1381, 1413; *see also* Arch. Pharm. 1912, 250, 424). This author calls it *α -hederin*; m.p. 256°–257°, $[\alpha]_D^{10} + 9.68$ in alcohol. The formula is possibly $C_{42}H_{66}O_{11} \cdot 2H_2O$. It forms small colourless needles, soluble in concentrated sulphuric acid with an orange colour, becoming bright red and finally colourless, as a violet precipitate deposits. It forms a penta-acetyl derivative, m.p. about 155°, and contains one methoxy group. It does not foam on shaking with water. It is hydrolysed slowly by boiling 4 p.c. sulphuric acid to *α -hederagenin*, arabinose, and rhamnose, probably according to the equation

forms rhombic prisms, and has $[\alpha]_D^{20} + 81.2^\circ$ in pyridine. It may be written

as it contains a lactone group, but no methoxy-group, and yields a diacetyl derivative (m.p. 110°). On distillation with zinc-dust a greenish fluorescent oil is obtained, containing a *sesquiterpene*, $\text{C}_{15}\text{H}_{24}$, which still gives the same violet-red coloration as hederagenin, and as the original glucoside. The portion non-volatile with steam is probably $(\text{C}_5\text{H}_8)_x$.

There seems little doubt that this glucoside is identical with the *hederin* of Houdas (Compt. rend. 128, 1463) ($\text{C}_{64}\text{H}_{104}\text{O}_{19}$, m.p. 248°), which on hydrolysis gave *hederedin*, $\text{C}_{26}\text{H}_{40}\text{O}_4$, m.p. 324° , rhamnose and hederose (=arabinose?), and it may further be the same as the *ivy glucoside* $\text{C}_{32}\text{H}_{54}\text{O}_{11} \cdot 2\text{H}_2\text{O}$, m.p. 233° , isolated by earlier investigators from the leaves, but mostly from the berries (Davies and Hutchinson, Pharm. J. [iii.] 7, 275; Davies, *ibid.* [iii.] 8, 205; Kingzett, *ibid.* [iii.] 8, 206; Vernet, J. 1881, 91; Vincent, Bull. Soc. chim. 35, 231;

Block, Arch. Pharm. [iii.] 26, 953). The leaves may be exhausted with hot water and then with hot 90 p.c. alcohol, or the berries may be exhausted with ether, and then with alcohol. The alcoholic extract is treated with charcoal, or, after evaporation, washed with cold benzene, and then dissolved in hot alcohol or acetone, when on cooling and concentration the glucoside crystallises. (Houdas's *hederin* dissolved in 54 parts of alcohol at 18° and in 6.22 parts at 78° .) Ivy glucoside gives a violet colour reaction with sulphuric acid like that described above, and is stated by Block to be hydrolysed to a substance $\text{C}_{20}\text{H}_{42}\text{O}_6$ (?), m.p. 280° , and a sugar.

Posselt has described amorphous hederotannic acid and hederic acid from the berries (Annalen, 69, 62).

The physiological action of ivy glucosides has been examined by Joannin (Compt. rend. 128, 1476), and by Moore (J. Pharm. exp. Therap. 1913, 4, 263).

A peroxylase from ivy has been prepared in a purified condition by van der Haar (Ber. 1910, 43, 1327), who regards it as a gluco protein.

For ivy gum resin, see GUM RESINS. G. B.

J

JABORANDI AND ITS ALKALOIDS. The leaves of *Pilocarpus Jaborandi* (Holmes) were introduced into European medicine by Coutinho and Gubler in 1874 (Rep. de Pharm. 2, 171) under the name 'jaborandi,' which has since been employed generally for the leaves of various species of pilocarpus indigenous to the eastern parts of S. America. *Pilocarpus Jaborandi* (Pernambuco Jaborandi) is no longer obtainable in quantity, the Jaborandi of commerce being usually the leaves of *P. microphyllus* (Stapf.) (Maranham Jaborandi), although the leaves of *P. pennatifolius* (Lem.), *P. racemosus* (Vahl.), *P. spicatus* (A. St. Hill), and *P. trachyphylus* (Holmes) have also appeared in trade.

The leaves of *P. Jaborandi* were official in the B.P. 1898, but have been omitted from the B.P. 1914. In the U.S.P. these leaves and those of *P. microphyllus* are official. Owing to the fact that the sole physiological activity of the leaves has been shown to be due to the pilocarpine they contain (Jowett and Marshall, British Medical Journal, 13th Oct. 1900), and to the greater convenience attained by the use of the salts of this alkaloid, the employment of the galenical preparations of Jaborandi has practically ceased and they are no longer used to any appreciable extent in medicine. No preparation of the drug is recognised in the B.P. and the fluid extract only in the U.S.P., but galenical preparations of Jaborandi have been used as an ingredient in hair washes and restorers. Of the salts of pilocarpine, the nitrate is usually employed in Great Britain, being stable and sufficiently soluble in water for practical purposes, though the hydrochloride, which is more soluble in water, but deliquescent in the air, is preferred on the Continent of Europe and America. The drug was examined

by Hardy (Bull. Soc. chim. 1875, [ii.] 24, 497), Gerrard (Pharm. J. 1875, [iii.] 5, 865, 965; 1877, [iii.] 7, 225), Harnack and Meyer (Annalen, 1880, 204, 67), Jowett (Chem. Soc. Trans. 1900, 77, 474, 851; 1901, 79, 581, 1331), Jowett and Pyman (Chem. Soc. Proc. 1912, 28, 268), and Pyman (Chem. Soc. Trans. 1912, 101, 2260; cf. Léger and Roques, Compt. rend. 1912, 155, 1088; 1913, 156, 1687). The results of these researches show that *P. microphyllus* leaves contain pilocarpine, *iso-pilocarpine* (β -pilocarpine of Brühl, Hjelt, and Aschan; pilocarpidine of Petit and Polonowsky (J. Pharm. Chim. 1897, [vi.] 5, 370, 430, 475; 1898, 6, 8), and pilosine. Harnack and Meyer's pilocarpidine (Chem. Zeit. 1885, 628) and jaborine (Annalen, 1880, 204, 67) may occur in *P. Jaborandi* leaves, which are no longer obtainable in commerce. A sample of jaborine obtained from Merck and examined by Jowett (Chem. Soc. Trans. 1900, 77, 492) proved to consist of a mixture of *isopilocarpine*, pilocarpidine, and possibly pilocarpine, with non-alkaloidal substances. Petit and Polonowsky have stated that *P. spicatus* leaves contain ψ -pilocarpine and ψ -jaborine (*l.c.*). Pilocarpine, *isopilocarpine*, and pilocarpidine produce similar effects on the secretory activity of the sweat and salivary glands, though pilocarpine is much the most powerful, and they also cause contraction of the pupil of the eye, and in this respect are antagonistic to atropine.

Preparation of the alkaloids.—These alkaloids are characterised by being soluble in water and in chloroform, and in being remarkably stable to acids and alkalis (except that pilocarpine on heating for a long time or on long contact with the fixed alkalis becomes converted into *iso-pilocarpine*). The general methods of the extraction of alkaloids modified to suit these

properties can be successfully employed. The usual procedure is as follows:—

The finely powdered leaves are extracted with alcohol containing hydrochloric acid. The solvent is distilled off, the aqueous residue filtered, neutralised with ammonia, and evaporated to a low bulk. Excess of ammonia is then added and the alkaloids extracted with chloroform. The chloroform is distilled off, the residue dissolved in as little water as possible, and neutralised with dilute nitric acid. The crystalline nitrates which form are separated into pilocarpine nitrate and isopilocarpine nitrate by recrystallisation from alcohol until each is of constant melting-point.

Estimation.—A weighed quantity of the finely powdered drug is extracted in a Soxhlet apparatus with alcohol containing 1 p.c. of ammonia. The alcohol is distilled off and the residue dissolved in water, made alkaline with ammonia if necessary, and extracted with chloroform. The chloroform solution is separated, the solvent distilled off, and the residue dried at 100° and weighed. It represents the total alkaloids. Jowett (Pharm. J. 1899, [iv.] 9, 91) has proposed a method for the approximate estimation of pilocarpine in this residue by conversion into the crystalline nitrate and observation of the optical rotation of the product. Of the important varieties of Jaborandi leaves met in commerce, the most common *P. microphyllus* (Stapf.), contains from 0.75 p.c. to as much as 1 p.c. of total alkaloid of which about 75 p.c. is pilocarpine, whilst *P. Jaborandi* (Holmes) contains about 0.72 p.c., of which 93 p.c. is pilocarpine (Paul and Cownley, Pharm. J. 1896, [iv.] 3, 1).

Pilocarpine $C_{11}H_{15}O_2N_2$ is a colourless oil, soluble in water, alcohol, or chloroform, b.p. 260° under 5 mm. pressure, being partially converted into isopilocarpine (see below) in the process. Dextrorotatory, $[\alpha]_D +100.5^\circ$; the rotation is reduced by the addition of alkali. The salts crystallise well; the nitrate $B \cdot HNO_3$ forms well-defined prisms, m.p. 178°; the hydrochloride $B \cdot HCl$ white deliquescent crystals, m.p. 204°–205°; the aurichloride $B \cdot HAuCl_4$, lemon-yellow needles, m.p. 117°–130° (dry); and the picrate, characteristic long needles, m.p. 147°. The B.P. 1914 only recognises the nitrate, m.p. about 176°, and soluble in 8 parts of water. The U.S.P. 1916 includes both the nitrate and hydrochloride with the following constants: Nitrate, m.p. 170°–173°, soluble in 4 parts of water and in 75 parts of alcohol at 25°, and the hydrochloride, m.p. 195°–198°, soluble in 0.3 part of water and in 3 parts of alcohol at 25°. The U.S.P. evidently refers to an impure pilocarpine nitrate, as the pure salt as prepared by Jowett (*l.c.*) melts at 178° and is soluble in 6.4 parts of water at 20°.

Isopilocarpine $C_{11}H_{15}O_2N_2$. When pilocarpine is heated alone or with alcoholic soda it is changed into isopilocarpine, which also occurs in *P. microphyllus* and *P. Jaborandi* leaves, and, according to Jowett (Chem. Soc. Trans. 1900, 77, 473), is frequently found in commercial pilocarpine nitrate. It is an oil, b.p. 261°/10 mm. $[\alpha]_D = +42.8^\circ$ in alcohol. The nitrate $B \cdot HNO_3$, m.p. 159°, crystallises in prisms, and is less soluble in alcohol than pilocarpine nitrate

(Jowett, *l.c.*); the hydrochloride $B \cdot HCl$, m.p. 127°, is stable in the air (unlike the pilocarpine salt, which is hygroscopic). The aurichloride, m.p. 158°–159°, forms lemon-yellow needles, and the picrate, long yellow needles, m.p. 161°.

Reactions and constitution.—On solution in alkalis both alkaloids form unstable sodium salts, viz. sodium pilocarpate and sodium isopilocarpate, from which salts of other metals may be prepared. On oxidation with permanganate isopilocarpine produces homopilocic acid $C_8H_{12}O_4$, and pilopic acid $C_7H_{10}O_4$. The former on fusion with potash yields α -ethyltricarballic acid, and the second, on similar treatment, gives *n*-butyric acid. By distillation with soda-lime isopilocarpine yields 1:4- (or 5-) dimethylglyoxaline (Jowett, Chem. Soc. Trans. 1900, 77, 474, 851; 1901, 79, 581, 1331; 1903, 83, 440; cf. Pinner and collaborators, Ber. 1900, 33, 1424, 2357; 1901, 34, 727; 1902, 35, 2241). One of the two following formulæ is regarded as representing *iso*-pilocarpine:—

Isopilocarpine (Jowett).

the balance of evidence being in favour of I. (Jowett, Chem. Soc. Trans. 1903, 83, 438; 1905, 87, 794; and Pyman, *ibid.* 1910, 97, 1814; cf. Pinner and Schwarz, Ber. 1902, 35, 2441). Pilocarpine or isopilocarpine nitrate is converted by the action of alcoholic potash into an equilibrium mixture consisting chiefly of isopilocarpine with a small percentage of pilocarpine and the alkaloids are thus probably stereoisomerides (Jowett, *l.c.*).

Pilocarpidine $C_{10}H_{14}O_2N_2$ occurs in *Pilocarpus Jaborandi* leaves, but not in those of *P. microphyllus*, and consequently is not obtainable from the Jaborandi leaves of present-day commerce. The alkaloid is liquid, but yields crystalline salts; the hydrochloride has $[\alpha]_D +72^\circ$.

The nitrate, m.p. 137°, $[\alpha]_D +73.2^\circ$ is much more soluble in alcohol than pilocarpine and isopilocarpine nitrates; the aurichloride, m.p. 124°–125°, is soluble in water. As in the case of pilocarpine the optical rotation of pilocarpidine is reduced by the addition of alkali (Harnack and Meyer, Chem. Zeit. 1885, 628; Merck, Arch. Pharm. 1898, 236, 141; Jowett, Chem. Soc. Trans. 1900, 77, 474). The name pilocarpidine was erroneously applied by Petit and Polonowsky to isopilocarpine.

Jaborine. This amorphous alkaloid may occur in *P. Jaborandi* leaves (Harnack and Meyer, Annalen, 1880, 204, 67). According to Jowett (*l.c.*), commercial jaborine is a mixture of isopilocarpine, pilocarpidine, and possibly pilocarpine, with colouring matter.

Pilosine $C_{16}H_{18}O_3N_2$. This alkaloid was obtained from the mother liquors from which pilocarpine and isopilocarpine had been isolated by Pyman (Chem. Soc. Trans. 1912, 101, 2260),

and almost simultaneously by Léger-Roques, who named it 'carpine'; it occurs to the extent of about 0.007 p.c. in the leaves of *P. microphyllus*. Pilosine forms large colourless plates, m.p. 187° , $[\alpha]_{D} +39.9^{\circ}$ in alcohol. The rotation is reduced by alkali, as in the case of pilocarpine and isopilocarpine. The salts do not crystallise well; the aurichloride $B \cdot HAuCl_4$, golden wedge-shaped plates, m.p. 143° - 144° .

Constitution.—Heated with alkali it yields benzaldehyde and pilosinine $C_9H_{12}O_2N_2$. The latter behaves like pilocarpine and isopilocarpine, and the constitutional formula of pilosine is therefore probably:—

(cf. formula for isopilocarpine I.). Both pilosine and pilosinine have a mild pilocarpine action, very much weaker than the latter base.

The microchemical detection of the alkaloids in the leaves of *Pilocarpus pennatifolius* (Lem.) has been investigated by Tunnmann (Chem. Zentr. 1909, i. 1510).

Of the constituents of Jaborandi which have been examined there only remains to be mentioned the volatile oil, which exists to the extent of about $\frac{1}{2}$ p.c. in the leaves. This consists of a dextrorotatory terpene which boils at 178° , pilocarpene $C_{10}H_{16}$, and some higher boiling liquid and solid compounds. Pilocarpene has the sp.gr. 0.852 and forms a crystalline hydrochloride $C_{10}H_{16} \cdot 2HCl$ which melts at 49.5° .

An examination of a species of Jaborandi, *Pilocarpus spicatus* (St. Hilaire) [Aracati jaborandi (Holmes)], by Petit and Polonowsky (J. Pharm. Chim. [vi.] 5, 369) has led to the isolation of two alkaloids. The leaves were extracted in the usual way and the mixture of the bases converted into nitrates. The mixed nitrates were then treated with sodium hydroxide and extracted with chloroform. From the chloroform solution, ψ -jaborine was obtained as a colourless oil with strongly alkaline properties, yielding a crystalline nitrate, m.p. 158° . The second alkaloid ψ -pilocarpine has very much the same properties as pilocarpine, except that it is optically inactive, and yields a crystalline nitrate, small needles, m.p. 142° , and a hydrochloride, prisms, m.p. 198° . H. A. D. J.

JABORINE v. JABORANDI.

J-ACID. 2-Amino-5-Naphthol-7-Sulphonic Acid (q.v.).

JADE. Under this term are included two distinct minerals differing widely in chemical composition, but strikingly similar to one another in external characters. These are nephrite and jadeite. They rank as precious stones, being especially valued in the East as the material for elaborately carved ornaments. Stone implements worked in these materials have been found in the ancient Swiss lake-dwellings and amongst prehistoric remains in many other countries. These minerals have, in common, a white to green (rarely a pale violet) colour, with a certain degree of translucency and a greasy appearance on highly polished surfaces. They

are remarkable for their extreme toughness (as distinct from hardness), it being very difficult to fracture pebbles by blows from a hammer. This toughness is a result of the peculiar texture of the material; thin sections examined under the microscope show a close, felted aggregate of short, minute fibres.

The name nephrite from the older name *lapis nephriticus*, meaning kidney-stone, refers to the ancient belief that when worn as a charm this stone was a remedy for kidney disease. The name jade has the same meaning, through the Spanish 'piedra de yjada.' A well-known Chinese name is 'yu,' and the ancient Mexican is 'chalchihuitl.' Jadeite was first distinguished chemically and so named by A. Damour in 1863.

Nephrite is a metasilicate of magnesium and calcium $CaMg_3(SiO_3)_4$, with usually a small and variable amount of ferrous oxide (to which is due the range in colour). It is a member of the amphibole group, differing from tremolite, actinolite, and amphibole-asbestos only by reason of the peculiar texture of the material. Under the microscope, the fibres show prismatic cleavages inclined at 124° and the optical characters of amphibole; sp.gr. 2.9-3.1; H. 6-6½.

Jadeite is a metasilicate of sodium and aluminium $NaAl(SiO_3)_2$; small amounts of ferrous and ferric oxides are often present, and in the dark green variety known as chloromelanite there is 6-10 p.c. Fe_2O_3 isomorphously replacing alumina. Jadeite is a member of the pyroxene group, having an angle $\phi 93^{\circ}$ between the prismatic cleavages and the optical properties characteristic of this group; sp.gr. 3.30-3.35 (3.4 in chloromelanite). The hardness (H. $6\frac{1}{2}$ -7) is rather greater in jadeite than in nephrite.

These two minerals are of course readily distinguished by chemical tests; and also by the easier fusibility of jadeite, which at the same time imparts a yellow colour to the flame. In thin sections under the microscope, the optical characters and cleavage angles afford distinguishing features. In many cases, however, it is the material of a carved ornament that requires determination, and then the only available test is that given by the difference in sp.gr. Some other minerals, e.g. the hard compact variety of serpentine known as bowenite (sp.gr. 2.6), which are often confused with jade, may also be readily distinguished by their sp.gr.

Nephrite and jadeite each occur as constituents of metamorphic silicate rocks, and they are frequently so intimately intermixed with other minerals that the material itself is at times of the nature of a rock. Much of the material used for carving is collected as pebbles and boulders from the beds of streams. Quarries in the solid rock are, however, worked in Eastern Turkestan (nephrite) and at Tawmaw in Upper Burma (jadeite). The well-known New Zealand 'greenstone' is a dark green nephrite. (On New Zealand nephrite, see A. M. Finlayson, Quart. J. Geol. Soc. 1909, 65, 366.)

Jade presents many points of interest to the ethnologist and collector as well as to the mineralogist, and it is the subject of a considerable literature. A monumental work in two huge, beautifully illustrated volumes is the 'Investigations and Studies in Jade,' based on the Heber R. Bishop collection (New York,

1906; a privately printed edition limited to 100 copies was prepared at enormous expense for free distribution to the principal royal and public libraries of the world). The subject is here dealt with by numerous contributors from all possible points of view; in the chemical portion 58 new analyses are given. A briefer and more accessible general account of jade is given in M. Bauer's *Edelsteinkunde*, 2nd edit. 1909; English translation, *Precious Stones*, by L. J. Spencer, 1904. L. J. S.

JADEITE v. JADE.

JAK-WOOD, or Jack-wood, is derived from the *Artocarpus integrifolia* (Linn.) which belongs to the *Urticaceæ*, and is cultivated throughout India, Burmah, and Ceylon, except in the north. It is largely used for carpentry, furniture, &c., and is stated to be imported to Europe for this purpose. The rasped wood is used by the natives of India and Java as a yellow dye in conjunction with alum, for the robes of the Burmese priests, also for dyeing silk and for general purposes.

An aqueous solution of the wood possesses the characteristic property that when it is treated with alkali and gently warmed, the yellow solution at first obtained assumes a beautiful blue tint.

Jack-wood (Perkin and Cope, Chem. Soc. Trans. 1895, 67, 937) is very similar to old fustic, and its dyeing properties are due to *morin* (see Old Fustic). Unlike old fustic, however, it contains no maclurin, but there is present a second substance, *cyanomaclurin*, which is devoid of tinctorial property. These compounds can be isolated from jack-wood by methods which are almost identical with those which have been applied to fustic itself, and their separation may be effected by means of lead acetate, as this precipitates only the morin.

Cyanomaclurin $C_{15}H_{13}O_8$ crystallises in colourless prisms, somewhat readily soluble in water, and gives with basic lead acetate a colourless precipitate, and with ferric chloride a violet-coloured liquid. Its solution in dilute alkalis is colourless, but if this be gently warmed a beautiful deep indigo coloration is produced, which on longer digestion passes into green and finally becomes brown-yellow. When used with alkali, it gives β -resorcylic acid and *phloroglucinol*.

Acetylcyanoacclurin $C_{15}H_7O_8(C_2H_5O)_5$, colourless needles, melts at 136° – 138° , and *benzoylcyanoacclurin* $C_{15}H_7O_8(C_6H_5O)_5$, colourless prisms, melts at 171° – 172° . *Disazobenzene cyanomaclurin* $C_{15}H_{10}O_8(C_6H_5N_2)_2$, scarlet needles, m.p. 245° – 247° (decomp.), gives an *acetyl* derivative, probably

orange-red needles, m.p. 209° – 210° (decomp.) (Perkin, Chem. Soc. Trans. 1905, 87, 715). In certain respects, *cyanomaclurin* resembles the catechins of gambier and acacia catechus, and more especially so in that by boiling with dilute acids it gives reddish-brown amorphous substances, which are very similar to the so-called catechin anhydrides. The product obtained by the action of hydrochloric acid on a boiling acetic acid solution of *cyanomaclurin* is insoluble in alkalis and all solvents, and has a percentage composition almost identical with the catechin anhydride similarly produced. According to

Perkin, *cyanomaclurin* is possibly a reduction product of morin, thus:

Jack-wood dyes shades very similar to those given by old fustic; that is, olive-yellow with chromium, dull yellow with aluminium, and a brighter yellow with tin mordant. On the other hand, the sample examined by Perkin and Cope possessed only about one-third of the dyeing power of old fustic. A. G. P.

JALAP v. RESINS.

JALAPIN v. *Scammony*, art. GUM RESINS; GLUCOSIDES.

JAMBA OIL is obtained from a plant belonging to a variety of the genus *Brassica*. The oil behaves, in most respects, very similarly to ordinary rape oil, but differs from it most distinctly in that it does not lend itself so readily to the manufacture of 'blown' oil as the other oils belonging to the rape oil group. Hence jamba oil is distinctly inferior to rape oil prepared from genuine rape seed oil, which accounts for its lower commercial value as compared with that of colza oil.

Jamba oil is most readily recognised by its peculiar taste and smell. It is chiefly used as a burning oil, although it does not burn so well as colza oil. It is also used for lubricating purposes, and takes its place, as regards quality, between Indian rape oil and ravison oil.

The following values have been recorded for genuine specimens of the oil: sp.gr. 0.9150 – 0.9158 ; solidification point, -10° to -12° ; iodine value, 95.2 – 102.5 ; and m.p. of fatty acids, 19° – 21° .

JAMESONITE. A sulphantimonite of lead, invariably containing 2–3 p.c. of iron, the formula being $4PbS \cdot FeS \cdot 3Sb_2S_3$ (W. T. Schaller, Zeitsch. Kryst. Min. 1911, 48, 562; L. J. Spencer, Min. Mag. 1907, 14, 207, 310). It is orthorhombic with a distinct basal cleavage, but only acicular crystals (*v.* FEATHER-ORE), columnar masses, or more usually finely fibrous masses have been found. Coarse columnar masses associated with stibnite have been mined at Endellion in Cornwall. The mineral is of frequent occurrence in Bolivia, and, as it sometimes contains small amounts of silver, it has been worked as a silver-lead ore as well as for antimony. L. J. S.

JANTHONE. A synthetic perfume obtained by condensing citral or lippial and mesityl oxide. *Lippial* $C_{10}H_{16}O$ is present in the oil of *Lippia citriodora* (H. B. & K.). Janthone is a tetrahydrobenzene derivative containing two ethylene bonds in the ketone side chain: b.p. 162° under 10 mm.; sp.gr. 0.9452 . When diluted it has a characteristic odour of violets and orris root. (D. R. P. 118288, 1898; Farb. Durand, Hugenin & Co., Zeitsch. angew. Chem. 1901, 14, 346.)

JAPAN BLACK v. BRUNSWICK BLACK.

JAPAN EARTH. *Terra japonica* v. CATECHU.

JAPANESE SARDINE OIL is obtained from *Clupanodon melanosticta* (T. and S.), a fish belonging to the *Clupeidae*. Japanese sardine oil differs distinctly from the ordinary sardine

oil (see SARDINE OIL) in its higher iodine value, which in pure specimens reaches as high a figure as 187. The commercial oil has, until recently, been prepared in a very crude manner, the fish refuse having been boiled with water to separate the oil. Japanese sardine oil is characterised by a considerable proportion of *clupanodonnic acid*, of which as much as 14.2 p.c. is yielded by genuine specimens.

Genuine specimens examined by Tsujimoto gave the following values: Sp.gr. at 15.5°, 0.9316-0.9347; saponification value, 194.8-196.2; refractive index at 20°, 1.4802-1.4808; iodine value, 180.6-187.3; and m.p. of fatty acids, 35.4°-36.2°.

The commercial Japanese sardine oil has hitherto been more or less mixed with other fish oils, so that the commercial specimens of oil have much lower iodine values than the genuine oils. Japanese fish oil (which must not be confounded with Japanese cod-liver oil) is largely exported to Europe and to Australia, where it is used in soap making and in the leather industries.

JAPAN WAX (Japan tallow) is obtained from the berries of several species of the sumach tree, viz.: *Rhus succedanea* (L.), known in Japan as 'hazé'; *R. acuminata* (DC.); *R. vernicifera* (DC.), known in Japan as 'urushinoki'; *R. sylvestris* (Sieb. et Zucc.). The first-named species is grown chiefly in China, whereas the last-named one flourishes especially in the western provinces of Japan; the species *R. succedanea* grows also in Indo-China and in India. In China, Japan, and Tonkin, the trees are cultivated chiefly for the sake of the lacquer which they exude. Japan wax must therefore be considered as a by-product of the lacquer industry.

The seeds of the several species of *Rhus* consist of a small kernel surrounded by a greenish, striated, shrivelled mass. In China the wax is prepared by crushing the seeds, together with their coating, and steaming them in perforated cylinders so that the fat melts and runs off. In Japan the manufacture is still carried out in a somewhat crude fashion, by storing the berries in straw until they are fully matured, then crushing them by hand in a wooden funnel-shaped trough, and winnowing the mass so as to separate the kernels. The powdered mass thus obtained is put into hempen sacks and subjected to pressure in wooden wedge presses. The yield from the berries ranges from 15 to 20 p.c. The fat is a coarse greenish tallow-like mass. It is refined by remelting, pressing through cotton sacks, and allowing the fat to drop into cold water. The thin flakes of the wax are then bleached by exposure to the sun in shallow baskets (in a similar manner as is done in the process of bleaching beeswax), the material being continually turned over and sprinkled with water. The bleached wax is finally melted and cast into slabs, in which form it is exported to Europe.

The production of Japan wax cannot be largely extended, as it takes 7 to 8 years for a wax tree to reach maturity, and if the tree promises to become a fruitful source of lacquer, this leads to its sacrifice as a source of wax.

Japan wax is a pale yellow, slightly hard

substance of conchoidal, somewhat lustrous fracture. On keeping, Japan wax turns deep yellow and becomes coated with a white powder consisting of microscopical prismatic needles. The term 'wax' is a misnomer, as Japan wax is a glyceride, consisting chiefly of palmitin and free palmitic acid. Hence, it is more appropriately termed Japan tallow.

Japan wax is insoluble in cold alcohol, but dissolves readily in boiling alcohol, separating almost completely on cooling as a granular, crystalline mass. In addition to palmitic acid, which differs in some respects from the palmitic acid from animal fats, it also contains small quantities of dibasic acids, as also of a soluble acid, the proportion of which has been found to amount to almost 6 p.c. The proportion of dibasic acids amounts to nearly 1 p.c.; amongst these, the largest in amount is *japanic acid* $C_{19}H_{38}(COOH)_2$ (nonadecamethylenedicarboxylic acid), which is accompanied by its lower homologues, *heptadecamethylenedicarboxylic acid* $C_{17}H_{34}(COOH)_2$, and *octodecamethylenedicarboxylic acid* $C_{18}H_{36}(COOH)_2$. These dibasic acids probably occur as mixed glycerides of palmitic and dibasic acids. The constitution of Japan wax being that of a glyceride, it is most readily differentiated from the true waxes by yielding glycerol on saponification. The iodine value of genuine Japan wax is about 4. The commercial wax has a higher iodine value—from 10 to 15—as in consequence of the increased demand for Japan wax it has become the practice in Japan to extract the press residues with the (hazé) kernel oil. In the Chinese mode of manufacture, the kernel oil passes automatically into the 'wax.' At a temperature of 16°-18°, Japan wax has the density of water of the same temperature.

The wax melts at about 50°-60°, and it shows the phenomenon of double melting-point, a sample melting many degrees lower after having once been melted and rapidly cooled. It has sp.gr. of 0.984-0.993 at 15°, Hehner value, 189-191, and its insoluble fatty acids melt at about 54°-62°. The commercial product usually contains about 0.06 p.c. of mineral matter.

Japan wax is largely used for waxing floors, and as a constituent of polishes. As it forms an emulsion with water, it can be used for currying leather. Notwithstanding its high proportion of palmitic acid, it does not constitute a suitable candle material. The proposal to use it as an admixture with edible fats, or with margarine, is to be strongly deprecated. The adulterants of Japan wax include water and starch, whilst, on the other hand, it has been used as an adulterant of beeswax.

J. L.

JAPACONITINE *v.* ACONITINE.

JAPANESE WAX *v.* *Insect wax*, art. WAXES.

JAPANIC ACID *v.* JAPAN WAX; AND WAXES.

JAPANING. A term synonymous with

'lacquering' (*v.* LACQUER).

In Europe, japaning is also taken to mean the art of coating surfaces with varnishes which are then hardened by subjecting them to a high temperature, an art which holds an intermediate position between painting and enamelling. The varnishes are transparent and durable bodies, in black or other colours, black being the hue which is most extensively used. Black varnish

is composed of pure natural asphaltum mixed into a preparation of gum anise dissolved in linseed oil and turpentine. This in thin coatings appears brown, and requires several courses to acquire the requisite blackness; the article treated being placed in a stove at about 150° after each coating. For colours, the necessary mineral pigments or metallic powders are mixed with a transparent copal varnish of less body than ordinary painters' varnish.

European japanning, although very far behind the work produced by the process described as in use among the Japanese, produces a very brilliant and durable coating to small articles of metal work and papier mâché. It is also applied as a facing for stone to imitate marble.

JAPAN SAGO. Starch obtained from the stem of *Cyras revoluta* (Thunb.).

JARGON or **JARGOON** *v.* ZIRCON.

JAROSITE. Hydrated basic sulphate of potassium and ferric iron $K_2O \cdot 3Fe_2O_3 \cdot 4SO_3 \cdot 6H_2O$ or $K_2Fe_6(OH)_{12}(SO_4)_4$, crystallised in the rhombohedral system and isomorphous with alunite. The potassium (K_2O , 9.4 p.c. according to the formula) is often partly replaced isomorphously by sodium, Na_2O reaching 6.18 p.c. in the variety *natrojarosite*; and in the variety *plumbojarosite* lead (PbO , 19.7 p.c.) takes the place of potassium. The small crystals have the form of cuboidal rhombohedra, the interfacial angles being 90° 45'; or they may be tabular in habit owing to the predominance of the basal planes. Closely aggregated they line cavities in the massive material, or they may be loose as a glistening powder. The mineral also forms granular, fibrous, and concretionary masses. The colour is yellowish-brown and the streak ochre-yellow; sp.gr. 3.1-3.2 (3.66 in *plumbojarosite*); H. 2½-3½. The name is from the Jaroso ravine in the Sierra Almagrera, Spain, where the mineral occurs with limonite in a silver-lead mine. Several other localities are known, especially in Bohemia and the United States.

L. J. S.

JASMAL. The active odoriferous principle of the jasmine flower. Is the methylene acetal

of phenyl glycol, $\begin{array}{c} CH_2 \cdot O \\ | \\ CH_2 \cdot O \end{array} \rangle CH \cdot C_6H_5$, and may

be synthetically formed by condensation of phenyl glycol and formaldehyde in presence of sulphuric acid; b.p. 218°; sp.gr. 1.1334 (Verley, Compt. rend. 1899, 128, 314).

JASPER. A compact and opaque variety of quartz, intimately intermixed with iron oxide and hydroxide, clay, &c.; these impurities being present sometimes to the extent of 20 p.c. The material has a dull, even fracture, but it takes a good polish; the colours are various—red, yellow, brown, green, &c. It is cut and polished as an ornamental stone, and was much prized by the ancients, but their *jaspis* included other minerals than those now designated as jasper. The well-known *Egyptian jasper* is found as nodules and pebbles in the Nile Valley, and resembles a brown flint, with dark zones and cloudings. *Banded jasper* is a striped variety, well illustrated by the beautiful red and green 'riband jaspers' of the Ural Mountains. Some banded jaspers appear to be metamorphic sedimentary rocks, whilst others are striated felsitic

tuffs. The so-called *porcelain-jasper* is merely a shale highly indurated by exposure to a high temperature.

Agate-jasper or *jasp-agate* is intermediate in character between jasper and agate or chalcedony; and in other directions no sharp line can be drawn between jasper and hornstone or chert, all of which are simply compact varieties of quartz.

Red jaspers owe their colour to intermixed ferric oxide. They are sometimes so highly ferruginous and interlaminated with bands of hæmatite that they constitute ores of iron, e.g. the so-called *jaspilite* of the Lake Superior district.

L. J. S.

JASPILE *v.* JASPER.

JATEORRHIZINE *v.* CALUMBA.

JAUNE ACIDE. Acid yellow (*v.* AZO-COLOURING MATTERS).

JAUNE ANGLAIS. Victoria yellow (*v.* CRESOL).

JAUNE BRILLIANT. Cadmium sulphide (*v.* CADMIUM).

JAUNE DE FER, JAUNE DE MARS. Mars yellow (*v.* PIGMENTS).

JAUNE D'OR. Martius's yellow (*v.* NAPHTHALENE).

JAUNE N. Curcumein; Orange N. (*v.* AZO-COLOURING MATTERS).

JAUNE SOLIDE. Fast yellow (*v.* AZO-COLOURING MATTERS).

JAVA WAX, FIG WAX *v.* WAXES.

JECORIC ACID $C_{18}H_{30}O_{21}$. An isomer of linolenic acid, said to occur in sardine oil and other fish oils, associated with clupanodonic and aseltinic acids.

JERVINE *v.* CEVADINE.

JESACONITINE *v.* ACONITINE.

JESSENIA POLYCARPA (Karst.). The nuts of this Colombian palm, known locally as the 'sejen' or 'unamo' palm, yield a pale yellow oil closely resembling olive oil in physical and analytical characters. It is used in Bogota and other Colombian towns for culinary and medicinal purposes and could, presumably, be used for all purposes for which olive oil is employed (Bacharach, Analyst, 1918, 289).

JESTERIN *v.* GLUCOSIDES.

JET. (Fr. *Jais*, *Jaët*; Ger. *Gagat*, *Agstein*.)

A variety of fossil coal or lignite, similar in appearance to cannel-coal. Being hard (H. 3-4) and capable of taking a lustrous surface by polishing, it is used for making small ornamental articles; sp.gr. 1.35. It is found on the Yorkshire coast near Whitby, in Spain, France, and Würtemberg, occurring in the shale and limestone formations. The name is supposed to be a corruption of the *Gagates* of Pliny and Dioscorides, who described the mineral as found near the mouth of the river Gagates in Lycia, Asia Minor.

The jet of Whitby is evidently a fossilised coniferous wood, as shown by its structure in thin sections under the microscope. On its surface impressions of fossils, especially ammonites, frequently appear.

Whitby jet is divided into 'hard' and 'soft,' of which the former is the more esteemed; it is found near the base of the Upper Lias and, sparingly, in other parts of that formation. Soft jet occurs in the sandstones and oolitic shales. The hard variety is obtained in compressed layers varying from an inch or two in length

and $\frac{1}{4}$ th in thickness, to 6 feet long, 30 inches wide, and 4 inches thick. The largest piece ever found was 6 feet 4 inches long, $4\frac{1}{2}$ to $5\frac{1}{2}$ inches wide, and 1 and $\frac{1}{2}$ inches thick; it weighed 11 lb. 8 oz.

The collection of jet was formerly effected by cutting down the cliffs until the jet-veins showed themselves; to-day the cliffs are almost abandoned and the works are carried on inland to a distance of 20 miles. The operation is described by J. A. Bower (Jour. Soc. of Arts, 22) in these words: 'The process of obtaining jet here is simple; the faces of the hills are turned down bodily, and by then tunnelling for some distance, and after carrying several passages parallel from the face of the hill, transverse shafts are cut. When the rock becomes too hard the miners retire, pulling down the roofs on their return; in these falls the bulk of the jet is found.' The rough jet obtained from the inland mines is encased in a brown skin; that from the cliffs is covered with a blue skin. This is chipped off, the pieces of jet are sawn into suitable sizes and handed over to the carver or turner. (See J. A. Bower, Whitby Jet and its Manufacture, Jour. Soc. of Arts, 1874, 22, 80; John Phillips, Illustrations of the Geology of Yorkshire, Part I. The Yorkshire Coast, 1835; 2nd ed. 1875; A. C. Seward, The Structure and Origin of Jet, Rep. Brit. Assoc. 1901, 856; P. E. Spielmann, The Origin of Jet, Chem. News, 1906, 94, 281; 1908, 97, 181. Special Reports on the Mineral Resources of Great Britain, Mem. Geol. Survey, 1918, vol. 7.) L. J. S.

JOHANNITE. Hydrated sulphate of uranium (UO_3 , 67.7 p.c.) and copper of uncertain formula. Sp.gr. 3.19; soluble in water. It occurs as small, transparent, green, monoclinic crystals as an alteration product of pitchblende at Joachimsthal in Bohemia and Johanngeorgenstadt in Saxony. L. J. S.

JOSEITE *v.* TETRADYMIT.

JUAR-ROOT. A powerful narcotic used in India to enhance the intoxicating power of bhang.

JUDSON POWDER *v.* EXPLOSIVES.

JUGLONE *v.* NAPHTHALENE.

JUNIPER. (*Genièvre*, Fr.; *Wacholder*, Ger.)

The berries have been employed in medicine from very early times and have sometimes been used as an article of food. They are a reputed diuretic. The large proportion of dextrose (15-20 p.c.) renders them available for fermentation and the distillation of spirit. Such a product was in France called *genièvre*, and hence the contracted form *gin* employed in this country for a spirit which now is merely flavoured with juniper.

The essential oil from the berries, *Oleum juniperi* (B.P.; U.S.P.) is now alone official, and is obtained from the ripe fruits of *Juniperus communis* (Linn.) (Bentl. a. Trim. 255), a well-known evergreen shrub which inhabits the northern regions of both hemispheres. The fruits are gathered chiefly in Hungary, Austria, and Southern France (Flück. a. Hanb. 624; Morel, Pharm. J. [iii.] 8, 886). The oil is a colourless or pale yellow-green limpid liquid of aromatic, burning taste. The density is generally between 0.867 and 0.875 (0.862-0.890 at 15°, B.P.; 0.854-0.879 at 25°, U.S.P.);

$[\alpha]_D -3^\circ$ to -15° ; usually -4° to -6° ; $n_{25^\circ} 1.472-1.488$. On keeping the oil gradually resinifies and becomes viscid, and the density increases. The chief constituents are *pinene*, b.p. 156° , predominating in the oil from unripe fruits (65 p.c. or more), a sesquiterpene *cadinene*, b.p. 274° ; and *terpene alcohols*, particularly *terpineol*, b.p. $209^\circ-212^\circ$; the higher boiling constituents predominate in the oil from ripe fruits, which also contains small quantities of *juniper camphor*, m.p. $165^\circ-166^\circ$, and an *ester*, perhaps *terpineol acetate*. According to the B.P. the oil should dissolve in 4 parts of 95 p.c. alcohol. An alcoholic solution is largely used as *gin essence*. The oil from the leaves is very similar but dextrorotatory, $[\alpha]_D = +8^\circ 46'$.

Oil of cade (*Oleum cadinum*, B.P.; U.S.P.) is a reddish-brown or nearly black liquid obtained by destructive distillation of the woody portions of *Juniperus oxycedrus* (Linn.). It has a specific gravity of about 0.980-1.055 at 25° (U.S.P.). The principal constituent is *cadinene*, and the oil is incorporated in ointments and soaps for use in skin diseases.

G. B.

JUNIPER, OIL OF, *v.* OILS, ESSENTIAL.

JUTE is the bast fibre almost exclusively of two plants of the natural order *Tiliaceæ*, viz. *Corchorus capsularis* (Linn.) and *Corchorus olitorius* (Linn.), cultivated for the most part in Bengal, where they are indigenous. Although differing in size and in the form of their seed-pods, the plants are not greatly dissimilar in appearance and are not commercially distinguished from each other. The seed is sown annually, in April or May, and the plants after flowering, which takes place from August to September, and having now attained a height of 5 or 6 feet in the case of *C. olitorius*, and of 5 to 10 feet in that of *C. capsularis*, are cut down and thrown into pits of water to soak, after the manner of steeping flax. From a few days to a month is required to bring the stalks into a condition for stripping the bast from the wood and freeing it from cortex, these operations being purely manual. After being washed and dried the jute is made up into bales for sale.

Jute is very largely used for the manufacture of sacking and wrapping cloths (Hessians), as a paper-making fibre, and as a substitute for hair in making theatrical wigs. It is also employed for carpet-making and inferior cordage and, in India, for making small domestic articles such as nets and muzzles for oxen. In these islands the principal seat of the jute industry is Dundee.

The fibre occurs in strands of considerable length, 6-12 feet; the spinning unit or filament is of various lengths, according to the degree of subdivision practised. The filament is a complex of the ultimate fibres, of which from 5 to 12 are usually seen in the section at any point. They are polygonal in section and much thickened (lignified); their length does not exceed 2-3 mm., whereas those of flax and hemp—also bast fibres—are from 25-40 mm. long. This structural inferiority, together with the fact that the fibre substance yields somewhat readily to the action of oxidants (air and light) in presence of water, characterises jute as a 'weak fibre.'

Treated by the 'line spinning' process it

may be spun into yarns of considerable fineness, but, owing to the large proportion of waste ('tow'), at relatively large cost. These yarns when bleached—preferably by 'soda bleach' (sodium hypochlorite)—have considerable lustre; they are soft and of a cream shade, and take up the majority of colouring matters—wood and aniline dyes—directly from the dye-bath. Jute fabrics are also successfully printed in steam styles, the presence of sodium sulphide being necessary to preserve the fibre substance from the action of the steaming process (*Développement de l'Industrie de Jute*, Cross and Witt, Bull. Mulhouse, 1881).

According to the investigations of Cross and Bevan, jute does not contain cellulose as such, but in the form of bastose or lignocellulose, which is a link between the carbohydrates and the aromatic compounds. Treated with chlorine it gives a yellow chlorinated derivative which

when hydrolysed yields substances belonging to the tannic acid group. Hence it may be said that jute possesses a mordant which makes it receptive of aniline colours in a degree possessed by none of those fibrous materials which require the intervention of a mordant. When quantities of the fibre are kept in a damp situation, more especially when exposed to sea-water, it is decomposed into substances analogous to tannin and to acids of the pectic acid group. Under treatment by acids, jute is disintegrated, yielding xylose and furfural (*v. also* Tollens, *Annalen*, 254, 325). It is easily bleached by potassium permanganate after cleansing with soap or alkali, with a loss in weight of 3 to 4 p.c. In practice this is generally too expensive a process, and the substances usually employed are hypochlorites, in which great care is necessary, as chlorinated compounds may be formed and the fibre destroyed (*supra*) (*v. CELLULOSE*).

K

K ACID. 1-Amino-8-Naphthol-4:6-Di-sulphonic acid.

KACHIN. A pyrocatechol photographic developer.

KAFIRIN. The alcohol-soluble protein of kafir; closely resembles zein, the alcohol-soluble protein of maize, but differs from it in containing a small quantity of tryptophan, in addition to leucine and glutamic acid, but is free from glycine (Jones and Johns, *J. Biol. Chem.* 1918, 36, 323).

KAINITE. A hydrated double salt

occasionally found in the potash-salt deposits as sharply-developed, water-clear, monoclinic crystals; sp.gr. 2.13, H. 2½-3. It contains KCl 30 p.c. (K 18.9 p.c.). As granular masses of a white, grey, or reddish colour, it forms large beds near Stassfurt in Prussia, Asse in Brunswick, and at Kalusz in Poland (*v. POTASSIUM*). It occurs, intermixed with kieserite, carnallite, rock-salt, and anhydrite, in the uppermost layers of the 'carnallite zone.' The mineral was first recognised in 1865 in the Anhalt shaft at Stassfurt, and was named from *kavós*, new, with the mineralogical termination *ite*. Unfortunately, the German spelling 'Kainit' is in common usage, although the correct English equivalent is familiar to mineralogists. Raw kainite is extensively used as a fertiliser, and it is also employed for the preparation of potassium chloride and sulphate. On the artificial production of kainite, see van 't Hoff, *Sitz.-Ber. Akad. Wiss. Berlin*, 1901, 420; 1903, 678.

L. J. S.

KAIRINE, KAIROCOLL, KAIROLINE, v. QUINOLINE.

KAISERGELB v. AURANTIA.

KAISERROTH. The sodium salt of dinitro-dibromfluorescein. Called also Eosin Scarlet, Safrosine, and Lutétienne.

KALADANA, (B.P.), or PHARBITIS SEEDS. The dried seeds of *Ipomœa hederacea* (Jacq.).

KALIASTRAKANITE KALIBLÖDITE, v. LEONITE.

KALIBORITE. Hydrate borate of magnesium and potassium $\text{K}_2\text{Mg}_4\text{B}_{22}\text{O}_{33} \cdot 14\text{H}_2\text{O}$ crystallised in the monoclinic system. It occurs as small, colourless to white, crystals embedded in nodules of sulphur-yellow pinnoite ($\text{MgB}_2\text{O}_4 \cdot 3\text{H}_2\text{O}$) in the 'carnallite zone' and the overlying potash-salts at Leopoldshall near Stassfurt and Westeregeln in Prussia. Sp.gr. 2.12, H. 4-5; readily soluble in hydrochloric acid. Curiously, the mineral was twice described independently in 1890 under the names heintzite and hintzite; whilst in the previous year a massive, granular form, from Schmidtmannshall near Ascherleben, was described under the name kaliborite. The last name has priority besides being descriptive. On the artificial production see van 't Hoff, 1902. L. J. S.

KALINITE. The mineralogical name for native potash-alum $\text{K}_2\text{SO}_4 \cdot \text{Al}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$. Although readily obtained artificially as sharp octahedral crystals, the natural mineral usually occurs as white silky fibres, or less often as granular masses. It is found as an efflorescence on shale, having been produced by the action of the products of decomposition of pyrites on the aluminous rock (*e.g.* at Whitby in Yorkshire); or as a volcanic sublimation (*e.g.* at Vulcano in the Lipari Islands, and Vesuvius). The alum from Vulcano contains traces of caesium and rubidium. Since the mineral has been formed at the surface and is readily soluble in water, it is never found in large masses.

L. J. S.

KALIOPHILITE v. NEPHELITE.

KALMOPYRIN or SOLUBLE ASPIRIN.

Trade names for calcium acetylsalicylate.

KAMALA or KAMELA is the orange-red powder which exists as a glandular pubescence on the exterior of the fruits of the *Mallotus philippinensis* (Muell.) (*Rottlera tinctoria* [Roxb.]), a small evergreen tree, met with throughout tropical India, Burma, and Ceylon, also in Java, China, the Malay Islands, and Australia. The ripe capsules are gathered in February or March, and shaken in bags until the powder separates.

Kamala is employed by the Hindoos as an

antihelmic drug and for dyeing silk and wool a bright orange colour. The fabric is dyed in a boiling bath containing 4 parts kamala, 1 part alum, and 2 parts sodium carbonate (native barilla), previously well rubbed together in the powdered state with a small quantity of oil of sesamum. The alum is sometimes omitted, but the addition of alkali is absolutely necessary in order to dissolve the colouring matter, which is of a resinous character and quite insoluble in water. Kamala is also apparently used for the adulteration of annatto, for according to Perkin (private communication), samples of calico obtained from India and presumably dyed with kamala have proved on examination to owe their colour partially if not entirely to annatto. Kamala was formerly employed in this country as a remedy for *taenia*, but appears now to be very little used for this purpose.

Anderson was the first chemist to investigate kamala (Edin. New. Phil. J. 1, 300), and he isolated from it by means of ether a crystalline compound *rottlerin* $C_{11}H_{10}O_3$, a wax $C_{20}H_{34}O_4$, and a resin melting below 100° , to which he gave the formula $C_{30}H_{30}O_7$. Leube (J. 1860, 562) was unable to obtain any crystalline product from this drug, but he describes two resins, $C_{15}H_{15}O_4$, m.p. 80° , and $C_8H_{12}O_4$, m.p. 191° . Oettingen (Dissert. St. Petersburg, 1862) also could not obtain any crystalline substance from kamala. A. and W. Perkin (Ber. 1886, 19, 3109), however, isolated the crystalline *rottlerin* ('mallotoxin') of Anderson, and its existence was subsequently confirmed by Jawein (Ber. 20, 182).

As the result of a more extended examination of kamala and employing carbon disulphide for the extraction, A. G. Perkin (Chem. Soc. Trans. 1893, 63, 975) isolated not only Anderson's compounds, but small quantities of two crystalline substances, *homorottlerin*, which is yellow, and *isorottlerin*, a salmon-coloured powder, together with a high melting resin.

Rottlerin $C_{11}H_{10}O_3$ (Perkin, *ibid.* 1895, 67, 230), salmon coloured plates, melts at 191° – 191.5° (P.), 200° (Jawein), 202° – 204° (Telle, Arch. Pharm. 1906, 244, 441), readily soluble in ether. Solutions of the alkali carbonates and hydroxides dissolve *rottlerin*, the former only on gently warming. On boiling these orange-coloured liquids, decomposition gradually takes place, an odour of benzaldehyde is evolved and a resinous product separates. An alcoholic solution of *rottlerin* is coloured brown on the addition of ferric chloride.

Acetyltrottlerin $(C_{11}H_9O_3(C_2H_3O)_2)_3$, yellow crystalline powder, m.p. 130° – 135° (P.), and *benzoyltrottlerin* $C_{33}H_{24}O_9(C_7H_5O)_6$, yellow powder (Bartolotti, Gazz. chim. ital. 24, [ii.] 480), have been prepared.

Rottlerin forms the following salts :

orange-brownglistening leaflets; $C_{33}H_{29}O_9K, H_2O$ leaflets; $(C_{33}H_{29}O_9)_2Ba$, minute reddish-brown prisms; $(C_{33}H_{29}O_9)_2Sr$, $(C_{33}H_{29}O_9)_2Ca$, and $C_{33}H_{29}O_9Ag$, fine yellow needles.

Fused with alkali, *rottlerin* gives *benzoic acid*, *acetic acid*, and *phloroglucinol* (P.), and when oxidised with hydrogen peroxide in alkaline solution, *benzaldehyde* and *benzoic acid* are produced. With potassium permanganate

(Bartolotti), benzoic acid is also formed. Nitric acid (sp.gr. 1.5) gives *p-nitrocinnamic acid*, *o-nitrocinnamic acid*, *p-nitrobenzaldehyde*, and *p-nitrobenzoic acid* (P.). When heated with 2 p.c. sodium carbonate solution, a compound termed *rottlerone* separates (P.), which crystallises in garnet-red prisms, and to which the formula $C_{25}H_{26}O_6$ has been provisionally assigned.

According to Telle, if *rottlerin* is heated for 10 minutes with barium hydroxide solution, *phloroglucinolmethylether*, a resinous substance and *ψ-rottlerin*, m.p. 235° , are produced. When heated for 10 minutes with zinc powder and sodium hydroxide, *rottlerin* gives 60 p.c. of resin and about 30 p.c. of phenols, also *β-phenylpropionic acid*, *acetic acid*, and a small quantity of a crystalline acid, m.p. 185° – 185.5° . From the mixture of phenols, *phloroglucinolmonomethylether* and *phloroglucinoldimethylether*, were isolated: *Phloroglucinoldimethylether* and a camphor-like substance, m.p. 170° – 172° , were produced, when, with the zinc powder, only 2 p.c. sodium hydroxide solution was employed. The molecular weight of *rottlerin*, determined cryoscopically in naphthalene, was 486, and agrees with that assigned to this substance by Perkin (*l.c.*).

Homorottlerin $C_{33}H_{36}O_9$ (?), pale yellow needles, m.p. 192° – 193° , is present in exceedingly small amount in kamala. It differs from *rottlerin* in being much less soluble in toluene chloroform, or acetic acid, but otherwise the properties of these two compounds are similar (P.).

iso-Rottlerin $C_{12}H_{12}O_5$ (?), has been obtained in the form of plates, m.p. 198° – 199° , insoluble in hot benzene, carbon disulphide, or chloroform. Cold solutions of the alkali carbonates dissolve it readily, and these solutions when boiled do not deposit resinous matter or emit an odour of benzaldehyde, as is the case with the alkali salts of *rottlerin* itself. It is probable that this compound, very little of which has been yet obtained, may prove to consist of *hydroxyrottlerin* (P.).

The low-melting resin of Anderson, $C_{30}H_{30}O_7$ (?) $C_{12}H_{12}O_3$ (P.), consists of a brittle transparent dark red mass, melting below 100° , and is readily soluble in carbon disulphide, ether, or chloroform. With hot alkaline solutions, it behaves similarly to *rottlerin* and evolves an odour of benzaldehyde, and with nitric acid (sp.gr. 1.5) gives *p-nitrobenzoic acid*. Perkin's *high-melting resin* is a pale straw-coloured mass, m.p. about 150° , and in general properties resembles the low-melting variety.

According to Hummel and Perkin (J. Soc. Chem. Ind. 1895, 14), for silk dyeing it is best to add 1 part of kamala, and 0.5–1 part sodium carbonate to boiling water, then to enter the silk and to dye at the boiling temperature for 2–5 minutes only. Other experiments indicated that the amount of sodium carbonate to employ should be regulated by the quantity of water used rather than by that of the kamala, namely at the rate of 13–14 grams ($Na_2CO_3, 10aq$) per litre. After dyeing for a short time with the addition of alkali only, to the extent of one-fifth of the weight of the kamala used, the addition of alum of stannous chloride to the dyebath makes the colour fuller and more orange. A similar but

by no means identical effect is obtained by making a slight addition of sulphuric acid.

As pointed out by Perkin (*l.c.*), rottlerin is decomposed by boiling sodium carbonate solution, and the colour ultimately fixed on the fibre most probably consists of rottlerone. Although rottlerin itself does not dye mordanted fabrics, the potassium and sodium salts of this colouring matter give on calico mordanted with aluminium and iron, pale orange red and brownish-black shades.

Pure Java kamala contains, according to Flückiger (Arch. Pharm. 1892), 1·363 to 1·488 p.c. of ash, whereas in the kamala examined by Anderson (*l.c.*), 3·49 p.c. was present. The best commercial varieties usually contain about 5 p.c. of mineral matter (Seidler and Waage, Ber. Deut. pharm. Ges. 1891, 80); but the inferior qualities are highly adulterated (50 to 87 p.c.) with sand, earthy impurities, red brick-dust, &c. (Perkin (*l.c.*) and J. Soc. Chem. Ind. 1900). A. G. P.

KAMALA RESINS *v.* RESINS.

KAMBARA EARTH. A product of the type of fuller's earth or Florida earth, usually of a white or yellowish colour, sometimes bluish and occasionally greenish, found in the province of Echigo, and in Fukushima and Ishi Rawa, Japan. It is said to be more efficient than fuller's earth as a decolorising agent; appears to be composed chiefly of aluminium silicate and silicic acid. The decolorising power of the earth is increased by heating to 100°–150°. Its action appears to depend upon its acidity, fineness, and proportion of hydrates of silica. It decolorises crude petroleum, and is useful for the purification of animal and vegetable oils. (Kobayashi, J. Ind. Eng. Chem. 1912, 4, 891; Ueno, *ibid.* 1915, 7, 596; J. Soc. Chem. Ind. 1913, 32, 12; *ibid.* 1915, 7, 596.)

KAMPHERITRIN *v.* GLUCOSIDES.

KAOLIN *v.* KAOLINITE.

KAOLINITE. A mineral species consisting of hydrated aluminium silicate $H_4Al_2Si_2O_9$, crystallising in the monoclinic system. Analyses of the pure crystallised material agree closely with the theoretical quantities: SiO_2 , 46·5; Al_2O_3 , 39·5; H_2O , 14·0 p.c. The water is expelled only at a high temperature (above 330°). As a white, glistening, crystalline powder, the mineral is occasionally met with in small amount in cavities and fissures in sedimentary rocks and in mineral veins. The best crystals have been found near Almwch in the island of Anglesey, and in the National Bell mine near Silverton in Colorado. These crystals have the form of six-sided plates or pyramids with a perfect micaceous cleavage parallel to the base; and do not exceed 0·1 to 0·2 mm. across. Their mean index of refraction is 1·563, and their birefringence (0·004) is much lower than that of mica (with small scales of which the mineral might be confused); sp.gr. 2·62; H_2 . On the optical characters of crystals of kaolinite, see A. B. Dick, Min. Mag. 1888, 8, 15; 1908, 15, 124; A. Johnsen, Centr. Min. 1911, 33. The 'nacreite' of the Einigkeit mine, Freiberg, Saxony, and 'pholerite,' also from Saxony, form fan-shaped aggregates of rather large pearly scales of kaolinite.

The mineralogical name *kaolinite* was proposed by S. W. Johnson and J. M. Blake in 1867

for this crystallised mineral, which is usually assumed to form a large part of kaolin or china-clay. The name *kaolin* is a French corruption of the Chinese name *kau-ling* for the white, earthy material long used in the manufacture of porcelain at King-te-chin (prov. Kiangsi), and first brought to Europe in the year 1712. This material is obtained in the neighbouring Kau-ling Hills (= 'high ridge') from a compact green stone occurring in clay-slates, and somewhat resembling jade in appearance, from which when crushed the finer particles are separated by washing (F. von Richthofen, Amer. J. Sci. 1871, 1, 180). This material, although a hydrated aluminium silicate, differs essentially from our kaolin, containing as much as 73 p.c. of silica and only a few p.c. of water. It is perhaps the same as the Japanese 'rōseki,' which has been referred to the agalmatolite (*q.v.*) variety of pyrophyllite.

It is thus seen that the name kaolin has been loosely applied to any white clays suitable for the manufacture of porcelain (*v.* CLAY), such as those found near Limoges in France, St. Austell in Cornwall, &c. These white clays have been formed by the decomposition of granite under somewhat special conditions; and when separated from grains of quartz, scales of mica, &c., by a process of washing, they yield the china-clay of commerce. In composition this varies between wide limits; but in many instances it approximates to the kaolinite formula given above. Microscopical examination very rarely reveals the presence of any six-sided scales that can be definitely referred to the species kaolinite.

KAPOK, strictly speaking, is the seed hair of *Eriodendron anfractuosum*, but the term is also applied to other vegetable downs. It is used as a stuffing for life-saving appliances at sea, due to its power of resisting the penetration of water owing to the peculiar structure of the fibre. In these appliances the kapok stuffing occupies about 15 c.c. per gram of fibre: a jacket containing 700 grams of stuffing represents a floating power of 10·5 kilos. After 72 hours in water with a weight of 9 kilos attached, this jacket still required 1·3 kilos more to submerge it; after 192 hours the weight required was 0·9 kilo. For the characteristics of the true kapok and of other substances classed under that name, see Cross & Bevan, J. Soc. Dyers and Col. 1916, 32, 274; J. Soc. Chem. Ind. 1917, 36, 79.

KAPOK OIL. Kapok oil is mainly derived from the seed kernels of *Eriodendron anfractuosum* (Malvaceæ), a tree which is common in the West Indies, Malay Archipelago, and various parts of Africa, but the commercial product is also obtained from the seeds of different species of bombax (*B. malabaricum*, *B. mexicanum*).

Kapok seeds are exported in large quantities, especially to Holland, where the oil is expressed and used for soap making, and, after refining, as an edible oil. The expressed oil, the yield of which is about 25 p.c. of the weight of the seeds, is of a greenish-yellow colour, and, like cotton seed oil, gives a deposit of 'stearine' when allowed to stand. From the analytical point of view the oil is of interest from the fact that it

contains a constituent which gives the same coloration as cotton seed oil in Halphen's test. It may be distinguished from cotton seed oil, however, by its lower iodine value, and by its different behaviour in Milliau's modification of Bechi's test. The fatty acids are washed with cold water, rapidly dried at 105°, and shaken with an equal volume of a 1 p.c. solution of silver nitrate in absolute alcohol. Under these conditions the fatty acids from kapok oil give a deep brown coloration, whilst cotton seed oil fatty acids show only a slight brown tint.

The following values of genuine specimens of kapok and bombax oils are given by Sprinkmeyer and Diedrichs (Z. Nahr. Genussm. 1913, 26, 86, 450):—

Oil	Sp.gr. at 15°/15°	Ref. Index (40°), Zeiss	Iodine value	Acid value	Saponif. value
Kapok oil (Java, Ceylon, E. Africa, &c.)	0.9235-0.9236	51.7-59.7	85.2-95.3	18.5-21.0	189.2-194.5
<i>Bombax malabaricum</i>	0.9600	57.0	73.6	3.0	194.3
<i>B. mexicanum</i>	—	57.4	95.7	12.6	192.8

The fruit hairs both of kapok and bombax trees are used as upholstery material and especially as a filling material for lifebelts, but owing to their structure, are unsuitable for textile purposes (cf. Bull. Imperial Inst. 1920, 18, 335). C. A. M.

KATAMEN. Pyrazalone-phenyl-dimethyl sulphamino-benzoate.

KAURI-COPAL (-Bush Copal, -Gum or -Resin) is the solidified turpentine of the Kauri tree (*Dammara australis* [Steud.]) and occurs in great abundance in a fossil condition in various parts of New Zealand. It is dug up on the driest fern-hills as well as in the deepest swamps, but that from the latter is of inferior quality, as is also the gum obtained from the forks of living trees (J. Soc. Chem. Ind. 1893, 71; *ibid.* 1895, 528; *ibid.* 1898, 621; Bull. Imp. Inst. 1904, 2, 91). To obtain kauri-copal, it is first searched out a little below the surface by feeling for it with a steel-pointed piece of iron, after which it is dug out with an ordinary spade. It is then prepared for the market by scraping off the outer crust by hand, or better, by machinery (Eng. Pat. 17009, 1890).

Four types of kauri-copal are known in commerce: (1) Pale kauri or fossil copal found in large masses varying from yellowish-white to clear yellow in colour, has an aromatic smell, brilliant fracture and can be pulverised to a white powder. It has sp.gr. 1.036, m.p. 165°, acid value 70.9, saponification value 73. (2) Brown kauri fossil copal is of a yellow-brown or deep yellow colour. It is difficult to powder, has a conchoidal fracture and an aromatic camphor-like odour. It has sp.gr. 1.053; m.p. 185°, acid value 78.8, saponification value 89.7. (3) Bush kauri is obtained at the foot of trees in irregular amber-like masses. It can readily be reduced to a yellow powder with an aromatic odour, and has sp.gr. 1.03, m.p. 150°, acid value 83.1, saponification value 78.5. (4) Bush kauri gathered from the tree itself has a vitreous fracture; sp.gr. 1.038, m.p. 125°, acid value 81.8, saponification value 87 (Coffignier, Bull.

Soc. chim. 1909, 5, 289; see also Tschirsch and Niederstadt, Arch. Pharm. 1901, 239, 145; Worstall, J. Amer. Chem. Soc. 1903, 25, 860). The various kinds of kauri differ in their solubilities in organic solvents, but all of them are only very slightly soluble in turpentine and more readily so in alcohol (Coffignier, *l.c.*). They are all almost completely soluble in amyl-alcohol, amyl acetate, benzaldehyde, or aniline.

Kauri-copal is readily attacked by chlorine, bromine, or concentrated nitric acid (Muir, J. 1874, 923). On dry distillation it yields pinene and dipentene (Wallach, Annalen, 271, 309; Rennie, Chem. Soc. Trans. 1881, 240).

A recent fossil specimen of kauri-copal was found by Tschirsch and Niederstadt (*l.c.*) to consist of the following substances: 50 p.c. α and β -kaurolic acids $C_{12}H_{20}O_2$, m.p. 81°-83° and 85°-87° respectively (the α -acid yields a lead salt insoluble in alcohol, whereas the β -acid gives a soluble lead salt); 20 p.c. kaurinolic $C_{11}H_{18}O_2$, m.p. 128°-130°, and kauronolic acids $C_{12}H_{24}O_2$, m.p. 86°-89° (all these acids are monobasic and give a moniodide); 12.0 p.c. kauroresene a light yellow indifferent substance, m.p. 63°-65° and not volatile in steam; 12.5 p.c. of an ethereal essential oil, b.p. 150°-160°, sp.gr. 0.835 at 15°; 1.5 p.c. kauric acid $C_{10}H_{16}O_2$, m.p. 192°, forming microscopic crystals [α_D +51.66°. It is a monobasic acid, yielding an iodine number corresponding to a moniodide and a potassium and lead salt. Only about 2 p.c. of carbon was left on distillation of the kauri-copal (see also Thomson, Annalen, 1843, 47, 351). Kaurigum is used in the manufacture of oil varnishes, as an ingredient of the cement for linoleum manufacture, and also for dressing glazed calico. The transparent and semitransparent varieties are employed as substitutes for amber in the manufacture of mouthpieces for cigar-holders, pipes, &c.

The commercial product often contains as an admixture dammar resin, which is a much cheaper substance. Whether the kauri contains

the latter can be determined rapidly in the following way: 0.5 gram of the finely ground sample is stirred up with chloroform in a porcelain crucible. It is then filtered through a small filter into a test tube, washed once and absolute alcohol added to the filtrate, when if the sample is pure kauri, the solution will remain clear, whereas if dammar is present a cloudiness or a precipitate will appear, according to the amount (Stewart, J. Soc. Chem. Ind. 1909, 349).

KAWA. The peeled dried rhizome of *Piper methysticum* (Forst., fl). Contains a resin which by treatment with caustic soda solution gives, on cooling, sodium kawaate. The corresponding acid, $C_{13}H_{15}O_3$, yellow needles, m.p. 164° – 165° , appears to be either α or γ -cinnamyliden-acetoacetic acid, probably the latter (Borsche and Roth, Ber. 1921, 54, 2229).

KAYA OIL. Kaya oil is obtained from the kernels of the nuts of a Japanese tree, *Torreya nucifera* (Tazaceæ), and when separated by cold expression is used as an edible oil. For the preparation of the commercial oil the seeds are crushed, steamed, and pressed while hot. Kaya oil has good drying properties, and is used as a lamp oil, and in the manufacture of paper. A specimen of the cold-drawn oil examined by Tsujimoto had the following characteristics: sp.gr. 0.9236; saponification value, 188.4; Gehner value, 95.7; and iodine value, 142.2. When brominated the fatty acids yield linolic tetrabromide. C. A. M.

KEENE'S CEMENT v. CALCIUM.

KELP v. IODINE.

KEPHALDOL. A pharmaceutical preparation of phenetidine, salicylic and citric acids.

KEPHIR v. MILK.

KERACYANIN v. ANTHOCYANINS.

KERAMYL. An aqueous solution of commercial hydrofluosilicic acid used as a disinfectant.

KERATIN is the principal constituent of the epidermis, hair, nails, hoofs, horns, wool, feathers, the skin of egg shells, &c. (Hedin, Zeitsch. physiol. Chem. 1894, 20, 186; Mohr, *ibid.* 1895, 20, 403; Abderhalden, *ibid.* 1905, 46, 31, 40; *ibid.* 48, 530, 535; *ibid.* 1907, 52, 348; *ibid.* 1908, 57, 339; Breinl and Baudisch, *ibid.* 1907, 52, 159; Friedmann, Chem. Zentr. 1903, i. 15).

It can be prepared from any of these substances by treating them successively with ether, alcohol, water, and dilute acids, or successively with artificial gastric juice, artificial pancreatic juice, boiling alcohol and boiling ether, keratin remaining as a residue, after removal of the fat and protein. Keratin is an albuminoid or sclero-protein, rich in sulphur (Bibra, Annalen, 96, 292; Raikow, Chem. Zeit. 1905, 29, 900; Baudisch, *ibid.* 1908, 32, 620), and like the other members of this class of substances, it is insoluble in all neutral solvents. When treated with concentrated alkalis it swells and dissolves on warming, but it is more sparingly soluble in dilute acids.

When boiled with acids and generally on hydrolysis, it yields a variety of decomposition products amongst which may be mentioned leucine, cystine, glycine, tyrosine, aspartic, and glutamic acids, alanine, arginine, &c., the relative quantities of the products as well as

their nature depending on the source of the keratin (see above references; also Bleunard, Ann. Chim. Phys. 1882, [v.] 26, 40). Keratin is not acted on by pepsin and trypsin. When treated with hydrogen peroxide it gives sulphur, ammonia, sulphuretted hydrogen, carbon dioxide, acetaldehyde, and nitric, sulphuric, acetic, oxalic, succinic, and a small quantity of aromatic amino acids (Brienl and Baudisch, *l.c.*). On oxidation by potassium permanganate, the bulk of the sulphur remains as a water-soluble organic compound: 10 p.c. is split off as H_2SO_4 (Lissizin, Biochem. Bull. 1915, 18). According to Lissizin (Zeitsch. physiol. Chem. 1909, 62, 226), azelaic acid is also an oxidation product of keratin. Keratin gives Millon's protein reaction and a yellow colour with nitric acid, this being the origin of the yellow colour when nitric acid comes in contact with the skin. Keratin has been converted into useful products which can be used instead of casein for many purposes, by treating horn scraps, hair, &c., with 15 p.c. hydrochloric acid at ordinary temperature. After 10 days the liquid is decanted, the residue washed with water, digested with 6 p.c. sodium hydroxide solution for 24 hours; potassium permanganate is then added and after standing for 12 hours the residue is washed and subjected to a pressure of 400 atmospheres (Eng. Pat. 360895; J. Soc. Chem. Ind. 1906, 548).

Keratin or keratin substances can be converted into digestible albumoses and peptones containing sulphur by treatment with dilute mineral acids at moderate temperatures. These are isolated when a diluted sample, after treatment with phosphotungstic acid or other reagent for albumoses, gives a filtrate containing but little amino acid (U.S. Pat. 926999, 1909). By digesting horn for 14 days with $\frac{N}{2}$ NaOH at $40^{\circ}C$. it is completely dissolved: on neutralising, H_2S is evolved and a precipitate formed. From the filtrate, a protalbumose is precipitated by saturation with salt. The filtrate deposits deuterio-keratose on acidifying it (Langecker, Zeitsch. physiol. Chem., 108, 230).

Atmidkeratin and *atmidkeratose* are the products obtained when keratin is acted on by superheated steam; the gaseous products of this reaction being sulphuretted hydrogen and methyl mercaptan (Bauer, Zeitsch. physiol. Chem. 1902, 35, 343; see also Krukenberg, Jahrb. Tierchem. 1886, 27). Thermoplastic keratin compounds have been obtained by mixing intimately keratin with β -naphthol and subjecting the mixture to heat and pressure (U.S. Pat. 922692; J. Soc. Chem. Ind. 1909, 721).

KERMES. Kermes is the most ancient dyestuff on record, for it was known in the time of Moses, and is mentioned in Scripture by its Hebrew name, 'tola' or 'tolaschani.' According to Tychem (Bancroft's Philosophy of Permanent Colours, 1, 394), 'the scarlet or kermes dye was known in the East in the earliest ages before Moses, and was a discovery of Phœnicians in Palestine, but certainly not of the small wandering Hebrew tribes.' Under the name 'coccus' it is frequently referred to by the Greek and Latin writers.

Kermes is an insect found on the oak kermes (*Quercus coccifera*, Linn.), and when living the female insects, which are fixed to the twigs of the tree, resemble bluish berries, and are covered with a whitish powder. As soon as their eggs are on the point of hatching these insects should be collected, killed by exposure to the steam of vinegar, and dried, and the product has then the appearance of pale reddish-brown grains. According to Bancroft, it would require 10 or 12 lbs. of kermes to produce the effect of a single lb. of cochineal.

Kermesic acid $C_{18}H_{12}O_8$, the colouring matter of kermes, was first isolated, in the crystalline condition, by Heisse (Arbeit. a. d. K. Gesundheitsamte, 1895, 513), and has since been examined by Dimroth (Ber. 1910, 43, 1387; and Annalen, 1913, 399, 43). To isolate the kermesic acid, the kermes is first extracted with ether to remove wax, and this has been examined by Dimroth and Sherndal (Annalen, 1913, 399, 43), and identified as ceryl cerotate $C_{52}H_{104}O_2$. The residue is then allowed to stand overnight with an ethereal solution of hydrochloric acid, by which means the kermesic acid, which exists in kermes in the form of a salt, is liberated and made capable of removal by repeated extraction with ether. For the purification of the substance, it is converted into its sparingly soluble sodium salt, which allows of its separation from *flavo-kermesic acid*,—a substance stated by Dimroth to be present in kermes dye to the extent of about 0.06 p.c.—the sodium salt of this being soluble in hot 2N sodium acetate solution, whereas the disodium salt of kermesic acid is almost insoluble. The sodium salt when dissolved in boiling sodium hydroxide solution and treated, whilst boiling, with excess of hydrochloric acid, yields a crystalline precipitate of kermesic acid.

Thus obtained, the acid consists of brick-red needles which decompose, without melting, at about 250°. It is distinguished from carminic acid by the fact that it is soluble in ether, and is much more sparingly soluble in cold water. On the other hand, the colour of the alkaline solutions of both colouring matters is practically identical. Kermesic acid is soluble, without decomposition, in concentrated sulphuric acid giving a violet-red solution, which, on addition of boric acid, becomes clear blue—if *flavo-kermesic acid* is present as impurity only a dull bluish-violet results.

Disodium kermesate $C_{18}H_{10}O_8Na_2$, prepared by means of sodium acetate, consists of a red-brown crystalline powder, sparingly soluble in water with a violet-red colour.

Barium kermesate $(C_{18}H_{11}O_8)_2Ba$ is brown and contains water of crystallisation.

Tetra-acetyl kermesic acid $C_{18}H_8O_8(C_2H_3O)_4$, yellow needles, melts at 245°. *Kermesic acid trimethyl ether* $C_{21}H_{16}O_8$, orange-red needles, m.p. 310°, dissolves in sulphuric acid with a violet colour, and is prepared from the potassium salt by means of methyl sulphate in the presence of boiling toluene.

Flavo-kermesic acid $C_{13}H_8O_6$ crystallises in needles, or prisms, and differs considerably from kermesic acid in its dyeing properties and in the colour of its solutions.

Kermesic acid is decomposed by warm concentrated nitric acid yielding *nitro-coccic acid*

(trinitro-cresotinic acid), identical with the acid

obtained in a similar way from carminic acid.

Kermesic acid contains no methoxy groups, and treatment with hydriodic acid gives the reduction product $C_{18}H_{12}O_8$, which decomposes at 275°.

When oxidised with hot potassium permanganate, kermesic acid trimethyl ether produces two products, the one being *methylcochenillate monomethyl ether*

which melts at 178°–180°, with formation of the anhydride, m.p. 149°. Digestion with boiling potassium hydroxide (25 p.c.) solution converts this ester into *cochenillic acid methyl ether* $C_{11}H_{10}O_7$, m.p. 200° (decomposition), whilst complete demethylation of ester, or acid, by means of hydriodic acid, yields *hydroxyuvitic acid*.

The second product of the oxidation is the *dimethyl ether of cresotinyloxyl-dicarboxylic acid*

m.p. 108°–110° if anhydrous. The hydrated acid has m.p. 86°, and this, by oxidation with alkaline permanganate, is converted into the above-described *methyl cochenillate methyl ether*.

When kermesic acid is heated with water at 150°, carbon dioxide is evolved, and *dicarboxykermesic acid* $C_{17}H_{12}O_7$ is produced. This forms red needles (no melting-point), almost insoluble in sodium bicarbonate, soluble in caustic soda, and in concentrated sulphuric acid containing boric acid, yielding solutions which resemble, in colour, similar solutions of kermesic acid.

Bromination of kermesic acid yields (i) in boiling 50 p.c. acetic acid, *α-bromocarmin*; (ii) in boiling glacial acetic acid, *bromococcin* $C_{16}H_9O_8Br$; (iii) in methyl alcohol, followed by treatment with concentrated hydrobromic acid, *tribromococcin* $C_{16}H_7O_8Br_3$. (This product is also obtained when bromococcin is treated in the same way.)

Bromococcin $C_{16}H_9O_8Br$ crystallises in red needles, m.p. 259°–260° (decomposition); it yields an acid potassium salt

and a tetra-acetyl derivative

which forms yellow crystals. When oxidised by means of warm alkaline hydrogen peroxide, in the presence of a catalyst, bromococcin yields cochenillic acid

and from these facts Dimroth and Scheurer conclude that bromococcin has the structure

or

either of which is in agreement with the fact that, in respect of its dyeing properties, it resembles purpurin, not anthragallol.

Tribromococcin is formulated as either

or

It crystallises from acetic acid in long red needles, m.p. 245°-248°, is soluble in concentrated sulphuric acid giving a red-violet solution, the colour of which changes to deep blue when boric acid is added.

Tetra-acetyl-tribromococcin

crystallises in green-yellow needles, m.p. 223°; it yields nitro-coccus acid when treated with fuming nitric acid.

Dimroth and Scheurer point out the close relationship that exists between bromococcin

and kermesic acid, and assign to the latter the structure

or

They support this by the results of the distillation of kermesic acid with zinc-dust, whereby they obtained α -methyl-anthracene (and from it prepared α -methyl-anthraquinone). They also consider it probable that anthracene is simultaneously produced.

Dimroth and Fick (A. 1916, 411, 315) have shown that the latter of these two formulae represents the correct constitution of kermesic acid.

They arrive at this from a comparison of hydroxyanthrapurpurine (1) and hydroxyflavopurpurine (2), obtained respectively from anthrapurpurine and flavopurpurine by means of sodium nitrite, boric acid and sulphuric acid.

Thus as regards dyeing properties and absorption spectra hydroxyflavopurpurine and hydroxyanthrapurpurine differ sharply, and the latter only agrees with decarboxykermesic acid in these respects.

Also hydroxyanthrapurpurine when brominated under the conditions by which kermesic acid yields tribromococcin forms a tribromo-hydroxyanthrapurpurine. This shows a complete analogy to tribromococcin which must therefore be 2:4:7 tribromo-3:5:6:8 tetrahydroxy-1-methylantraquinone.

Kermesic acid is thus closely related to carminic acid, which has been shown by Dimroth and Kämmerer (Ber. 1920, 53, 471) to

differ from it only by possessing a side chain $C_6H_{11}O_5$ in place of the acetyl group.

Dyeing properties.—According to Hellot (Bancroft, *Philosophy of Permanent Colours*, 1, 404), 'the red draperies of the figures exhibited in the ancient Brussels and other Flemish tapestries were all dyed with kermes.' 'The fine red or crimson colour of these tapestries, which was originally called simply scarlet, took the name of *Venetian scarlet*, after the cochineal scarlet upon a tin base was discovered. . . .'

For the production of this scarlet, the wool, previous to dyeing, was mordanted with alum and tartar; and, according to Bancroft, there is no evidence even in more recent years of the employment of a tin mordant in respect of this colouring matter, although the experiments he carried out indicated that by this latter method a scarlet could be produced 'in every respect as beautiful and estimable as any which can be dyed with cochineal.'

A. G. P.

KERMESITE. *Red antimony. Antimony blende, Pyrantimonite. Pyrostibite.* An oxy-sulphide of antimony formed by the oxidation of antimony sulphide, and occurring associated with grey and white antimony in Hungary, Saxony, Dauphiné, &c. Found in monoclinic crystals or in capillary tufts of six-sided prisms, of a cherry-red colour and adamantine lustre. Composition $Sb_2O_3 \cdot 2Sb_2S_3$ (v. ANTIMONY).

KEROSENE or **KEROSINE** v. PETROLEUM.

KETENES. A series of compounds containing the group $>C:CO$. They were discovered in 1905 by Staudinger, the first member to be isolated being diphenylketene $(C_6H_5)_2C:CO$. Ketenes may be prepared: (i) by the action of zinc on the chloride or bromide of an α -halogen substituted fatty acid; or (ii) by the action of heat on the anhydride of a dibasic acid. The ketenes are very reactive substances, and may be divided into two groups:—

I. *Aldo-ketenes.* These consist of ketene itself, monoalkyl derivatives and carbon suboxide. They are colourless and do not undergo auto-oxidation. They are polymerised by pyridine and quinoline, and do not form additive compounds with substances containing the $>C:O$ and $>C:N$ —groups.

II. *Keto-ketenes.* The dialkyl derivatives of ketene belong to this group. They are coloured substances, and readily undergo auto-oxidation. They yield ketene bases with pyridine and quinoline, and form additive compounds with substances containing the $>C:O$ and $>C:N$ —groups, such as quinone and benzylideneaniline.

Both groups combine readily with water, alcohols, and amines, and also with chlorine and bromine (Staudinger and Klever, *Ber.* 1908, 41, 906).

Ketene $H_2C:CO$. Discovered by Wilsmore and Stewart, who obtained it by the action of a heated platinum wire on the vapour of acetic anhydride. The gaseous products were liquefied, and then submitted to fractional distillation (*Nature*, 1907, 75, 510; *Chem. Soc. Trans.* 1907, 1938). Schmidlin and Bergman (*Ber.* 1910, 43, 2821) obtained a 14 p.c. yield of ketene by passing the vapour of acetone through a hard glass tube filled with porous earthenware, heated at 500° – 600° . It may also be prepared by the action of zinc on bromoacetyl bromide in

ethyl acetate. The products of the reaction are rapidly distilled, the ketene being removed from the warm solvent in a current of hydrogen, condensed in liquid air, and freed from traces of ethyl acetate by repeated fractionation at -60° (Staudinger and Klever, *Ber.* 1908, 41, 594). By the last method the yield of ketene from bromoacetyl bromide is 7–13 p.c.; from bromoacetyl chloride 3–4 p.c.; from chloroacetyl chloride or chloroacetyl bromide *nil* (Staudinger and Kubinsky, *Ber.* 1909, 42, 4213).

Ketene is a colourless liquid, b.p. -56° , and can be solidified to a mass of colourless crystals, m.p. -151° . It has a very penetrating odour, and its vapour attacks the mucous membrane. It combines with water, alcohol, aniline, &c., to form acetic acid, ethyl acetate, and acetaldehyde respectively, and with bromine in ethereal solution to form bromoacetyl bromide. Liquid hydrogen chloride and sulphuretted hydrogen at the ordinary temperature yield acetyl chloride and thioacetic anhydride. When it reacts with water no trace of glycollic aldehyde is produced, and for this and other reasons, ketene is represented as $H_2C:CO$ and not as $CH:C'OH$ (Staudinger and Klever, *l.c.*; Chick and Wilsmore, *Chem. Soc. Proc.* 1908, 77). It does not give an additive compound with quinone, nor ketene bases with pyridine and quinoline. Metallic chlorides and tertiary bases induce polymerisation to a dark-coloured liquid, this change also taking place when ketene is kept for some time. The chief constituent of this polymer is a colourless liquid of pungent odour, b.p. 126° – 127° , and when frozen, m.p. -6° to -7° . It has the formula $C_4H_4O_2$, and hence is formed by the condensation of two molecules of ketene. It combines with water and aniline to form acetoacetic acid and acetoacetaldehyde respectively, but only combines with alcohol to produce ethyl acetoacetate on addition of a trace of acid. On standing in sealed tubes, or by the addition of pyridine, dehydracetic acid is formed. Hence this substance may be acetylketene $CH_3COCH:CO$ or Δ' -cyclobutene-1-ol-3-one $CO<\begin{smallmatrix} CH_2 \\ CH \end{smallmatrix}>C'OH$, the semi-enol of cyclobutane-1:3-dione. The action of bromine was found to result in the formation of a γ -derivative $CH_2<\begin{smallmatrix} COBr \\ COCH_2Br \end{smallmatrix}>$ and not an α -derivative, $CH_3CO<CHBrCOBr$, thus proving it to have the latter configuration (Chick and Wilsmore, *Chem. Soc. Trans.* 1908, 946; 1909, 1978; cf. Staudinger and Bereza, *Ber.* 1909, 42, 4908).

Methyl ketene $CH_3CH:CO$. Obtained in dilute ethereal solution by the action of zinc on an ethereal solution of α -bromopropionyl bromide.

Ethyl ketene $C_2H_5CH:CO$. Similarly from α -bromobutyl bromide.

Carbon suboxide $O:C:C:C:O$. Obtained by action of zinc on dibromomalonyl bromide v. CARBON SUBOXIDE.

Dimethyl ketene $(CH_3)_2C:CO$. Prepared by the action of zinc on a solution of α -bromo- β -butylbromide in ethyl acetate, and distilling the resulting product under 15–16 mm. at -20° (Staudinger and Klever, *Ber.* 1906, 39, 968). Also by heating dimethylmalonic anhydride under 12 mm. pressure at 160° – 180° (Staudinger and Ott, *Ber.* 1908, 41, 2208). It is a mobile

yellow liquid, b.p. 48.5° (12 mm.); m.p. -97.5°; stable at -20° under atmospheric pressure, but at ordinary temperature polymerises to a colourless substance, m.p. 112°, apparently the diketone $(C(CH_3)_2CO)_2$. Water converts dimethylketene into isobutyric acid, and it undergoes the other reactions common to the keto-ketenes. Dimethylketene bases *v.* Staudinger, Klever, and Kober, *Annalen*, 1910, 374, 1. In the preparation of this ketene a liquid polymeric $(C_4H_8O)_2$, b.p. 170°-171°, having an odour of peppermint, is also formed (Staudinger and Klever, *Ber.* 1907, 40, 1149).

Diethylketene $(C_2H_5)_2C:CO$. Prepared by heating diethylmalonic anhydride under 12 mm. pressure at 160°-180°. It forms a yellow liquid, b.p. 91°-92° (749 mm.), solidifying to a mass of yellow crystals in liquid air (Staudinger and Ott, *l.c.*).

Diphenylketene $(C_6H_5)_2C:CO$. Prepared by the action of zinc on diphenylchloroacetyl chloride in ethereal solution (Staudinger, *Ber.* 1905, 38, 1735); by the action of tertiary bases on diphenylacetyl chloride (*Ber.* 1907, 40, 1145); or by the interaction of benzil and hydrazine, oxidation of the hydrazibenzil, and warming the azibenzil to 60° (Curtius, *Ber.* 1889, 2161; *J. pr. Chem.* [ii.] 4, 182; Schroeter, *Ber.* 1909, 2346). It is a liquid having the colour of a concentrated solution of potassium dichromate, and solidifies in a freezing mixture to a mass of yellow crystals; b.p. 146° (12 mm.). Water converts it into diphenylacetic acid, and it undergoes similar reactions to the other keto-ketenes. On exposure to air it becomes viscid, addition of light petroleum throwing out a white oxidation product. Dry hydrogen chloride passed into a benzene solution of the ketene yields diphenylacetylchloride, whilst a dilute solution of hydrochloric acid yields diphenyl acetic anhydride. It shows no tendency to polymerise, and treated with magnesium phenylbromide, yields triphenylvinyl alcohol. With quinone the β -lactone $O:C_6H_4\langle\begin{smallmatrix} C(C_6H_5)_2 \\ O \end{smallmatrix}\rangle CO$ is formed, and with benzylidene aniline the β -lactam $C(C_6H_5)_2\langle\begin{smallmatrix} CO \\ CH(C_6H_5) \end{smallmatrix}\rangle N\cdot C_6H_5$. The former, on heating, yields compounds of the type of diphenylquinomethane and tetraphenylquinodimethane, and the latter acyclic fulvenes (Staudinger, *Ber.* 1908, 41, 1355, 1493).

Diphenylene ketene $\begin{smallmatrix} C_6H_5 \\ C_6H_5 \end{smallmatrix} \rangle C:CO$. Prepared by the action of zinc on chlorodiphenylene acetyl chloride (from phosphorus pentachloride and diphenyleneglycollic acid) in ether in absence of air and moisture. It forms red crystals, m.p. 90° to a red liquid, decomposing at 150°; gives an indigo-blue colour with sulphuric acid. With excess of water diphenylene acetic acid is formed, and with the requisite quantity diphenylene acetic anhydride. It undergoes the usual reactions (Staudinger, *Ber.* 1906, 39, 3062).

Ethylketene carboxylate

An ethereal solution of ethylbromomethylmalonate chloride $C_2H_5\cdot CBr\langle\begin{smallmatrix} CO_2C_2H_5 \\ COCl \end{smallmatrix}\rangle$ reacts with zinc, producing ethylketenecarboxylate, which

rapidly polymerises into 1:3-diethyl-cyclobutane-2:4-dione-1:3-dicarboxylate

This, on heating at 180°-200°, yields the ketene as a colourless liquid, b.p. 48° (15 mm.), m.p. 57.8° (Staudinger and Bereza, *Ber.* 1909, 42, 4908).

KETOHYDRINDENE *v.* INDENE.

KETONES. The ketones are a class of organic compounds characterised by the presence of the carbonyl group $>C:O$, united by each of its valencies to carbon. They are differentiated in this way from the aldehydes which contain the carbonyl group united on the one hand to hydrogen, and on the other to hydrogen or carbon. The characteristic groupings of aldehydes and ketones are shown as follows:—

Ketones proper have hydrocarbon radicles or simple derivatives thereof (substituted by halogens, &c.) united with the carbonyl group, but a large number of other compounds of ketonic character are known, such as the keto-alcohols (*e.g.* $CH_3\cdot CO\cdot CH_2OH$), and the ketonic acids (*e.g.* $CH_3\cdot CO\cdot CO_2H$). Such compounds, besides showing specific properties due to the presence of the carbinol or carboxyl groups, also exhibit ketonic reactions due to the presence of the carbonyl group.

Ketones may be classified according to the number of carbonyl groups into *simple ketones*, *diketones*, &c., whilst, according to the radicles united with the carbonyl, they may be separated into *aliphatic*, *aromatic*, and *mixed ketones*.

Another type of ketone is furnished by those compounds in which the carbon atom of the carbonyl group is a member of a closed ring; such *cyclic ketones*, in which the carbon chain is saturated, closely resemble the aliphatic ketones in their properties. Unsaturated cyclic ketones also exist; one class, the quinones, will be treated separately, as they possess many distinctive properties not shared by the other ketones.

Respecting the nomenclature of the ketones, a few are known by trivial names, *e.g.* acetone, benzophenone, acetophenone, &c., but usually a more systematic nomenclature is adopted. This may refer either to the radicles attached to the carbonyl group, or to the position of the carbonyl groups in the chain. Acetone $CH_3\cdot CO\cdot CH_3$ may be more systematically termed dimethylketone or propanone; benzophenone $C_6H_5\cdot CO\cdot C_6H_5$ diphenylketone or diphenylmethanone; and acetophenone $C_6H_5\cdot CO\cdot CH_3$ phenyl methyl ketone or ethylphenone.

Whilst for simple ketones the second systematic nomenclature, that recommended by the Geneva Congress, has no striking advantages; in the case of polyketones it is very useful, as it enables the trivial names given to various substances to be replaced and rational names to be given to new compounds as they are discovered. Thus diacetyl becomes butane-dione, acetylacetone is pentane-2:4-dione, and is thus completely differentiated from acetylpropional which is pentane-2:3-dione.

OPEN CHAIN MONOKETONES.

Preparation.—(1) By addition of water to hydrocarbons of the type $R:C:C:H$; thus allylene, if led into an aqueous solution of mercuric chloride at 90° – 95° , yields acetone (Kutscherow, Ber. 1884, 17, 15)

Béhal and Desgrez find that hydrocarbons of the formula C_nH_{2n-2} add the elements of acetic acid at 280° , the addition products being decomposed by water with formation of ketones.

(2) Secondary alcohols are directly oxidised to ketones. The use of manganic salts for this purpose has been patented by W. Lang (D. R. P. 166357). Ketones may also be obtained from secondary alcohols by passing their vapours over heated, finely divided copper (P. Sabatier and J. B. Senderens, Ann. Chim. 1905 [viii.] 4, 433).

(3) Primary alcohols of the type

give formic acid and a ketone on oxidation (Kannonikow and Saytzev, Annalen, 1875, 175, 377):

(4) Hydrolysis of some halogen compounds which might be expected to yield unsaturated tertiary alcohols furnishes ketones in their place:

(Oppenheim, Annalen, 1868, Spl. 6, 365).

It has also been found that certain chlorhydrins when heated with water under pressure, yield ketones instead of glycols:

(K. Krassusky, J. Russ. Phys. Chem. Soc. 1901, 33, 791; 1902, 34, 287).

(5) On warming pinacones (ditertiary glycols) with dilute acids pinacones (ketones containing a tertiary alkyl radicle) are produced:

The mechanism of the reaction discovered by G. Darzens is probably similar. Ethyl α -chloropropionate condenses with ketones $R \cdot CO \cdot R'$ to form $\alpha\beta$ -trisubstituted glycidic esters

of the general type $CRR' \overset{\Delta}{C} (CH_3)CO_2C_2H_5$. When these are hydrolysed the unstable acid loses carbon dioxide, and the oxide isomerises to a ketone

(Compt. rend. 1905, 139, 1214; 141, 766; also R. Stoermer, Ber. 1906, 39, 2288; 1907, 40, 488; M. Tiffeneau and Dorlenourt, Compt. rend. 1906, 143, 126; Ann. Chim. 1907, viii.] 10, 322; Delacre, Bull. Soc. chim. 1911,

[iv.] 9, 1024; Parry, Chem. Soc. Trans. 1915, 107, 108).

Changes of the types

have attracted much attention (A. Orékhoff, Bull. Soc. chim. 1919, [iv.] 25, 9, 108, 111, 115, 174, 179, 182, 186; Tiffeneau and Orékhoff, Compt. rend. 1920, 171, 400, 473; 1921, 172, 387; Bull. Soc. chim. 1921, [iv.] 29, 422, 445, 809; Billard, Bull. Soc. chim. 1921, [iv.] 29, 429; Lévy, *ibid.*, 820]. Pinacones of the type $CR_3 \cdot CO \cdot R$ cannot exhibit tautomerism, but when one of the groups R is replaced by H , tautomeric change is possible so that the compound produced by the action of aluminium chloride on trichloroacetyl chloride and benzene (Delane, Bull. Soc. chim. 1895, [iii.] 13, 857; Gardeur, Bull. Acad. roy. Belg. 1897, [iii.] 34, 67) may be triphenylethanone as originally formulated or possibly triphenylvinyl alcohol (Biltz, Ber. 1899, 32, 650; Anna'en, 1897, 296, 242). The latter structure was accepted on many sides but Kohler (Amer. Chem. J. 1906, 36, 177), Orékhoff (Bull. Soc. chim. 1919, [iv.] 25, 9, 186) and Meyer and Gottlieb-Billroth (Ber. 1921, 54, 575) reverted to the ketonic formula. McKenzie and Boyle (Trans. Chem. Soc. 1921, 119, 1131) also think the substance is probably triphenylethanone having studied its reaction with phenyl magnesium bromide.

(6) By the dry distillation of the calcium or barium salts of acids

The products obtained in this way are never pure; calcium acetate, for example, yields not only acetone, but also homologous ketones (R. Fittig, Annalen, 1859, 110, 17). When a mixture of the calcium salts of two acids is distilled together the separate ketones corresponding to each salt and their usual impurities are obtained, together with a greater or less yield of the mixed ketone.

The aliphatic acids are directly converted into ketones by heating with iron-filings or passing their vapours over heated aluminium, thorium, zirconium or uranium oxides

A number of other oxides can be used. Mailhe has employed zinc oxide and, more especially, cadmium oxide as a catalyst, whilst either ferrous or ferric oxide may be used at 430° – 490° (W. Ipatiew, J. Russ. Phys. Chem. Soc. 1908, 40, 514; Ber. 1910, 43, 3383; J. B. Senderens, Compt. rend. 1909, 148, 297; 149, 995; 1910, 150, 111, 1336; 1911, 152, 384; Ann. Chim. 1913, [viii.] 28, 243; Bull. Soc. chim. 1914, [iv.] 15, 84; Easterfield and Taylor, Chem. Soc. Trans. 1911, 2298; Mailhe, Compt. rend. 1913, 157, 219; Bull. Soc. chim. 1913, [iv.] 13, 666).

Small amounts of acetone have been obtained by heating acetic anhydride to 290° – 300° (Bamberger, Ber. 1910, 43, 3517).

Higher ketones, e.g. stearone, have been prepared from higher acids and catalysts (Schicht and Grün, D. R. PP. 295657, 296677).

(7) Ketones are obtained from tertiary

α -hydroxy acids either by oxidation (chromic acid) or by heating with mineral acids :

Since acids of the type $\text{CRR}'\text{H}\cdot\text{CO}_2\text{H}$ may be oxidised by alkaline permanganate to acids with the structure $\text{CRR}'(\text{OH})\text{CO}_2\text{H}$, they might serve as a source of ketones ; in fact, electrolytic oxidation of *isobutyric* acid leads directly to acetone (M. Moest, D. R. P. 138442).

An analogous reaction is that by which the amides of α -bromo acids lose hydrogen bromide and cyanide on heating with aqueous or alcoholic sodium hydroxide, an aldehyde or a ketone being produced (G. Mossler, Monatsh. 1908, 29, 69) :

Aldehydes and ketones are respectively obtained from amino acids $\text{R}\cdot\text{CH}(\text{NH}_2)\text{CO}_2\text{H}$ and $\text{RR}'\text{C}(\text{NH}_2)\text{CO}_2\text{H}$ by the action of hypochlorites :

(8) The β -ketocarboxylic acids, or their esters, undergo 'ketonic fission' on heating with dilute acids or alkalis (heating with concentrated alkaline solutions effects acid fission) :

A simple method of effecting the ketonic fission of higher members of this series of esters by heating for a few minutes with sulphuric acid, pouring into water and distilling in a current of steam has been described by L. Bouveault and R. Locquin (Bull. Soc. chim. 1904, [iii.] 31, 1153 ; *cp.* Michael and Wolgast, Ber. 1909, 42, 3176).

(9) Ketones are produced by the interaction of acid chlorides and organo-metallic compounds (Freund, Annalen, 1861, 118, 1) :

(10) Latterly magnesium alkyl halides (Grignard's reagents) have been largely applied to the synthesis of ketones. Nitriles yield imino derivatives, which are hydrolysed by dilute acids to ammonia and ketones (E. E. Blaise, Compt. rend. 1901, 132, 38 ; 133, 1217) :

A similar reaction using the esters of α -bromo acids and zinc leads to the synthesis of β -ketonic esters

Ketones may also be obtained from cyanogen by the action of magnesium alkyl halides :

(11) Acid amides may be employed in place of nitriles (C. Béis, Compt. rend. 1903, 137, 575 ; Vol. III.—T.

Ryan and Nolan, Proc. Roy. Irish Acad. 1912, 30, B, 1) :

The yields obtained by this method vary from 20 to 50 p.c., increasing as the complexity of the radicle R increases.

Imino esters (*e.g.* $\text{C}_6\text{H}_5\cdot\text{C}(\text{N}\cdot\text{C}_6\text{H}_5)\cdot\text{OCH}_3$) and imino chlorides may also be employed (R. Marquis, Compt. rend. 1906, 142, 711), whilst H. Fournier finds ketones amongst the products of the reactions between Grignard's reagents and acid anhydrides (Bull. Soc. chim. 1910, [iv.] 7, 836).

In certain cases ketones may be obtained by the action of organo-magnesium compounds on dried sodium salts, *e.g.* methyl *isobutyl* ketone from magnesium *isobutyl* bromide and sodium acetate (Salkind and Beburischwili, Ber. 1909, 42, 4500). For other syntheses involving organo-metallic compounds *v.* Blaise and Maire (Ann. Chim. 1908, [viii.] 15, 556 ; Barbier and Locquin, Bull. Soc. Chim. 1911, 9, 717, 722 ; Reynolds, Amer. Chem. J. 1911, 46, 198 ; Darzens a. Rost, Compt. rend. 1911, 153, 772).

(12) The nitrile oxides yield ketones on reaction with magnesium alkyl halides. Thus benzonitrile-oxide and magnesium methyl iodide yield benzonitrile (by reduction), acetophenone, and its oxime :

(H. Wieland, Ber. 1907, 40, 1667).

(13) Ketones containing one methyl group can be obtained by the reaction of diazomethane with aldehydes. In this case it is probable that an unstable furodiazole is first produced, which breaks down into nitrogen and a ketone :

The method is of general applicability ; ketones may be obtained from *isovaleraldehyde*, benzaldehyde, &c., whilst trichloroacetone has been obtained in a pure condition by using chloral (Schlotterbeck, Ber. 1907, 40, 479, 1826, 3000 ; 1909, 42, 2559, 2565).

(14) In certain cases ketones may be converted into higher homologues by the action of sodamide and an alkyl halide. In this way diethyl ketone yields ethyl *isopropyl* ketone, *diisopropyl* ketone, and a compound $\text{C}_{15}\text{H}_{26}\text{O}$:

(A. Haller and Bauer, Compt. rend. 1910, 150, 661 ; 1911, 153, 21, 1415 ; 1912, 154, 555 ; 1913, 156, 1199, 1295 ; Ann. Chim. 1913, [viii.] 29, 313 ; Zerner, Monatsh. 1911, 32, 677 ; Dumesnil, Ann. Chim. 1917, [ix.] 8, 70).

(15) Formaldehyde acts on ketones in presence of alkaline condensing agents, giving

keto alcohols, which may be dehydrated to unsaturated ketones (Farbenfab. vorm. Fr. Bayer & Co. D. R. PP. 222551 and 223207):

Hydroxy ketones have also been obtained by the action of carbon monoxide on the Grignard reagents

(Egorova, J. Russ. Phys. Chem. Soc. 1914, 46, 1319).

Saturated ketones can be prepared from ketones possessing ethylene linkages by reduction with hydrogen in presence of palladium or platinum (Skita and Meyer, Ber. 1912, 45, 3579, 3589; Vavon and Faillebin, Compt. rend. 1919, 169, 66).

The hydroxymethylene compounds obtained from ketones and formaldehyde can be reduced to saturated compounds by hydrogen in presence of a colloidal palladium catalyst. This is virtually a method of methylating a saturated ketone (J. D. Riedel, A. G., D. R. P. 266405; Kötzt and Schaeffer, J. pr. Chem. 1913, [ii.] 88, 604).

(16) Aromatic ketones (also mixed ketones) can be obtained by the action of acid chlorides on aromatic hydrocarbons in presence of aluminium chloride, &c. (Friedel and Crafts, Ann. Chim. 1884, [vi.] 1, 507):

This reaction may sometimes extend to the aliphatic series: thus benzoyl chloride and ethylene react in presence of aluminium chloride to give phenyl irayl ketone (Norris and Couch, J. Amer. Chem. Soc. 1920, 42, 2329).

Ketones in which both radicles attached to the carbonyl group are the same may be obtained by the action of carbonyl chloride on aromatic hydrocarbons in presence of aluminium chloride:

When acetyl chloride acts on a solution of cyclohexene in carbon disulphide solution under the influence of aluminium chloride, an addition

which tertiary bases remove the elements of hydrogen chloride with production of tetrahydroacetophenone (Darzens, Compt. rend. 1910, 150, 707).

(17) The introduction of amino or hydroxyl groups renders aromatic nuclei still more liable to attack. Dimethylaminobenzoyl chloride and tetramethyldiaminobenzophenone (Michler's ketone) are successively produced by the reaction of phosgene with dimethylaniline, no condensing agent being necessary (Ber. 1876, 9, 715, 1900). *p*-Aminoacetophenone is formed by boiling 2 parts of aniline with 5 parts of acetic anhydride and 3 parts of zinc chloride for 4–5 hours (Klingel, Ber. 1885, 18, 2688); whilst 2:4-dihydroxyacetophenone (resacetophenone) is obtained when 2 parts of resorcinol and 3 parts each of acetic acid and zinc chloride are heated to 150° (Nencki and Sieber, J. pr. Chem. 1881, [ii.] 23,

147). Probably acyl derivatives are first formed which subsequently undergo isomerisation, e.g.:

For the mechanism of isomerisation of acyl anilides, see F. D. Chattaway (Chem. Soc. Trans. 1904, 85, 340, 386, 589, 1663; Angel, *ibid.* 1912, 101, 615).

The conversion of acetanilide into aminoacetophenone is of interest in connection with the formation of flavaniline, which may be obtained by several hours' heating at 250°–270° of 2 parts of acetanilide with 1 part of zinc chloride (O. Fischer and Rudolph, Ber. 1882, 15, 1500); or a mixture of *o*- and *p*-aminoacetophenones with zinc chloride at 90° (O. Fischer, Ber. 1886, 19, 1038):

An acyl group generally enters the aromatic nucleus para to a hydroxyl group, if the position is free. α -Naphthol, however, gives α -hydroxy- β -naphthyl methyl ketone, m.p. 103° (Friedländer, Ber. 1895, 28, 1946). Another modification, m.p. 98°, has been described (Torrey, J. Amer. Chem. Soc. 1910, 32, ii. 1477; see also Witt and Braun, Ber. 1914, 47, 3216).

Hydroxyketones can also be obtained by condensing phenols with nitriles in presence of hydrogen chloride (Hoesch, Ber. 1915, 48, 1122; Stephen, Trans. Chem. Soc. 1920, 117, 1529).

(18) Aromatic ketones may be obtained by the oxidation of diaryl methanes with chromic acid (Zincke, Annalen, 1871, 159, 377):

(19) Ketones (and aldehydes) are produced by the reduction of ozonides, particularly with potassium ferrocyanide in presence or absence of acids (C. Harries, D.R.P. 321567).

General properties and reactions.—(1) The aliphatic ketones are generally liquid, the aromatic ketones solid at ordinary temperatures; usually they possess an ethereal or aromatic odour; most of them are insoluble in water, but dissolve easily in alcohol, ether, &c. They usually boil without decomposition; on passing the vapour of acetone over baked clay at 500°–600°, methane and ketene $\text{CH}_2 : \text{CO}$ are produced (J. Schmidlin and M. Bergman, Ber. 1910, 43, 2821).

Metallic derivatives of ketones are known. Below 0°, acetone yields a sodium derivative

from which an unsaturated tertiary alcohol may be obtained by reaction with acetylene (Fr. Bayer & Co., Fr. Pat. 474745).

(2) Reduction of ketones by sodium amalgam

gives secondary alcohols, ditertiary glycols (pinacones) are formed at the same time :

Pinacone may be obtained from acetone by reduction with sodium in presence of a liquid, such as ether, indifferent to sodium (B. A. S. F., D. R. P. 248252). Some ketones are reduced to pinacones when their alcoholic solutions are exposed to light (Cohen, Chem. Weekblad, 1916, 13, 590). Hydrogen in presence of platinum black gives secondary alcohols; the reaction is very general (Vavon, Compt. rend. 1912, 155, 286).

The reduction of ketones by aluminium or zinc amalgam in presence of 80 p.c. alcohol gives secondary alcohols and pinacones. With benzophenone, the formation of the pinacone is found to be favoured by a slight acid reaction; benzhydrol, on the other hand, by addition of ammonia (Böeseke and Cohen, Proc. K. Akad. Wetensch. Amsterdam, 1913, 16, 91; Cohen, Rec. trav. chim. 1919, 38, 72, 113; 1920, 39, 243; Montagne, *ibid.* 339, 350).

Fatty aromatic and aliphatic ketones are reduced to the corresponding hydrocarbons by heating with hydrochloric acid and amalgamated zinc (Clemmensen, Ber. 1913, 46, 1857; 1914, 47, 51, 681). The CO-group may be reduced to CH_2 by reducing hydrazones, &c. (Wolff, Annalen, 1912, 394, 86).

The phytochemical reduction of ketones and diketones gives somewhat poor yields of the corresponding secondary alcohols; these occur as optically active forms (Neuberg and Nord, Ber. 1919, 52, 2237, 2248).

(3) Ketones resist the action of oxidising agents to a far greater extent than aldehydes. They do not readily reduce ammoniacal silver solutions; the resistency to alkaline oxidation is instanced by the fact that substances may be dissolved in acetone for treatment with permanganate. Ketones are, however, attacked by chromic acid, the carboxyl group usually remaining attached to the smaller hydrocarbon radicle; thus methyl propyl ketone yields a mixture of acetic and propionic acids, but a good deal depends on the nature of the radicle (Popov, Annalen, 1872, 161, 285). Wagner has found that propyl isobutyl ketone gives propionic and isovaleric acids, whilst, when ethyl isopropyl ketone is oxidised, for every molecule of acetic and isobutyric acids produced, 4 molecules of acetone and propionic acid are formed (Ber. 1882, 15, 1194; 1885, 18, 2266; J. Russ. Phys. Chem. Soc. 1884, 16, 645).

Oxygen may also be added to ketones without rupturing the molecule; thus by the use of Caro's acid, acetone gives a peroxide $\text{C}_3\text{H}_6\text{O}_2$ (A. v. Baeyer and V. Villiger, Ber. 1899, 32, 3627; 1900, 33, 124, 859; see also J. Pastureau, Bull. Soc. chim. 1909, [iv.] 5, 227).

(4) Ketones react less readily than aldehydes with ammonia. Moureu and Mignonac have published a collected account of their work on ketimines (Ann. chim. 1920, [ix.] 14, 322). Keto-anils are obtained by the action of aromatic amines on aliphatic ketones in the presence of iodine (E. Knoevenagel, Ber. 1921, 54, 1722).

Ketones resemble aldehydes in giving oximes, although not always as easily as aldehydes

(V. Meyer, and Janny Ber. 1882, 15, 1324; Janny, *ibid.* 1778; cf. Lapworth and Steele, Chem. Soc. Trans. 1911, 1884; Clarke, Lapworth and Wechsler, *ibid.* 1908, 30).

When the radicles connected with the carbonyl group are different, two oximes may be produced from a monoketone. The isomerism in such cases is generally referred to different spatial arrangement (Hantzsch and Werner, Ber. 1890, 23, 11). In determining the configuration of stereoisomeric oximes considerable use has been made of the Beckmann rearrangement (Ber. 1886, 19, 992), whereby they may be converted into one of two structurally isomeric substituted acid amides :

In effecting the transformation, a very dilute and strongly cooled ethereal solution of the oxime is treated with a considerable excess of phosphorus pentachloride, which is added in small portions at a time. The ethereal solution is decanted from the excess of the pentachloride and shaken with ice-cold water, separated and dried by potassium carbonate. The substituted amide is left on evaporation.

The rearrangement may sometimes be effected by warming for 1 hour with 10 parts of sulphuric acid on the water bath, whilst benzene-sulphonyl chloride has been used by Tiemann and Pinnow (Ber. 1891, 24, 4162) and A. Werner and A. Pignet (Ber. 1904, 37, 4295). The latter chemists determined the configuration of the oximes of benzoin in the following manner: 5 grams of α -benzoin oxime were dissolved in 20 c.c. of pyridine, 4 grams of benzene-sulphonyl chloride added drop by drop, and the mixture allowed to stand 3 hours at the ordinary temperature. After adding dilute sulphuric acid, the benzaldehyde and benzoinitrile were extracted with ether :

The isomeric β -oxime treated in the same way gave phenylglycollanilide :

Doubt has been cast on the stereochemical interpretation of the isomerism of the oximes. The structural identity of *syn*- and *anti*-benzal-oximes (Goldschmidt, Ber. 1889, 22, 3113) is difficult to reconcile with the fact that both compounds give the same derivative with phenyl-carbimide (Brady and Dunn, Trans. Chem. Soc. 1916, 109, 655). Atack (Trans. Chem. Soc.

1921, 119, 1175) supposes that oximes may correspond to the three constitutions:

Substances of type (II) would be difficult to isolate, but alkyl compounds would be more stable and the N-phenyl ether of benzophenone oxime, $(\text{C}_6\text{H}_5)_2\text{C}:\text{N} \begin{array}{c} \text{C}_6\text{H}_5 \\ \diagup \\ \text{O} \end{array}$, has been described by Staudinger and Miescher (Helv. Chim. Acta, 1919, 2, 562). It is of interest that the direct methylation of benzophenone oxime gives N— and O—methyl ethers (Semper and Lichtenstadt, Ber. 1918, 51, 933; see also Alessandri, Gazzetta, 1921, 51, i, 75).

(5) Ketones containing the group $\cdot\text{CO}\cdot\text{CH}_2\cdot$ react with nitrous acid, giving the monoximes of diketones:

(L. Claissen and Manasse, Ber. 1889, 22, 526; O. Diels, Ber. 1902, 35, 3290; 1907, 40, 4336).

(6) Ketones react with hydrazine to give ketazines (Curtius and Thun, J. pr. Chem. 1891, [ii.] 44, 161):

In using phenylhydrazine, a dilute acetic acid solution is generally employed; where hydrazone formation only takes place with difficulty the ketone may be dissolved in glacial acetic acid, treated with a slight excess of phenylhydrazine and allowed to stand in the cold. In certain cases (*e.g.* carvole, v. Baeyer, Ber. 1894, 27, 813) the ketone and phenylhydrazine may be mixed in equimolecular proportions without solvent and allowed to stand.

In many cases the use of phenylhydrazine for the isolation and identification of aldehydes and ketones may be advantageously replaced by one of the following hydrazino compounds:

p-Bromophenylhydrazine (E. Fischer, Ber. 1891, 24, 4221; L. Michaelis, *ibid.* 1893, 26, 2190).

p-Nitrophenylhydrazine (A. Purgotti, Atti R. Accad. Linc. 1892, 7, ii, 266; E. Bamberger and H. Sternitzki, Ber. 1893, 26, 1306; E. Hyde, *ibid.* 1899, 32, 1810; H. D. Dakin, J. Biol. Chem. 1908, 4, 235).

as-Methylphenylhydrazine $\text{C}_6\text{H}_4(\text{CH}_3)\text{N}\cdot\text{NH}_2$ (C. Neuberg, Ber. 1902, 35, 959, 2626).

Semicarbazide $\text{NH}_2\cdot\text{CO}\cdot\text{NH}\cdot\text{NH}_2$ (Baeyer, Ber. 1894, 27, 1918). With unsaturated ketones of type $\text{C}_6\text{H}_5\cdot\text{CO}\cdot\text{CH}:\text{CH}\cdot\text{R}$, semicarbazido-semicarbazones are formed (Von Auwers, Ber. 1921, 54, 987).

Aminoguanidine $\text{NH}_2\cdot\text{C}(\text{NH})\cdot\text{NH}\cdot\text{NH}_2$. The condensation products with ketones may be isolated as well-crystallised picrates (Baeyer, Ber. 1894, 27, 1919).

Thiosemicarbazide $\text{NH}_2\cdot\text{CS}\cdot\text{NH}\cdot\text{NH}_2$. The resulting thiosemicarbazones

give insoluble or sparingly soluble salts of the heavy metals (C. Neuberg and W. Neimann, Ber. 1902, 35, 2049).

Benzhydrazone $\text{C}_6\text{H}_5\cdot\text{CO}\cdot\text{NH}\cdot\text{NH}_2$ and its *o*-, *m*-, and *p*-nitro-derivatives

With aromatic ketones it is advisable to warm in alcoholic solution; aldehydes react more readily (Curtius and co-workers, J. pr. Chem. 1894, [ii.] 50, 275, 295; 1895, 51, 165, 353).

Dichloroketones do not necessarily react with semicarbazide to give monosemicarbazones. Thus whilst dichloromethyl ethyl ketone reacts normally to give a monosemicarbazone

the isomeric methyl dichloroethyl ketone gives the disemicarbazone of diacetyl

(Blaise, Compt. rend. 1913, 156, 1549).

References to earlier work on the action of hydrazines on α -chloroketones are given by Bodforss, Ber. 1919, 52, 1762.

(7) Ketones react with phosphorus pentachloride as follows:—

Sometimes chlorination of one of the radicals R, R' occurs (Favorski, J. Russ. Phys. Chem. Soc. 1912, 44, 1339).

(8) Some ketones, usually those containing the group $\text{CH}_3\cdot\text{CO}\cdot$, unite with acid sodium sulphite; acetone, for example, gives

The ketone is regenerated by sodium carbonate solution.

(9) Hydrogen cyanide yields nitriles

which react with ammonia to give the nitriles of α -amino acids $\text{RR}'\text{C}(\text{NH}_2)\text{CN}$.

A convenient way of preparing α -amino-nitriles is to dissolve a ketone (or aldehyde) in glacial acetic acid and leave this with a concentrated aqueous solution of potassium cyanide (Von Walthier and Hübner, J. pr. Chem. 1916, [ii.] 93, 119).

Aromatic isonitriles react with ketones in presence of acetic acid yielding products of the type $\text{CH}_3\cdot\text{CO}\cdot\text{O}\cdot\text{C}(\text{R}\cdot\text{R}')\cdot\text{CONHR}$ (Passerini, Gazzetta, 1921, 51, ii, 126, 181).

Many ketones react with ethyl cyanoacetate in presence of ammonia to form piperidones, *e.g.* benzyl methyl ketone yields 3:5-dicyano-2:6-diketo-4-benzyl-4-methylpiperidone (Guareschi, Gazzetta, 1918, 43, ii, 83. Compare J. F. Thorpe, Trans. Chem. Soc. 1911, 99, 1:24, and Kon and Thorpe, Trans. Chem. Soc. 1919, 115, 636).

(10) Hydrogen sulphide converts the ketones into thioketones, *e.g.* acetone yields thioacetone (W. Spring, Bull. Acad. Roy. Belg. 1883, [iii.] 5, 236).

(11) The ketones do not so readily form addition products as the aldehydes, *e.g.* with water and alcohol, but when a mixture of a ketone and a mercaptan is treated with gaseous

hydrogen chloride a marcaptol is formed (Baumann, Ber. 1885, 18, 887):

(12) Polyhalogenated ketones and polyketones are exceptional, thus trichloroacetone gives a hydrate $\text{CCl}_3 \cdot \text{C}(\text{OH})_2 \cdot \text{CH}_3$.

(13) The acetals of the ketones (as well as of the aldehydes) may be obtained by the action of orthoformic esters (Claisen, Ber. 1907, 40, 3903):

The ketone and calculated amount of ethyl formate are dissolved in alcohol (3 or more molecular proportions) and a small amount of mineral acid, ferric chloride, &c., as catalysing agent added. The mixture is either warmed for a short time or allowed to stand for a longer period at the ordinary temperature.

Nascent ethyl orthoformate from alcohol and ethyl iminoformate hydrochloride may also be used (*cp.* E. Hess, D. R. P. 197804):

(*see* Pinner, Ber. 1883, 16, 356).

(14) Many ketones, notably cyclic ketones, behave towards acylating agents as if they possessed the tautomeric enolic structure, thus cyclohexanone gives esters of cyclohexenol (C. Mannich, Ber. 1906, 39, 1594; 1908, 41, 564; *cp.* F. W. Semmler, *ibid.* 1909, 42, 584, 1161, 2014). A striking example is the conversion of diethyl and dipropyl ketones into acetyl derivatives of their enolic forms by heating with $1\frac{1}{2}$ parts of acetic anhydride, and $\frac{1}{2}$ part of fused sodium acetate for 70 hours at 205°–215° (V. Hancu, Ber. 1909, 42, 1052). Keto-enol tautomerism is discussed more fully in connection with ethyl acetoacetate.

(15) Magnesium alkyl halides react with ketones, giving tertiary alcohols:

(V. Grignard, Compt. rend. 1900, 130, 1322; Bull. Soc. chim. 1901, [iii.], 25, 497; Ann. Univ. Lyon. 1901, No. 6, 1–116).

(16) A mixture of alkyl halide and sodium frequently behaves like the Grignard reagents. P. Schorigin has obtained diphenyl ethyl carbinol $\text{C}(\text{C}_6\text{H}_5)_2(\text{C}_2\text{H}_5)\text{OH}$ by the action of 21.5 grams of sodium wire on 30 grams each of ethyl iodide and benzophenone dissolved in 150 c.c. of dry benzene (Ber. 1908, 41, 2711).

(17) Ketones containing at least one aliphatic radicle react with esters and sodium ethoxide to give β -diketones. In this way benzoylacetone may be obtained from ethyl benzoate and acetone (Claisen, Ber. 1887, 20, 655), or from ethyl acetate and acetophenone (Beyer and Claisen, *ibid.* 2180; *see also* R. W. L. Clarke, A. Lapworth, and E. Wechsler, Chem. Soc. Trans. 1908, 93, 30).

(18) Ketones of suitable structure react with 1 or 2 molecules of an aldehyde giving unsaturated ketones. Methyl styryl ketone (monobenzalacetone) may be prepared by adding 10 parts of 10 p.c. caustic soda solution to a mixture of 10 parts of benzaldehyde, 900

parts of water, and 20 parts of acetone, allowing to stand 2 or 3 days in the cold, extracting with ether and distilling under reduced pressure:

Benzalacetone forms shining tabular crystals, m.p. 41°–42°, b.p. 260°–262°, b.p. (at 25 mm.) 151°–153° (Claisen and Ponder, Annalen, 1884, 223, 139; Langlois, Compt. rend. 1919, 168, 1052).

On reducing the ethylenic linkage by hydrogen in presence of platinum black, α -phenylbutane- γ -one, b.p. 110°–112°/12 mm., is produced. Further reduction gives α -phenylbutane- γ -ol and α -cyclohexylbutane- γ -ol (Vavon, Compt. rend. 1912, 154, 1705).

Substitution derivatives, e.g. *o*-hydroxystyryl methyl ketone, are of interest (Harries, Ber. 1891, 24, 3180; Decker and Feher, Ber. 1908, 41, 2997; Heilbron and Buck, Trans. Chem. Soc. 1921, 119, 1503).

If, however, to 20 parts of benzaldehyde, 6 parts of acetone and 40 parts of acetic acid, 30 parts of sulphuric acid are added drop by drop whilst the mixture is cooled very thoroughly, dibenzalacetone is formed. The mixture, after standing 6–8 hours at 0°, is poured into water, the precipitate washed with caustic soda and crystallised from ether. Monoclinic crystals, m.p. 112°–112.5°.

Reduction of distyryl ketone by Paal's method gives di- β -phenylethyl ketone, b.p. 224°/18 mm. (Borsche, Ber. 1912, 45, 46). Into the latter compound, four methyl groups can be introduced by means of sodamide and methyl iodide (Haller, Compt. rend. 1912, 154, 555). The reaction with phosphorus pentachloride is abnormal (Annalen, 1912, 393, 235).

pp'-Tetramethyldiaminodistyryl ketone (Sachs and Lewin, Ber. 1902, 35, 3576) lacks reactivity towards β -diketones and β -ketonic esters in presence of piperidine (Borsche, Annalen, 1910, 375, 145). On the other hand, 4'-dimethylamino-2-hydroxydistyryl ketone (m.p. 154° decomp.) is a very reactive compound which forms a number of coloured addition products (Heilbron and Buck, Trans. Chem. Soc. 1921, 119, 1500).

p-Amino and *p*-acetamino-acetophenone may be condensed with aldehydes (Giua and Bagiella, Gazzetta, 1921, 51, ii. 116).

The coloration produced by strong acids with dibenzalacetone is attributed by Baeyer and Villiger to the formation of quinonoid carbonium salts (Ber. 1902, 35, 1189, 3013), e.g.:

Confirmation is afforded by the isolation of the nitrate $\text{C}_{17}\text{H}_{14}\text{O} \cdot \text{HNO}_3$ (Reddelien, Ber. 1912, 45, 2904; *cp.* Stobbe, Annalen, 1909, 370, 90 *et seq.*).

Acetophenone can only react with one molecule of benzaldehyde giving phenyl styryl ketone (chalkone). Hydroxy-derivatives of phenyl styryl ketone occur in nature.

Numerous derivatives of chalkone have been prepared. The original method of preparing phenyl styryl ketone (Claisen, Ber. 1887, 20, 665) has been improved by Abell (Chem. Soc.

Trans. 1912, 101, 1000), who adds 12 c.c. of 20 p.c. solution of sodium methoxide in methyl alcohol to a mixture of 48 grams of benzaldehyde and 48 grams of acetophenone.

(19) Ketones react with carbon disulphide in presence of caustic alkalis, giving 4-keto-3:5-dialkylphenylthiophen-2:6-dithiols:

(H. Apitzsch, Ber. 1904, 37, 1599; 1905, 38, 2888; 1908, 41, 4028, 4039, 4047; 1909, 42, 2940; 1910, 43, 1259).

(20) At 180°-200° hydrogen (with nickelised asbestos as catalytic agent) reduces unsaturated to saturated ketones (G. Darzens, Fr. Pat. 350390).

Differentiation of Ketones from Aldehydes.

Aldehydes and ketones possess many reactions in common, but, on oxidation, the ketones do not give acids containing the same number of carbon atoms as the ketone (General Reaction 3).

A. Einhorn finds that aldehydes react with catechol monocarbazinic ester

in dilute alcoholic solution, whilst ketones do not, although condensation may be effected in a few cases when glacial acetic acid or zinc chloride is employed as condensing agent (Annalen, 1898, 300, 135; 1901, 317, 190). Resorcinol and quinol monocarbazinates behave similarly.

A. Angeli finds that nitrohydroxylamine and other 'nitroxyl' (NOH) yielding substances convert aldehydes directly into the corresponding hydroxamic acids (Gazz. chim. ital. 1904, 34, i. 50).

Hydroxyl and Amino Substituted Ketones.

The substituted ketones usually exhibit the specific ketonic characters as well as properties due to the substituent groups. Thus keto alcohols form esters, and amino ketones are basic. The different groupings may, however, affect one another, keto alcohols of the type $R \cdot CO \cdot CH_2OH$ usually give osazones, as levulose when warmed with phenylhydrazine solutions gives phenylglucosazone:

(E. Fischer, Ber. 1884, 17, 579; 1887, 20, 821).

The salts of aminoketones may be prepared from the halogenised ketones by condensation with potassium phthalimide and subsequent hydrolysis (Gabriel, Ber. 1907, 40, 2649; 1908, 41, 242, 513, 1127, 2010, 2014; 1909, 42 1238,

1249, 1259; 1910, 43, 356; 1911, 44, 57, 3090; 1914, 47, 1336).

Other recent papers on amino-ketones: Forster, Chem. Soc. Trans. 1911, 99, 239; Mannich, Ber. 1911, 44, 1542; André, Compt. rend. 1912, 155, 52; Böttcher, Ber. 1913, 46, 3158; Haller and Ramart-Lucas, Ann. Chim. 1917, [ix.] 8, 5; Hale and Britton, J. Amer. Chem. Soc. 1919, 41, 841, 1020; McKenzie and Barrow, Trans. Chem. Soc. 1921, 119, 69).

α -Aminoketones, when isolated from their salts, condense in the following manner:

β -Aminoketones are capable of existence as free bases, e.g. diacetoneamine

γ - and δ -aminoketones condense internally, giving substituted pyrrolines and tetrahydropyridines respectively, e.g.:

ϵ -Aminoketones are stable.

INDIVIDUAL OPEN-CHAIN MONOKETONES.

I. Aliphatic Ketones.

Acetone is treated in a separate article (q.v.). It forms basic products with ammonia, diacetoneamine $CH_3 \cdot CO \cdot CH_2 \cdot C(CH_3)_2 \cdot NH_2$ (Heintz, Annalen, 1877, 189, 214; Everest, Trans. Chem. Soc. 1919, 115, 588; Patterson and McMillan, Trans. Chem. Soc. 1921, 119, 269) and triacetoneamine $NH \cdot C(CH_3)_2 \cdot CH_2 \cdot CO + H_2O$ Heintz, *ibid.* 1875, 178, 305), the former of which has found application in the preparation of pharmaceutical products (Schering, D. R. PP. 95620, 95621, 95622, 95623; *cp.* Harries, D. R. PP. 99004, 99005).

The hypnotic, 'sulphonal'

is obtained either by the oxidation of the mercaptol $(CH_3)_2C(SC_2H_5)_2$ with potassium permanganate (Baumann, Ber. 1886, 19, 2808), or by the methylation of ethylidene diethylsulphone $CH_3 \cdot CH(SO_2C_2H_5)_2$, or diethylsulphonemethane $CH_2(SO_2C_2H_5)_2$ with alcoholic potash and methyl iodide (Fromm, Annalen, 1889, 253, 147) (v. SULPHONAL).

The halogen derivatives of acetone affect the

eyes and nose painfully. The chloro-acetones and other chlorinated ketones have recently received considerable attention (Lippmann, Ber. 1912, 45, 2489; Blaise, Compt. rend. 1912, 155, 46; 1913, 156, 793; Bull. Soc. chim. 1914, [iv.] 15, 728; 1915, [iv.] 17, 425; Wohlgemuth, Ann. Chim. 1914, [ix.] 2, 403).

In preparing monobromoacetone and other monobromoketones, J. D. Riedel adds a solution of bromine in bromide liquor to a hot solution of acetone (or other bromoketone) containing bromoacetone (or bromoketone) in bromide liquor (D. R. PP. 298944, 298353). Thiocyanacetone (Hellon and Tscherniac, Ber. 1883, 16, 349; Tscherniac, Ber. 1892, 25, 2623; Trans. Chem. Soc. 1919, 115, 1071) yields 2-chloro-4-methylthiazole when treated with hydrogen chloride.

Methyl ethyl ketone (*Butanone*), b.p. 78.6°, sp.gr. 0.8101/15°/4° (Marshall, Chem. Soc. Trans. 1906, 89, 1376), occurs in the distillate from crude calcium acetate, and may be obtained from the water used in washing wool; this is evaporated with lime, and the resultant calcium salts distilled. About 45-50 p.c. of 'acetone oil' is obtained, 80 p.c. is soluble in water, and when fractionated 60 p.c. of methyl ethyl ketone is obtained. This compound is employed for the denaturation of alcohol, the similarity of boiling-points making separation by fractionation nearly impossible (A. and P. Buisine, Compt. rend. 1897, 125, 777; 1898, 126, 231; 1899, 128, 561) (*v. ACETONE OIL*). For production from *n*-Butyl alcohol, see King, Chem. Soc. Trans. 1919, 115, 1404. Vapour pressure of mixtures with acetone (T. W. Price, *ibid.* 1116).

Methyl ethyl ketone condenses with ethyl formate in presence of sodium ethoxide to give hydroxymethylene-butanone

The latter compound is also obtained from azibutanone $\text{CH}_3\cdot\text{CO}\cdot\text{C}(\text{N}_2)\cdot\text{CH}_3$ and formaldehyde (Diels and Ilberg, Ber. 1916, 49, 158). Other derivatives, see Sen-Gupta, Chem. Soc. Trans. 1914, 105, 403.

Isoprene can be obtained by condensing methyl ethyl ketone with diethylamino-methyl alcohol, reducing the diethyl- γ -keto- β -methylbutylamine so found to a hydroxy compound, forming a quaternary ammonium compound from the latter, and finally treating with alkali (Fr. Bayer & Co., D. R. P. 267040; cf. D. R. PP. 254714, 266656, 267347). Condensations of methyl ethyl ketone with a number of aldehydes are described by Ryan and Devine (Proc. R. Irish Acad. 1916, 32, B, 208). A diketone $\text{CH}_3\cdot\text{CO}\cdot\text{CH}(\text{CH}_3)\cdot\text{CH}(\text{CH}_3)\cdot\text{CO}\cdot\text{CH}_3$ is produced on exposing methyl ethyl ketone to light (Ciamician and Silber, Ber. 1912, 45, 1540).

Methyl ethyl ketone, like acetone, may be employed instead of formaldehyde for preparing sulphonylates (M. L. B., D. R. PP. 162875, 207846, 210467).

Methyl hydroxyethyl ketone

results from the condensation of acetone and formaldehyde; dehydrated by means of 2 p.c. of zinc chloride *methyl vinyl ketone*

b.p. 80°, is formed (Farbenfab. vorm. Fr. Bayer & Co., D. R. PP. 222551, 223207, 242612).

Methyl propyl ketone (2-pentanone) is found in the crude acetone obtained by distilling the calcium salts from pyroligneous acid, b.p. 101.7°.

Methyl-*n*-amyl ketone (2-heptanone) occurs in oil of cloves (Schimmel & Co., Ber. April, 1897, 50) and boils at 151°-152°. It possesses a penetrating fruity odour.

Methyl nonyl ketone (2-undecanone) forms the chief constituent of oil of rue (*Ruta graveolens* [Lin.]), being accompanied by a small amount of a ketone $\text{C}_{13}\text{H}_{24}\text{O}$ (Williams, Annalen, 1858, 107, 374). It also forms 75 p.c. of the ketonic portion of the 'essence' of cocoa-nut butter, in which it is accompanied by methyl heptyl and methyl undecyl ketones (A. Haller and A. Lassieur, Compt. rend. 1910, 151, 697).

Methyl nonyl ketone also occurs in palm kernel oil (Salway, Chem. Soc. Trans. 1917, 111, 407).

2-Methyl- Δ^2 -heptene-6-one

occurs in oil of linaloes (Barbier and Bouveault, Compt. rend. 1895, 121, 168), and is a constituent of lemon-grass oil (Bertram and Tiemann, Ber. 1909, 32, 834); b.p. 173°-174°, sp.gr. 0.8602, at 20° n_D^{20} 1.4445. This ketone has been artificially prepared by the slow distillation of cineolic anhydride $\text{C}_{10}\text{H}_{14}\text{O}_4 = \text{C}_8\text{H}_{14}\text{O} + \text{CO} + \text{CO}_2$ (Wallach, Annalen, 1890, 258, 324), and together with other substances by the oxidation of geraniol, geranial, and methylheptenol by chromic acid (Tiemann and Semmler, Ber. 1893, 26, 2722). The same authors also obtained it by boiling geranonitrile with alcoholic potash and by the oxidation of citral (Ber. 1895, 28, 2126).

Verley (Bull. Soc. chim. 1897, [iii.] 17, 175) obtains it by boiling 500 grams of citral with a solution of 500 grams of potassium carbonate in 5 litres of water for 12 hours, the ketone is then distilled in steam and fractionated under reduced pressure. Verley records the constants, b.p. 168° (84° at 26 mm.), sp.gr. 0.910 at 14°, n_D^{31} 1.437.

Methylheptenone gives an *oxime* and *phenylhydrazine*; it is converted into dihydro-*m*-xylene by the action of zinc chloride (Wallach) or concentrated sulphuric acid (Verley); whilst on reduction electrolytically, methylheptenol is produced (Law, Chem. Soc. Trans. 1912, 101, 1022).

Zibethone $\text{C}_{11}\text{H}_{20}\text{O}$, m.p. 32.5°, b.p. 206°-208°/17 mm., occurs in civet. *Oxime*, m.p. 92°; *semicarbazone*, m.p. 187° (Erwin Sack, D. R. P. 279313).

II. Hydroaromatic Ketones.

Of the non-cyclic ketones containing hydroaromatic nuclei, *irone*, and its isomers are of especial importance.

Irone $\text{C}_{13}\text{H}_{20}\text{O}$ was recognised by Tiemann and Krüger (Ber. 1893, 26, 2675; 1895, 28, 1754; Tiemann, *ibid.* 1898, 31, 808; Haarmann and Reimer, D. R. P. 72840) as the odorous principle of iris root (*Iris florentina* [Linn.], *I. germanica* [Linn.], *I. pallida* [Linn.]). Violet or iris oil is obtained chiefly from *I. florentina*; at ordinary temperatures it forms a fairly firm yellowish mass, possessing an intense odour of violets. It consists of about 80 p.c. of myristic acid associated with irone, methyl myristate, oleic aldehyde, acid, and esters. Irone and

volatile esters distil in a current of steam, the esters are saponified, the irone again steam distilled, and the product rectified under reduced pressure. Pure irone is dextrorotatory, b.p. (16 mm.) 144° , sp.gr. at 20° 0.939; *oxime* $C_{13}H_{20}:NOH$, m.p. 121.5° ; *p*-bromo-phenyl-hydrazone $C_{13}H_{20}:N:NH \cdot C_6H_4Br$, m.p. $140^{\circ}-145^{\circ}$.

Tiemann and Krüger (*l.c.*) determined the constitution of irone as

and attempted to synthesise it from citral (lemon-grass oil).

Ionones (α - and β). These ketones, isomeric with irone, and differing from it and from one another by the position of the double linkage in the ring, were actually obtained from citral; as they also have an odour of violets they have attained very considerable technical importance (Haarmann and Reimer, D. R. PP. 73089, 75128).

Citral and acetone are condensed to ψ -ionone:

which, on boiling with sulphuric acid, gives a mixture of

and

The formation of the former is favoured by a dilute acid, the latter when more concentrated sulphuric acid is employed. The separation of the two isomerides is effected by the more sparing solubility of the bisulphite compound of α -ionone (Tiemann, Ber. 1898, 31, 870), the process may be aided by salting out with sodium chloride (P. Chuit, Rev. gén. Chim. pure appl. 1903, 6, 422).

According to patent D. R. P. 129027 α -ionone is formed preferentially with concentrated phosphoric acid at 30° , β -ionone almost exclusively when 70–100 p.c. sulphuric acid is employed in the cold (Haarmann and Reimer).

Citral may be isomerised to α - and β -cyclocitral, which condense with acetone, yielding ionones (Haarmann and Reimer, D. R. P. 123747; Tiemann, Ber. 1900, 33, 3721). Other

information about the preparation of ionones and higher homologues using methyl ethyl and methyl isopropyl ketones in place of acetone is given in Haarmann and Reimer's patents (D. R. PP. 126959, 126960, 127424, 127831, 129027, 132222, 133758, 150827, 183855).

α -Ionone is an oil with strong, sweet smell of fresh violets, b.p. (12 mm.) 127.6° , sp.gr. at 20° 0.9301; *oxime* $C_{13}H_{20}:NOH$, m.p. $89^{\circ}-90^{\circ}$; *semicarbazone* $C_{13}H_{20}:N:NH \cdot CO \cdot NH_2$, m.p. $107^{\circ}-108^{\circ}$.

β -Ionone is also an oil smelling pleasantly like violets, b.p. (10 mm.) $127^{\circ}-128.5^{\circ}$; sp.gr. at 20° 0.9442; *oxime*, oily; *semicarbazone*, m.p. $148^{\circ}-149^{\circ}$. Four hydrogen atoms may be added to α - and β -ionones or to irone in presence of colloidal palladium or platinum black (Ruzicka, Helv. Chim. Acta, 1919, 2, 352).

A ketone $C_9H_{14}O$, isolated from the Indian deodar (*Cidrus deodara*), is probably a *p*-methyl-tetrahydroacetophenone (Roberts, Chem. Soc. Trans. 1916, 109, 793).

III. Mixed Ketones.

Acetophenone $C_6H_5 \cdot CO \cdot CH_3$, used medicinally as *hynnone*, is formed by distilling a mixture of calcium acetate and benzoate, and is conveniently prepared by the action of acetyl chloride on benzene in the presence of aluminium chloride (Friedel and Crafts, Ann. Chim. 1884, [vi.] 1, 507), m.p. 20.5° , b.p. 202° , sp.gr. 1.032 at 15° .

Acetophenone does not combine with sodium bisulphite; phosphorus pentachloride gives $C_6H_5 \cdot CCl_2 \cdot CH_3$; halogens substitute in the methyl group (Gautier, Bull. Soc. chim. 1886, 45, 875). The *phenylhydrazone* has m.p. 105° .

The methyl group of acetophenone may be alkylated in presence of sodamide (Haller and Bauer, Compt. rend. 1909, 143, 70). When acetophenone is heated with sodium ethoxide to $130^{\circ}-140^{\circ}$, some 3:5-diphenyl-methyl-benzene is formed (Gastaldi and Cherchi, Gazz. chim. ital. 1915, 45, ii. 251; 1920, 50, i. 71).

Acetophenone condenses with benzaldehyde, giving *styryl phenyl ketone*

derivatives of this compound occur naturally; e.g. hesperitin and homöridictyol to which are assigned the respective structures:

(Power and Tutin, Trans. Chem. Soc. 1907, 91, 887; *cp.* Tiemann and Will, Ber. 1881, 14, 970; Perkin, Chem. Soc. Trans. 1898, 73, 1037; and Tutin and Caton, *ibid.* 1910, 97, 2062). Butein is 2:4-dihydroxyphenyl-3:4-dihydroxystyryl ketone, its synthesis was effected by Göschke and Tambor (Ber. 1911, 44, 3502; 1912, 45, 186).

ω -Chloroacetophenone (phenacyl chloride) $C_6H_5 \cdot CO \cdot CH_2Cl$ is obtained by leading the theoretical amount of chlorine into boiling

acetophenone. The product is distilled, the portion passing over below 200° is chlorinated again, whilst the fraction between 240° and 250° is collected separately, and the monochloro-derivative crystallised by cooling; m.p. 58° – 59° ; b.p. 244° – 245° (Staedel, Ber. 1887, 10, 1830).

***o*-Bromoacetophenone** $C_6H_5 \cdot CO \cdot CH_2Br$ is prepared by adding gradually one molecular proportion of bromine to acetophenone dissolved in carbon disulphide (Hunnius, Ber. 1877, 10, 2007), a current of dry carbon dioxide being led through (Staedel, Kleinschmidt, *ibid.* 1880, 13, 837; 1883, 16, 22); m.p. 50° .

Both phenacyl chloride and bromide are of use as synthetic agents; thus with ammonia 2:5-diphenylpyrazine is produced (Gabriel, Ber. 1908, 41, 1127; Tutin, Chem. Soc. Trans. 1910, 97, 2495) a compound previously described by Staedel and Rügheimer as *isindol* (Ber. 1876, 9, 563; 1880, 13, 836). Phenacyl sulphide is of interest on account of the stereoisomerism of certain derivatives (Fromm and Flaschen, Annalen, 1912, 394, 310).

***p*-Aminoacetophenone** $NH_2 \cdot C_6H_4 \cdot CO \cdot CH_3$; m.p. 106° ; b.p. 293° – 295° . One method of preparing this compound has been given previously (general methods of preparation, 17). F. Kuncell (Ber. 1900, 33, 2641) obtains *p*-acetylaminacetophenone by the action of 70 grams of aluminium chloride on a mixture of 20 grams of acetanilide, and 50 grams each of carbon disulphide and acetyl chloride, a yield of 15.5 grams (m.p. 166° – 167°) being obtained. The free aminoketone is readily obtained by boiling for half an hour with three times its weight of 15 p.c. hydrochloric acid, and precipitating with sodium carbonate.

The hydrochlorides of *o*- and *p*-aminoacetophenone give coloured solutions in alcohol; solutions made from the *m*-isomeride are colourless. This agrees with a quinonoid structure for the two former (Kuhara, Saito and Shinomura, Mem. Coll. Sci. Kyoto, 1920, 4, 201).

***o*-Hydroxyacetophenone** $HO \cdot C_6H_4 \cdot COCH_3$ was first obtained by ketonic fission of *o*-methoxybenzoylacetic ester and subsequent splitting off of the methyl group (Tahara, Ber. 1892, 25, 1306). It has been found by Dunstan and Henry in the oil of *Chiona glabra* (Chem. Soc. Trans. 1899, 75, 67), b.p. 213° /717 mm. *Acetyl derivative*, m.p. 89° ; *oxime*, m.p. 102° ; *phenylhydrazone*, m.p. 108° .

***m*-Hydroxyacetophenone**, m.p. 96° (Biginelli, Gazz. chim. ital. 1894, 24, i. 440; Besthorn, Ber. 1894, 27, 3042).

***p*-Hydroxyacetophenone** may be obtained from the amino compound by diazotisation; m.p. 107° (Klingel, Ber. 1885, 18, 2691).

Resacetophenone

a compound of synthetical importance, is obtained as described in General Method 17; m.p. 142° .

Gallacetophenone 2:3:4-(OH) $_3$ C $_6$ H $_2$ ·CO·CH $_3$ similarly obtained from acetic acid and pyrogallol. is used as a mordant dyestuff. The analogous purely aromatic hydroxy ketones, which are similarly employed, are described later.

Various condensations of resorcinol and phloroglucinol with fatty acids have been effected (P. Karrer and S. Rosenfeld, Helv.

Chim. Acta, 1921, 4, 707). Acetic acid condenses with the naphthols to hydroxynaphthyl methyl ketone (K. Fries, Ber. 1921, 54, 709).

o-, *m*-, and *p*-Tolyl methyl ketones (b.p.s. 211° , 221° , and 224° at 745 mm.) and other tolyl alkyl ketones have been prepared by passing the vapours of the corresponding aromatic and fatty acids over thorium oxide at 460° – 470° (Senderens, Compt. rend. 1911, 152, 90).

Zingerone C $_{11}$ H $_{14}$ O $_3$ has been isolated from the extract of ginger (*Zingiber officinalis*), m.p. 40° – 41° (Nomura, Chem. Soc. Trans. 1917, 111, 769) or 31° – 34° (Lapworth, Royle and Pearson, *ibid.* 177). Its constitution is that of 4-hydroxy-3-methoxyphenylethyl methyl ketone. It has been synthesised by condensing vaniline with acetone, and subsequently reducing (Nomura) and by reducing ethyl vanillylide-aceto-acetate, followed by hydrolysis (Lapworth). (See also, Pearson, Pharm. J. 1919, 103, 78.)

IV. Aromatic Ketones.

Diphenylketone (Benzophenone)

This ketone is obtained by several of the general methods (2, 4, 6, 7, 10, 11, 16).

Preparation.—(i.) Dry calcium benzoate mixed with one-tenth of its weight of lime is distilled from an iron retort. The distillate is fractionated, the portion distilling at 290° – 310° being collected separately. This for the most part solidifies on cooling, liquid impurities are removed by pressure, and the ketone crystallised from alcohol. The yield amounts to about one-fourth of the weight of the calcium benzoate used, the other products of distillation consisting of benzene, diphenyl, and anthraquinone.

(ii.) A mixture of equivalent amounts of benzene and benzoyl chloride dissolved in carbon disulphide is treated with aluminium chloride, equal in weight to the benzoyl chloride used. The reaction is completed under reflux on the water-bath, water is carefully added, and carbon disulphide, unattacked benzene, and benzoic acid removed in a current of steam. The residual oil is washed successively with dilute hydrochloric acid, dilute caustic soda and water, dried, and fractionated. Yield 70–75 p.c.

(iii.) Well-cooled benzene is saturated with carbonyl chloride, and aluminium chloride added in small quantities at a time. The operation is conducted under reflux, and the product worked up as in the last case. From 100 grams of benzene, 55 grams of phosgene and 36 grams of aluminium chloride, 33 grams of benzophenone may be obtained.

Properties.—Rhombic prisms; m.p. 48° – 49° . An unstable allotropic form (? monoclinic), melts at 26° – 27° (Zincke, Annalen, 1871, 159, 377; Oechsner de Coninck, Compt. rend. 1900, 130, 40); b.p. 306° (170° at 15 mm.). Tammann has described a third modification, m.p. 45° – 48° ; and Walther and Wahl a fourth, m.p. -51° (Chem. Zeit. 1913, i. 313). For variation of boiling-point with pressure, see Crafts (Bull. Soc. chim. 1883, [ii.] 282). *Oxime* (C $_6$ H $_5$) $_2$ C:OH; m.p. 139° – 140° ; *phenylhydrazone* (C $_6$ H $_5$) $_2$ C:N·NH·C $_6$ H $_5$; m.p. 137° .

Arylimines (Reddelien, Ber. 1909, 42, 4759; 1910, 43, 2476).

Nitrate, yellow in colour. Other salts have not been isolated, but their existence is probable (K. H. Meyer, Ber. 1910, 43, 157).

Addition products $\text{CO}(\text{C}_6\text{H}_5)_2 \cdot \text{AlCl}_3$, m.p. 130° , and $\text{CO}(\text{C}_6\text{H}_5)_2 \cdot \text{AlBr}_3$, m.p. 142° (Menschutkin, J. Russ. Phys. Chem. Soc. 1910, 42, 1298). The addition product with sodamide yields benzamide on decomposition with water

(Haller and Bauer, Compt. rend. 1908, 147, 824). Benzophenone reacts with benzyl acetate in sunlight, giving the monoacetyl derivative of triphenylethylene glycol (Paternò and Forlì-Forti, Gazz. chim. ital. 1910, 40, ii, 332).

The ketone gives benzhydrol ($\text{C}_6\text{H}_5)_2\text{CH}(\text{OH})$ when reduced with sodium amalgam, but it is preferable to add zinc dust to an alcoholic solution to which a small amount of aqueous potash has been added (Elbs, J. pr. Chem. 1886, [ii.] 33, 184).

The influence of substituents on the reduction of substituted benzophenones has been examined by Montagne and van Charante (Rec. trav. chim. 1912, 31, 298; 1917, 36, 258). For further information as to the mechanism of this reaction in presence of hydroxyl ions, see Böeseken and Cohen (Proc. K. Akad. Wetensch. Amsterdam, 1914, 16, 962).

Substitution (halogen, nitro, amino, &c.) derivatives are known; of these the amino and especially the dialkylamino derivatives are of considerable technical importance.

***p*-Aminobenzophenone** $\text{C}_6\text{H}_5 \cdot \text{CO} \cdot \text{C}_6\text{H}_4 \cdot \text{NH}_2$.

(i.) 75 grams of phthalanil $\text{C}_6\text{H}_4 \cdot \text{CO} \cdot \text{N} \cdot \text{C}_6\text{H}_5$ and 50 grams of benzoyl chloride are boiled for 10 or 12 hours, zinc chloride (1 gram) being added from time to time. The resulting phthalylbenzoanilide $\text{C}_6\text{H}_4 \cdot \text{CO} \cdot \text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{CO} \cdot \text{C}_6\text{H}_5$ may

be purified by crystallisation from glacial acetic acid; when hydrolysed by alcoholic potash it gives *p*-aminobenzophenone (benzoaniline) and phthalic acid (Doebner, Annalen, 1881, 210, 268).

(ii.) Aniline and 2 molecular proportions of benzoyl chloride are heated gradually at 220° – 230° , and the temperature maintained for 20 hours. The dibenzanilide first produced is thus isomerised to a mixture of *o*- and *p*-benzoylaminobenzophenones; the change may be aided by the addition of 10 p.c. of zinc chloride. After hydrolysis of the product the two aminobenzophenones may be separated by steam distillation, the ortho- compound being volatile. Calculated on the weight of aniline used, 15 p.c. of the ortho- and 45 p.c. of the para- derivatives are obtained (Chattaway, Chem. Soc. Trans. 1904, 85, 394).

Shining leaflets; m.p. 124° .

Aminobenzophenone and dimethyl- and diethylaminobenzophenones, as well as dimethylaminobenzophenone sulphonic acid condense with pyrogallol in acid solution to form triphenylmethane mordant dyestuffs (Ges. f. Chem. Ind. Basel, D. R. P. 58689).

***p*-Dimethylaminobenzophenone**

is obtained from malachite green and concentrated hydrochloric acid at 250° (Ber. 1880, 13, 2225), and by methylation of *p*-aminobenzophenone (Doebner, Annalen, 1881, 210, 270).

Technically, it is more easily prepared by interaction of benzanilide, dimethylaniline, and phosphoryl chloride, and hydrolysis of the resulting product:

20 kilos. benzanilide, 40 kilos. dimethylaniline, and 20 kilos. phosphoryl chloride are stirred and warmed until spontaneous heating takes place, the temperature is then kept below 120° , and the reaction subsequently finished by one or two hours' heating on the water-bath.

Hydrolysis may be effected in one of two ways:

(a) The mass is poured into 100 litres of water and 5 kilos. of hydrochloric acid warmed to 50° , the liquid allowed to stand, whereby a portion of the ketone separates, the remainder being precipitated by the addition of 500 litres of water and careful neutralisation with caustic soda. The ketone is collected, extracted with hydrochloric acid, washed, and dried.

(b) The mass is made alkaline, excess of dimethylaniline removed in a current of steam, and the granular residue hydrolysed at 50° – 70° with 100 litres of water and 10 kilos. of hydrochloric acid. A portion of the ketone is precipitated, the remainder is obtained by addition of aqueous caustic soda, care being taken not to throw the aniline out of solution. Other dialkylaminobenzophenones may be similarly obtained (Farb. vorm. Meister, Lucius, and Brünig, D. R. PP. 41751, 42853).

p-Dimethylaminobenzophenone forms colourless leaflets; m.p. 90° – 91° . It is a weak base, insoluble in water, sparingly soluble in cold alcohol. Phosphorus trichloride yields a yellow compound, probably

which can be purified by solution in chloroform and reprecipitation by petroleum spirit. It is easily converted into the original ketone by heating with water, and condenses directly with dimethylaniline, forming malachite green (B. A. S. F., D. R. P. 27789).

The hydrol $\text{C}_6\text{H}_5 \cdot \text{CH}(\text{OH}) \cdot \text{C}_6\text{H}_4 \cdot \text{N}(\text{CH}_3)_2$ (m.p. 69° – 70°), obtained by reduction of dimethylaminobenzophenone, condenses with dimethylaniline to leuco malachite green.

If the reduction is carried out electrolytically or by zinc and sulphuric or hydrochloric acid, the corresponding pinacone, m.p. 195° , is found. This yields a mixture of the ketone and hydrol when heated with alcoholic potash (Fischl, Monatsh. 1913, 34, 337).

Michler's ketone reacts with the Grignard reagents, malachite green can be obtained in this way (Votoček, Ber. 1913, 46, 1755, 1760).

4 : 4'-Diaminobenzophenone

(m.p. 172°), and its trimethyl derivative $(\text{CH}_3)_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{CO} \cdot \text{C}_6\text{H}_4 \cdot \text{NH}(\text{CH}_3)$ (m.p. 156°) are obtained from pararosaniline (or rosaniline) and pentamethyl violet, respectively by prolonged heating with hydrochloric acid (Wichelhaus, Ber. 1886, 19, 109).

Diaminobenzophenone and its derivatives can be condensed with pyrogallol to green or

blue mordant dyestuffs (Ges. f. chem. Ind. Basel, D. R. P. 61326).

Tetramethyldiaminobenzophenone (Michler's ketone) $\text{CO}[\text{C}_6\text{H}_4\cdot\text{N}(\text{CH}_3)_2]_2$ is a valuable intermediate product in the preparation of many dyestuffs, and was first obtained by Michler (Ber. 1876, 9, 716, 1900). Dimethylaniline is saturated at ordinary temperature with the theoretical quantity of phosgene, and the reaction completed by warming in a closed vessel to 100° . Water is added, excess of dimethylaniline removed by steam distillation, and the ketone purified from adherent blue colouring matter by repeated solution in hydrochloric acid and reprecipitation with soda.

Michler's ketone may also be prepared by carefully heating on the water-bath 10 kilos. of dimethylaminobenzanilide

18 kilos. of dimethylaniline, and 8.5 grams of phosphoryl chloride, the product being worked up in a similar manner to that adopted in the case of dimethylaminobenzophenone.

Disubstituted dialkylaminobenzamides (Meister, Lucius, Brüning, D. R. P. 44238) may also be employed. Thus 10 kilos. of dimethylaminobenzodiphenylamine $(\text{CH}_3)_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{CO}\cdot\text{N}(\text{C}_6\text{H}_5)_2$, 12 kilos. of dimethylaniline, and 5 kilos. of phosphoryl chloride are heated on the water-bath for 2 hours; the product being subsequently worked up by hydrolysis with hydrochloric acid, precipitation of the ketone and diphenylamine and separation of the latter by washing with alcohol (D. R. P. 44077).

The ketone forms silvery leaflets, m.p. 174° (corr.), boils with some decomposition above 360° ; it is easily soluble in alcohol and ether. The basic properties are weak. *Picrate*

m.p. 156° – 157° .

Tetraethyldiaminobenzophenone obtained similarly melts at 95° – 96° (Michler and Gradman, Ber. 1876, 9, 1914).

Replacement of oxygen in the above ketones by the imino group gives auramines (*q.v.*).

In presence of condensing agents (*e.g.* POCl_3 , COCl_2 , &c.) the tetraalkyldiaminobenzophenones condense with aromatic amines to give dyestuffs of the triphenyl (diphenyl-naphthyl, &c.) series, but cleaner products are generally obtained by reducing the ketones to hydrols, and condensing these with amines, &c., to leuco-compounds, which are subsequently oxidised to the corresponding dyestuffs.

Reduction to hydrols may be effected by sodium amalgam in alcoholic solution; technically zinc dust and caustic soda in amyl alcoholic solution are employed (B. A. S. F., D. R. P. 27032). Tetramethyldiaminobenzhydrol dissolves in acetic acid with an intense blue colour, which is discharged on rendering alkaline.

Amino (and acetamino) derivatives of tetraalkyldiaminobenzophenones may be obtained from nitro derivatives by reduction. Michler's ketone, when nitrated, gives 3-nitro- and 3:3'-dinitro-4:4'-tetramethyldiaminobenzophenone (Kliegl, Ber. 1906, 39, 1266); the latter compound has also been obtained by the action of dimethylamine on 3:3'-dinitro-4:4'-dichlorobenzophenone (Consonno, Gazz. chim. ital. 1904,

34, i. 386). Introduction of the nitro group in position 2 may be effected by nitrating tetramethyldiaminodiphenylmethane, and subsequently oxidising the CH_2 group (Farbenf. vorm. Fr. Bayer & Co., D. R. P. 79250).

Hydroxyl derivatives of Benzophenone.

Numerous hydroxyl derivatives of benzophenone have been prepared, many by reactions involving the condensation of benzoic acid and its derivatives with phenols:

The trihydroxybenzophenones obtained from pyrogallol contain the grouping

they are generally yellow in colour, and are used as mordant dyestuffs.

Alizarin yellow A, $\text{C}_6\text{H}_5\cdot\text{CO}\cdot\text{C}_6\text{H}_2(\text{OH})_3$, is obtained by heating 1 part of pyrogallol and 1 part of benzoic acid to 145° , and adding 3 parts of zinc chloride with continuous stirring. The end of the reaction, which takes about 3 hours to complete, is recognised by the solution of the product in hot water giving slender bright yellow needles, and not benzoic acid on cooling. The mass is dissolved in 60 parts of boiling water, boiled 2 hours with animal charcoal, filtered, and allowed to crystallise. It forms yellow needles (with $1\text{H}_2\text{O}$); m.p. 137° – 138° . *Acetyl* derivative, colourless; m.p. 119° . On cotton mordanted with alumina it dyes golden-yellow shades, which incline to orange in presence of calcium salts. A fine yellow is produced with aluminium acetate and tin salt; the chromium lake is brownish-yellow, and the iron lake dark olive. The colours produced are very fast.

Dyestuffs giving similar shades are produced by the condensation of pyrogallol with *m*- and *p*-hydroxybenzoic acid, and β -resorcylic acid; those from pyrogallol and salicylic or pyrogallol-carboxylic acids give redder lakes, whilst the lakes are of a greenish-yellow shade if dyestuffs obtained by condensing gallic acid with resorcinol or pyrogallol are employed. The chemistry of these hydroxyketone dyestuffs has been studied by C. Graebe and A. Eichengrün (Annalen, 1892, 269, 295).

New dyestuffs, greener in shade, are obtained by fusing alizarin yellow A or C with the ammonium salts of organic acids (Prud'homme, Rev. gén. Mat. col. 1906, 10, 225).

Two unsaturated aromatic ketones, the benzalacetones, have been described under general methods of preparation (No. 18).

Thioketones.

Thiobenzophenone $\text{C}_6\text{H}_5\cdot\text{CS}\cdot\text{C}_6\text{H}_5$ was first obtained by Bergreen (Ber. 1886, 21, 341) in an impure condition by the action of 2 parts of aluminium chloride on 1 part of thiophosgene (CSCl_2) dissolved in 5 parts of benzene, the reaction being completed on the water-bath. After treatment with ice, and extraction with ether, the ethereal solution was washed with soda and water, and the ether distilled off, the thioketone remaining as an oil.

L. Gattermann and H. Schulze (Ber. 1896, 29, 2944) found that it is impossible to obtain the thioketone in a pure condition by this

Pechmann, Ber. 1887, 20, 3213; 1888, 21, 1411).

(ii.) By conversion into salts of iminosulphonic acids by the action of alkaline bisulphites, and subsequently hydrolysing by boiling with 15 p.c. sulphuric acid:

(v. Pechmann, Ber. 1887, 20, 3162; 1889, 22, 2115).

(iii.) By warming with *isoamyl* nitrite (Manasse, Ber. 1888, 21, 2177):

Similarly diethyl acetosuccinate gives *is*-nitrosolævulinic acid, the latter compound yielding diacetyl on boiling with dilute sulphuric acid (Thal, Ber. 1892, 25, 1723).

The mixed aliphatic-aromatic diketones are obtained in a similar way from mixed *is*-nitrosoketones (v. Pechmann and Müller, Ber. 1888, 21, 2119; 1889, 22, 2128).

(2) Ketones of the structure $\text{CH}_3\cdot\text{CO}\cdot\text{CH}_2\text{R}$, when warmed with nitric acid (sp.gr. 1.38) give ketones $\text{CH}_3\cdot\text{CO}\cdot\text{CO}\cdot\text{R}$ (Fileti and Ponzio, Gazz. chim. ital. 1895, 25, i. 233).

(3) Aromatic (and some heterocyclic) diketones are obtained from aldehydes $\text{R}\cdot\text{CHO}$ by condensation to the keto alcohols

under the influence of potassium cyanide and subsequent oxidation with chlorine (Laurent, Annalen, 1836, 17, 91), or more frequently nitric acid (Zinin, *ibid.* 1840, 34, 188).

(4) By heating compounds of the type $\text{R}\cdot\text{CBr}\cdot\text{CBr}\cdot\text{R}$ with water to 200° (e.g. toluene bromide) (Limpricht and Schwanert, Ber. 1871, 4, 380):

(5) By hydrolysis of compounds

(X=halogen). Thus toluene tetrachloride, when heated with sulphuric acid to 165° , or with glacial acetic acid to $230^\circ\text{--}250^\circ$ (Liebermann and Homeyer, Ber. 1879, 12, 1975).

(6) The vinylidene-oxanilide prepared by v. Pechmann by 8 hours boiling of 1 part of oxanilide, 1 part of fused sodium acetate, and 10 parts of acetic anhydride (Ber. 1897, 30, 2791) reacts readily with the Grignard reagents, forming compounds which furnish diketones on decomposition with dilute sulphuric acid:

(L. Tschugaeff, Ber. 1907, 40, 186).

General properties and reactions.—(1) The most characteristic reaction of the α -diketones is their condensation with aromatic α -diamines to quinoxalines:

The resulting coloured compounds crystallise well, have definite melting-points, and are readily identified (Hinsberg, Ber. 1884, 17, 322; Annalen, 1887, 237, 327).

When monosubstituted α -diamines are employed, salts of ammonium type are produced:

(2) Phenylhydrazine gives *mono*- or *di*-hydrazones; for preparation of the former, see Petrenko-Kritschenko and Eltschaninoff (Ber. 1901, 34, 1699). The dihydrazones (usually called osazones) derived from aliphatic diketones or diketones containing only one aromatic radicle, are readily oxidised by ferric chloride to red or brown osotetrazones (v. Pechmann, Ber. 1888, 21, 2751):

Diacetylphenylmethylhydrazone condenses when shaken with warm hydrochloric acid to 2-acetyl-1-methylindole

(Diels and Kollisch, Ber. 1911, 44, 263). From this hydrazone and magnesium alkyl halides, keto-alcohols are obtainable when the phenylmethylhydrazone is again removed (Diels and Johlin, Ber. 1911, 44, 403).

For action of hydrazine v. Curtius and Kastner, J. pr. Chem. 1911, 83, 215.

(3) Hydroxylamine yields *mono*- or *di*-oximes, the former can exist in two, the latter

in three modifications, even when the original diketone is symmetrical in structure :

(K. Auwers and V. Meyer, Ber. 1888, 21, 810; 1889, 22, 705; A. Hantzsch and A. Werner, Ber. 1890, 23, 11). The *syndioximes* are characterised by the ease with which they lose water yielding furazane derivatives.

The discovery of a fourth benzildioxime cannot be reconciled with the stereochemical formulation (Atcock and Whinyates, Trans. Chem. Soc. 1921, 119, 1184).

(4) Semicarbazide gives *mono*- and *di*-semicarbazones and cyclic condensation products (*see* Thiele, Annalen, 1894, 283, 37; Posner, Ber. 1901, 34, 3973; Biltz and Arnd, *ibid.* 1902, 35, 344; Diels, *ibid.* 1902, 35, 347).

(5) With caustic potash the aromatic α -diketones yield diaryl glycollic acids (Liebig, Annalen, 1838, 25, 25; Zinin, *ibid.* 1839, 31, 329):

The aliphatic α -diketones, however, when warmed in alkaline solution undergo condensation with formation of quinones; thus diacetyl gives xyloquinone (v. Pechmann, Ber. 1888, 21, 1417):

(6) With aldehydes and ammonia, glyoxalines are formed amongst other products:

(Japp and Hooker, Chem. Soc. Trans. 1884, 45, 672; Japp and Wynne, *ibid.* 1886, 49, 464).

1 : 3- or β -Diketones.

The lowest member of the series, acetylacetone, or 2 : 4-pentanedione, was obtained by Combes by the action of aluminium chloride on acetyl chloride and decomposition of the resulting crystalline substance $\text{C}_5\text{H}_8\text{O}_4\text{Al}_2\text{Cl}_3$ with water (Compt. rend. 1886, 103, 814).

The usual method of preparation of the 1 : 3-diketones is given under general reaction 17 of monoketones (*vide supra*). As condensing agents for bringing about the reaction

Claisen has found that alcoholic sodium ethoxide works most feebly and in order of increasing activity, are anhydrous sodium ethoxide, metallic sodium (Annalen, 1894, 277, 168, and sodium amide (Ber. 1905, 38, 695).

The sodium derivatives are represented above as derived from enols. Knorr (Ber. 1911, 44, 2767) has isolated the enolic form of acetyl-

acetone, m.p. -9° , n_D^{15} 1.4609. K. H. Meyer and Hopff find n_D^{10} 1.4625 (Ber. 1921, 54, 579). This is transformed at 15° into the allelotropic mixture of diketone and enol-ketone, n_D^{15} 1.4550, the change being complete in 20 minutes (*cf.* for enolisation of benzoylacetone, Smedley, Chem. Soc. Trans. 1910, 97, 1486; Scheiber, Ber. 1913, 46, 1100, 1105).

Unsaturated β -diketones have been prepared by Ryan (Proc. Roy. Irish Acad. 1913, 32, B, 1, 9; 1916, 35, B, 199).

General properties and reactions.—(1) The 1 : 3-diketones form stable metallic derivatives. Acetylacetone, for example, forms compounds of the types $\text{M}(\text{C}_5\text{H}_7\text{O}_2)_3$, $\text{M}(\text{C}_5\text{H}_7\text{O}_2)_2$, &c., many of which are volatile without decomposition, and may be used for vapour density determinations, thus controlling the valencies of several metals; *e.g.* divalent Gl and Cu , and trivalent Al , Fe , Mn , Co , and Cr (A. Combes, Compt. rend. 1896, 119, 1221; Bull. Soc. chim. 1889, [iii.] 1, 345; Urbain and Debiere, Compt. rend. 1899, 129, 302; Claisen, Ber. 1889, 22, 1010; Annalen, 1893, 277, 170; Morgan, Chem. Soc. Trans. 1913, 103, 81; 1914, 105, 189; 1921, 119, 610, 1058; Weinland and Bässler, Zeitsch. anorg. Chem. 1916, 96, 109). The metallic radicle may be replaced by acyl groups, branched triketones resulting from the reaction :

Morgan regards the polyvalent metallic compounds of acetylacetone as coordination derivatives. In this connection, it may be noted that β -diketones occupy two positions at the central atom and acetylacetonate-diethylenediamine cobalt salts have been resolved into optically active forms (Werner, Schwyzer and Karrer, Helv. Chim. Acta, 1921, 4, 113).

(2) On warming with arylhydrazines, pyrazoles are produced :

(L. Knorr, Ber. 1885, 18, 311; Annalen, 1887, 233, 37). This reaction can be utilised as the basis of a colour test for β -diketones since pyrazoles are reduced by sodium in boiling alcoholic solution to pyrazolines. If when solution of the metal is complete, water be added and the alcohol boiled off, the pyrazoline may be extracted with ether, and is left when the solvent is evaporated. If the residue be dissolved in fairly concentrated sulphuric acid, addition of a drop of solution of sodium nitrite or potassium dichromate produces a beautiful coloration varying from fuchsine red to blue. This reaction, which can be carried out in test tubes, is general for all pyrazoles derived from phenylhydrazine, not, however, for those obtained from hydrazine itself (L. Knorr, Ber. 1885, 18, 2259; 1893, 26, 101; Annalen, 1887, 238, 200).

T. Zincke (Annalen, 1908, 362, 242; 363, 302) has also obtained 1:6-diketones by oxidising the ditertiary alcohols obtained from phenanthraquinone by the Grignard reagents:

Heptane- $\beta\zeta$ -dione

m.p. 33°–34°, b.p. 221°–222°, has been obtained from caoutchouc ozonide (Harries, Ber. 1914, 47, 784).

Certain hydroxy-1:5-diketones are claimed to be of pharmacological importance; e.g. octane- $\gamma\eta$ -dione- α -ol and $\beta\zeta$ -dimethyloctane- $\gamma\eta$ -dione- α -ol (Bayer & Co., D. R. PP. 227176, 227177).

The enolic and ketonic forms of unsaturated 1:5-diketones are discussed by Dilthey and Böttler (Ber. 1919, 52, 2040) in reference to their conversion to pyrylium compounds.

1:6-Diketones are also known, e.g. $\alpha\delta$ -dibenzoylbutane (Bauer, Compt. rend. 1912, 155, 285).

INDIVIDUAL OPEN-CHAIN DIKETONES.

Diacetyl $\text{CH}_3\cdot\text{CO}\cdot\text{CO}\cdot\text{CH}_3$ may be prepared by the method of O. Diels and E. Stephan (Ber. 1907, 40, 4336). Methyl ethyl ketone (850 c.c.) is converted into the isonitroso derivative (diacetyl monoxime) by amyl nitrite (1 litre) and hydrochloric acid (30 c.c., sp.gr. 1.19). The oxime is extracted with dilute sodium hydroxide solution; after acidifying the diacetyl is blown over in a current of steam and the ketone eventually separated from water. 4 kilos. of methyl ethyl ketone give 1300 grams of diacetyl; b.p. 87°–88°.

Diacetyl has also been obtained by the oxidation of acetylmethylcarbinol, a product of growth of certain bacteria on sugars (Harden and Norris, J. Physiol. 1911, 42, 332), and by the action of hydrochloric acid on α -triazomethyl-aceto-acetic ester (Forster and Newman, Chem. Soc. Trans. 1910, 97, 1360.)

The dimeric form of diacetyl discovered by von Pechmann probably possesses the structure

(Diels, Blanchard and von der Heyden, Ber. 1914, 47, 2355).

Diacetyldioxime (dimethylglyoxime)

has acquired importance as a reagent for nickel. The solution to be tested is treated with an excess of ammonia or sodium acetate and then a little dimethylglyoxime is added and the solution boiled. If nickel is present a scarlet precipitate is produced. Definite results may be obtained with solutions containing 1 part of nickel in 400,000 of water. When cobalt is present, the solution is first shaken with a large excess of ammonia, 0.1mg. of nickel can be detected in the presence of 500 mg. of cobalt (L. Tschugaeff, Ber. 1905, 38, 2520).

Convenient methods for the preparation of dimethylglyoxime have been given by Tschugaeff (l.c.), A. Gandarin (J. pr. Chem. 1908, [ii.] 77, 414), and H. Biltz (Zeitsch. anal. Chem. 1909,

48, 164). Biltz's method consists in passing gaseous hydrogen chloride through a well-cooled solution of 50 grams of methyl ethyl ketone in 100 grams of ether, 82 grams of amyl nitrite being added drop by drop. After a few hours the monoxime is extracted by caustic soda solution (150 c.c. iced water and 50 c.c. 33 p.c. caustic soda), the ethereal layer extracted a few times with dilute caustic soda, the alkaline solutions united, extracted with a little ether and somewhat evaporated. After cooling, the solution is carefully neutralised with dilute sulphuric acid, and 50 grams of hydroxylamine hydrochloride dissolved in 75 c.c. of water are added. The dioxime crystallises out on standing over-night, and is purified by recrystallisation. The yield amounts to 45–50 grams (v. DIMETHYLGLOXIME).

On oxidising the monohydrazone of diacetyl, azibutanone $\text{CH}_3\cdot\text{CO}\cdot\text{C}(\text{N}_2)\cdot\text{CH}_3$ is produced. It is a mobile deep orange liquid giving an olive-green vapour; b.p. 45°/12mm. (Diels and Pflaumer, Ber. 1915, 48, 223).

Hydrazoxime $\text{CH}_3\cdot\text{C}(\text{:NOH})\cdot\text{C}(\text{:N}_2\text{H}_2)\cdot\text{CH}_3$, m.p. 140° (Forster and Deay, Chem. Soc. Trans. 1912, 101, 2238).

Hexabromo-diacetyl, m.p. 100°–101° (Jackson and Adams, J. Amer. Chem. Soc. 1915, 37, 2322).

Benzil $\text{C}_6\text{H}_5\cdot\text{CO}\cdot\text{CO}\cdot\text{C}_6\text{H}_5$ is obtained by the oxidation of benzoïn $\text{C}_6\text{H}_5\cdot\text{CO}\cdot\text{CH}(\text{OH})\text{C}_6\text{H}_5$, which may be prepared by heating for a short time 200 grams of pure benzaldehyde with 20 grams of potassium cyanide dissolved in 800 grams of 50 p.c. alcohol under reflux. The solution is allowed to cool, benzoïn separates, and is collected, the filtrate yields a further quantity of benzoïn when heated with more potassium cyanide (Zincke, Annalen, 1879, 198, 151). The benzoïn is then heated with twice its weight of nitric acid (sp.gr. 1.4) until red fumes are no longer evolved, the whole is poured into water, and the benzil, which then solidifies, purified by crystallisation from alcohol (Zinin, Annalen, 1840, 34, 188).

Benzil crystallises in six-sided prisms; m.p. 95°; b.p. 346°–348° (corr. with slight decomposition). Easily soluble in alcohol and ether. Is reduced to benzoïn by iron and acetic acid, or zinc and hydrochloric acid (Zinin, Annalen, 1861, 119, 177) and to hydrobenzoïn

by sodium amalgam (Zincke and Forst, Ber. 1875, 8, 797). Other reactions have already been mentioned under 1:2-diketones.

Ammonia, in presence of air, forms several compounds. If air is excluded, triphenyl oxazole and ammonium benzoate are produced almost quantitatively (Schönberg, Ber. 1921, 54, 242). The condensation of benzil with benzinide has been studied by Cain and Mi-klethwaite (Trans. Chem. Soc. 1914, 105, 1437) and Ferriss and Turner (Trans. Chem. Soc. 1920, 117, 1140).

Benzil yields substitution products with difficulty, it may be nitrated by boiling with fuming nitric acid. Two dinitrobenzils (m.p.'s 131° and 147°) are produced; these may be mechanically separated as crystals. The mixture of dinitrobenzils can be reduced, the resulting diamino-compound (? a mixture), though not isolated, can be used as a component in the preparation of azo dyestuffs (Poirrier and Rosenstiehl, D. R. PP. 44269 and 45789).

Four di-oximes of benzil have been described, these are known as α , β , γ and δ modifications. δ -Benzil dioxime may be used for the estimation of nickel (Atack, Analyst, 1913, 38, 317).

OPEN CHAIN TRI- AND TETRA-KETONES.

Triketones. Preparation.—(1) F. Sachs and H. Barschall (Ber. 1901, 34, 3047) obtained triketopentane by condensation of nitrosodimethyl-aniline with acetylacetone and hydrolysis of the resulting azomethine compound :

Diphenyltriketone $\text{C}_6\text{H}_5 \cdot \text{CO} \cdot \text{CO} \cdot \text{CO} \cdot \text{C}_6\text{H}_5$ has been described by Gastaldi and Cherchi (Gazz. chim. ital. 1913, 43, i. 299).

(2) Aromatic triketones with open chain have been obtained by Wieland and Bloch (Ber. 1904, 37, 1524). By the action of nitrous gases evolved from a mixture of arsenious oxide and nitric acid (sp.gr. 1.38) on an ethereal solution of dibenzoylmethane, the bisnitroso derivative of the latter compound and diphenyltriketone are obtained. The latter crystallises with water, probably of constitution; in fact the colourless hydrates give coloured triketones by loss of water. The same behaviour is observed in the case of cyclic triketones: Ruhemann (Chem. Soc. Trans. 1910, 2025; 1911, 792, 1306, 1486) finds that the coloured triketohydrindene not only forms a colourless monohydrate, but also gives colourless addition products with guanidine, benzamidine, and hydrogen cyanide.

Branched triketones have been described. For the supposed stereoisomerism of dibenzoyl-acetylmethane, see Michael (Ber. 1906, 39, 203; Annalen, 1912, 390, 40) and Dieckmann (Ber. 1916, 49, 2203).

Tetraketones are also known.

2 : 4 : 5 : 7-Octametrone

is obtained by adding sodium ethoxide (free from alcohol) to an ethereal solution of acetone and diethyl oxalate (Claisen and Stylos, Ber. 1888, 21, 1142). With acetophenone, &c., corresponding aromatic compounds can be prepared.

o-*o'*-Dibenzil

has been obtained by Zincke and Tropp (Annalen, 1908, 363, 302). Phenanthraquinone is treated with magnesium benzyl halide, the resulting di-tertiary alcohol oxidised to dibenzyl-diphenylene diketone, the latter converted into a di-*o*-nitroso compound and hydrolysed :

Possessing two 1 : 2-diketo-groups, the compound condenses with 2 molecules of *o*-phenylenediamine to form the corresponding diquinoxaline.

CYCLIC KETONES.

In the cyclic ketones the carbonyl groups form members of a closed ring; the properties are very similar to those of the aliphatic ketones as a rule, but in the case of the ortho- and para-quinones, such special characteristics are exhibited that they will be treated in a separate article (*q.v.*).

Preparation.—The cyclic ketones may frequently be prepared by the general methods already given; the following syntheses, or special methods, resulting in the formation of closed chain ketones, may be mentioned.

(1) The distillation of the calcium salts of certain dibasic acids gives cyclic ketones. The earliest example is the preparation of suberone from calcium suberate :

(Boussingault, Annalen, 1836, 19, 308; Tilley, *ibid.* 1841, 39, 166; Dale and Schorlemmer, *ibid.* 1879, 199, 147). Cyclopentanone, cyclohexanone, and cyclooctanone can be obtained by similar methods from the calcium salts of adipic, pimelic, and azelaic acids (Wislicenus, Annalen, 1893, 275, 312, 364; v. Baeyer, *ibid.* 1875, 178, 112; Ber. 1893, 26, 229).

(2) The esters of certain dicarboxylic acids undergo intramolecular condensation when acted on by sodium :

(Dieckmann, Ber. 1894, 27, 102).

(3) Cyclohexanone and its derivatives may be obtained by the reduction of phenols. When phenol vapour mixed with an excess of hydrogen is passed over reduced nickel at 215°–230°, cyclohexanol and cyclohexanone are obtained. The mixed product may be entirely converted into the latter compound by passing the vapour over copper heated to 330° (Sabatier and Senderens, Compt. rend. 1904, 137, 1025; 138, 457, 1257).

(4) 3-Methyl- Δ^2 -cyclohexenone is a product of the interaction of ethyl sodioacetacetate and methylene iodide. Apparently the first formed 2 : 6-heptanedione undergoes intramolecular condensation :

(C. J. L. Hagemann, Ber. 1893, 26, 876).

*iso*Butylidene diacetoacetic ester undergoes a similar internal condensation, giving an ester from which 3-methyl-5-*isopropyl*- Δ^2 -cyclohexenone may be obtained (Knoevenagel, Annalen, 1896, 289, 131).

(5) Open chain ketones will condense with unsaturated aldehydes or unsaturated ketones

of the type of benzalacetone. Thus the latter compound, condensed with benzoin, gives 3 : 4 : 5-triphenyl-4-hydroxy- Δ^2 -cyclohexenone (Garner, Amer. Chem. J. 1904, 31, 143) :

(6) Cyclic 1 : 2-diketones may be obtained by the condensation of diethyl glutarate and its derivatives with diethyl oxalate in presence of sodium ethoxide :

(Dieckmann, Ber. 1897, 30, 1470; 1899, 32, 1933; cf. papers by W. H. Perkin, jun., and co-workers, Chem. Soc. Trans. 1906, 89, 1640; 1908, 93, 1943; 1909, 95, 2010).

(7) A derivative of cyclohexane-1 : 3-dione is obtained by dehydration of acetonedipropionic acid (v. Pechmann and Sidgwick, Ber. 1904, 37, 3816) :

(8) Two molecules of diethyl succinate are condensed by Claisen's reaction (Herrmann, Annalen, 1882, 211, 311) :

The resulting ester yields cyclohexanedione (*vide infra*).

INDIVIDUAL CYCLIC KETONES.

I. Monocyclic Monoketones.

cyclopentanone $\text{CH}_2 \begin{array}{c} \text{CH}_2 \cdot \text{CO} \\ | \quad | \\ \text{CH}_2 \cdot \text{CH}_2 \end{array}$ occurs in raw wood spirit, and may be obtained by the distillation of calcium adipate (J. Wislicenus and Hentschel, Annalen, 1893, 275, 312, 318; cf. Bayer & Co., D. R. P. 256622). The oil of wood spirit is distilled, and the fraction boiling at 120°-140° shaken with syrupy sodium bisulphite. The resulting crystalline bisulphite compound is well pressed, decomposed with warm saturated sodium carbonate solution, and the oil freed from pyridine bases by shaking with a saturated solution of oxalic acid. The compound obtained is identical with the 'Dumasin' obtained by Kane from acetone oil (J. pr. Chem. 1838, 13, 69).

Mobile oil smelling like peppermint; b.p. 130°-130.5°; sp.gr. 0.9416 at 21.5°/4°. *Oxime*

C_5H_8 ; NOH, m.p. 56.5°; b.p. 196°. Condenses with 2 molecules of aromatic aldehydes in presence of alkalis (Vorländer and Hobohm, Ber. 1896, 29, 1836) :

Since the resulting compounds crystallise well, and ketones and aliphatic aldehydes do not react with cyclopentanone, Mentzel recommends the reaction for the recognition of aromatic aldehydes (Ber. 1903, 36, 1499). Vorländer and Hobohm have shown that the 'pyroxanthin' obtained by Scanlan, Apjohn and Gregory (Annalen, 1837, 21, 143), by the action of alkalis on raw wood spirit is difural-cyclopentanone.

Hydrogenation of cyclopentanone in presence of reduced nickel at 125° yields cyclopentane, cyclopentanol (50 p.c.) and a ketone $\text{C}_{10}\text{H}_{18}\text{O}$, which is probably α -cyclopentylcyclopentanone (Godehot and Taboury, Compt. rend. 1911, 152, 881).

Numerous derivatives of cyclopentanone have been described (Perkin and co-workers, Chem. Soc. Trans. 1906, 89, 1641; 1908, 93, 573; 1912, 101, 405; Dieckmann, Ber. 1894, 27, 102, 965; Ruhemann, Chem. Soc. Trans. 1912, 101, 1729, 2542; Stobbe, J. pr. Chem. 1912, ii. 86, 209; 1914, ii. 89, 329; Godehot and Taboury, Compt. rend. 1911, 153, 1060; 1912, 155, 1522; 1913, 156, 332; Haller and Cornubert, Compt. rend. 1914, 158, 1616, 1739; Bauer, Ann. Chim. 1914, [ix.] 1, 393).

Unsaturated ketones containing 5-carbon rings are known. Methylcyclopentenolone $\text{C}_5\text{H}_8\text{O}_2$, m.p. 106°, b.p. 200°, occurs in wood vinegar (Meyerfeld, Chem. Zeit. 1912, 36, 549).

Methylcyclopentenone $\begin{array}{c} \text{CH}_2 \cdot \text{CH}_2 \\ | \quad | \\ \text{CH} \cdot \text{C}(\text{CH}_3) \end{array} \text{CO}$, b.p.

157°, found in wood oils, has been identified with synthesised material (Godehot, Compt. rend. 1914, 158, 506).

Camphorone $\begin{array}{c} \text{CH}_3\text{C}=\text{C}(\text{CH}_3)_2 \\ | \quad | \\ \text{CH}_2\text{CHCH}_3 \end{array} \text{CO}$, first ob-

tained by Gerhardt and Lies-Bodart (Annalen, 1849, 72, 293) by distillation of calcium camphorate, smells like peppermint; b.p. 200°-205° sp.gr. 0.9305 at 20°/4°.

Pulegone is isomeric with camphorone, both compounds give 2-methyl-5-isopropylcyclopentanone (dihydrocamphorone, dihydropulegone) on reduction. *Dihydrocamphorone*, b.p. 184°-185°; *oxime*, m.p. 77°-78°; *semicarbazone*, m.p. 193°-195° (Semmler, Ber. 1902, 35, 1022; Wallach, Annalen, 1903, 327, 125). For conversion of menthone into pulegone v. Wallach and Grote, Chem. Zentr. 1918, ii. 120; Abstr. Chem. Soc. 1918, i. 544.

Dihydrocamphoketone $\begin{array}{c} \text{C}(\text{CH}_3)_2\text{CH} \cdot \text{CH}_3 \\ | \quad | \\ \text{CH}_2\text{CH} \cdot \text{CH}_3 \end{array} \text{CO}$, re-

sults on fusion of camphoric acid with potash (W. H. Perkin, jun., and A. W. Crossley, Chem. Soc. Trans. 1898, 73, 26). Smells like peppermint, b.p. 180°-181°; *semicarbazone*

C_9H_{16} ; N·NH·CO·NH₂ m.p. 202°-203°.

cycloHexanone $\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}$
 $\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2$ occurs with other cyclic ketones in wood oil (Looft, Ber. 1894, 27, 1544); it may be obtained by distillation of calcium pimelate (*v.s.*); by the oxidation of synthetic cyclohexanol (v. Bayer, Ber. 1893, 26, 229; Annalen, 1894, 278, 88); or by the reduction of phenol by alternate current (Drechsel, J. pr. Chem. 1888, [ii.] 38, 65); or by reduction in presence of nickel (*v.s.*), the last method being used technically.

Cyclohexanone is obtained in 97 p.c. yield when a solution of nitrocyclohexane in caustic potash is oxidised by permanganate (Nameikin and Pozdujakova, J. Russ. Phys. Chem. Soc. 1913, 45, 1420).

Mobile oil, somewhat soluble in water, smells like peppermint; b.p. $155\cdot4^\circ$; sp. gr. $0\cdot9471$ at $22\cdot4^\circ$. Gives a bisulphite compound; condenses with 2 molecules of benzaldehyde (Vorländer and Hobohm, Ber. 1896, 29, 1840); yields a diisonitroso derivative (W. Borsche, Festschrift Otto Wallach, 1909, 31).

Oxime $\text{C}_6\text{H}_{10}:\text{NOH}$, m.p. 88° ; phenylhydrazone $\text{C}_6\text{H}_{10}:\text{N}\cdot\text{NH}\cdot\text{C}_6\text{H}_5$, m.p. $74\cdot77^\circ$ (Kötz and Grethe, J. pr. Chem. 1909, ii. 80, 473).

A very large number of derivations of cyclohexanone have been prepared. (Bodroux, Cornubert, Crossley, Darzens, Favorski, Guareschi, Haller, Kijner, Kötz, Leser, Perkin, Saytzeff, Squintani, Stobbe, Wallach, &c.)

4-Methylcyclohexanone $\text{CH}_2\text{—CH}_2\cdot\text{CO}$
 $\text{C}(\text{CH}_3)\text{CH}_2\cdot\text{CH}_2$ is

obtained by the oxidation of 4-methylcyclohexanol with nitric acid. Oxidation of methylcyclohexanone with alkaline permanganate gives β -methyladipic acid, a compound which finds employment in the manufacture of dyes and pharmaceutical products (Farbenf. vorm. Fr. Bayer & Co., D. R. P. 221849).

Menthanonones $\text{C}_{10}\text{H}_{18}\text{O}$. Ordinary menthone was first obtained in an inactive form by Moriya (Chem. Soc. Trans. 1881, 39, 77) by the oxidation of natural menthol; Atkinson and Yoshida obtained a strongly dextro-rotatory variety (*ibid.* 1882, 41, 50). Beckmann has examined the stereochemistry of the menthones at length (Annalen, 1889, 250, 325; 1896, 289, 362; J. pr. Chem. 1897, [ii.] 55, 14). Other derivatives (Böttker, Compt. rend. 1912, 154, 437).

Carvomenthone (tetrahydrocarvone) was discovered nearly simultaneously by v. Baeyer (Ber. 1893, 26, 822; 1895, 28, 1588; 1896, 29, 27) and Wallach (Annalen, 1893, 277, 133; 1895, 286, 102; 1899, 305, 266; 1900, 312, 302; Ber. 1895, 28, 1961). Ordinary menthone and carvomenthone can each exist in four stereoisomeric forms, their structures are given by

Ordinary menthone.

Carvomenthone.

The reactions of the methylene group adjacent to carbonyl in menthone and tanacetone have been studied by Cusmano (Gazzetta, 1919, 49, i. 26), and the electrolytic reduction of menthone by Matsui and Shimizu (Men. Coll. Sci. Kyoto, 1920, 4, 245).

Δ^2 -cycloHexenone $\text{C}_6\text{H}_8\text{O}$ has been obtained from cyclohexanone (A. Kötz and T. Grethe, J. pr. Chem. 1909, [ii.] 80, 473).

The characteristic smell of urine has been attributed to a substance, *urinod*, b.p. $108^\circ/28$ mm. This compound occurs in a conjugated state in urine, it is probably cyclohexene-4-one (Dehn and Hartmann, J. Amer. Chem. Soc. 1914, 36, 2136).

Methylcyclohexenone $\text{CH}_2\cdot\text{C}_6\text{H}_7\text{O}$. In addition to the compound synthesised from ethyl sodioacetate by methylene iodide (Hagemann, Ber. 1893, 26, 876), and formaldehyde (Knoevenagel, *ibid.* 1090), an isomeride (m.p. 12° , b.p. 192°) has been discovered in wood tar. Since this gives acetic and lævulic acids on oxidation with potassium permanganate the

constitution $\text{CH}\cdot\text{CH}_2\cdot\text{CO}$
 $\text{CH}_3\cdot\text{C}\cdot\text{CH}_2\cdot\text{CH}_2$ has been deduced (Béhal, Compt. rend. 1897, 125, 1036; 1901, 132, 342).

isoCamphor $\text{CH}_2\text{—CH}_2\text{—CO}$
 $\text{CH}(\text{C}_3\text{H}_7)\cdot\text{CH}\cdot\text{C}\cdot\text{CH}_3$ was obtained by Angeli and Rimini by acting on camphoroxime with nitrous acid and decomposing the resultant nitrimine with ice-cold sulphuric acid (Gazz. chim. ital. 1896, ii. 26, 34).

Pulegone (Δ^4)-3-menthenone)

is the most important of the seven possible structurally different *p*-menthenones. (Each of these exhibits stereoisomerism.) Beckmann and Pleissner (Annalen, 1891, 262, 1) obtained pulegone from oil of pennyroyal (*Mentha Pulegium* [Linn.]) of which it constitutes about 80 p.c. It is also found in the ethereal oils of *Hedeoma pulegioides* (Pers.) and *Pycnanthemum lanceolatum* (Pursh.). It is isolated from oil of pennyroyal by fractional distillation and conversion into the sodium bisulphite derivative. The synthesis from citronellal has been effected by Tiemann and Schmid (Ber. 1897, 30, 227; b.p. $221^\circ\text{--}222^\circ$; sp. gr. $0\cdot936$; $[\alpha]_D +22\cdot89^\circ$).

The crystalline hydrochloride $\text{C}_{10}\text{H}_{17}\text{OCl}$ (m.p. $24\cdot25^\circ$) and hydrobromide $\text{C}_{10}\text{H}_{17}\text{OBr}$ (m.p. $40\cdot5^\circ$) give pulegone on treatment with alcoholic potash.

Semicarbazone $\text{C}_{10}\text{H}_{16}:\text{N}\cdot\text{NH}\cdot\text{CO}\cdot\text{NH}_2$, m.p. 172° ; oxime $\text{C}_{10}\text{H}_{16}:\text{NOH}$, m.p. $118^\circ\text{--}119^\circ$. Addition of hydroxylamine at the double linkage gives 8-hydroxylaminomenthone

(m.p. 157° , $[\alpha]_D -83\cdot44^\circ$) which may be successively oxidised to 8-nitrosomenthone (chromic acid) and 8-nitromenthone, m.p. 80° (nitric acid, sp. gr. 1.16) (Harries and Roeder, Ber. 1899, 32,

3364). The so-called pulegone dioxime, m.p. 118°, has the constitution

(Semmler, Ber. 1905, 38, 147).

On reduction, the following products are obtained, viz.: pulegol (Tiemann and Schmidt, Ber. 1896, 29, 914); menthol (Beckmann and Pleissner, Annalen, 1891, 262, 30); and a bimolecular reduction product, m.p. 119°, probably the corresponding pinacone (Harries and Roeder, Ber. 1899, 32, 3367; Law, Chem. Soc. Trans. 1912, 101, 1029; Paolini, Atti. R. Accad. Lincei, 1919, [v.] 28, ii, 190).

For the identification of pennyroyal, v. Baeyer and Henrich recommend conversion into the bisnitroso compound $(\text{C}_{10}\text{H}_{15}\text{O}_2\text{N})_2$. 2 c.c. pulegone, 2 c.c. petroleum spirit, and 1 c.c. amyl nitrite are mixed, and very little concentrated hydrochloric acid added; the mixture becomes milky in 20–25 seconds, and solidifies to a paste of fine long needles of the nitroso compound. This compound cannot be recrystallised, it dissolves in cold ammonia with a yellow colour (Ber. 1895, 28, 654).

Δ^1 -3-Menthenone

prepared by Wallach and Meister (Annalen, 1908, 362, 261) from 1 : 3 : 4-trihydroxyterpane has been identified as a constituent of Japanese peppermint oil (Schimmel's Bericht, October, 1910), b.p. 235°–237°. Oxime, m.p. 107°–109°; oxaminooxime, m.p. 164°–165°; two semicarbazones, α , m.p. 224°–226°; β , m.p. 171°–172°.

Piperitone $\text{C}_{10}\text{H}_{16}\text{O}$ occurs in *Eucalyptus piperita*. The green leaves and twigs of *E. dives* yield about 4 per cent. of the oil which contains up to 40 per cent. of piperitone (J. Proc. Roy. Soc. N.S. Wales, 1900, 34, 316). Smith and Penfold (*ibid.* 1920, 54, 40) have shown that it is an unsaturated lævo-rotatory ketone which racemises on distillation under ordinary pressure. The maximum observed value of $[\alpha]_D$ was -42.8° ;

this specimen gave d_4^{20} 0.9348; n_D^{20} 1.4837; R_L 46.49; b.p. 106°–107°/10 mm., 229°–230°/760 mm. Practically the same values are given by the optically inactive substance.

Several derivatives of the *dl*-form have been described by J. Read and H. G. Smith (Trans. Chem. Soc. 1921, 119, 779). On oxidation with ferric chloride and acetic acid, thymol is produced, whilst Smith and Penfold obtained menthone on reduction with hydrogen in presence of a nickel catalyst.

d-Piperitone has been found by Simonsen in the essential oil of *Andropogon inarancusa*, the author ascribes to it the structure of *d*- Δ^1 -*p*-menthen-3-one (Trans. Chem. Soc. 1921, 119, 1644. See also L. Givaudan and Co., *Perf. Essent. Oil Rec.* 1921, 19, 80).

Carvone (*p*- Δ^5 , $\delta^{(9)}$ -menthadiene-2-one)

occurs naturally in dextro- and lævo-rotatory

forms. The former (b.p. 224°, sp.gr. 0.9598 at 20°/4° $[\alpha]_D + 62.07^\circ$) occurs in the oils of caraway (*Carum Carvi* [Linn.]), fennel (*Feniculum vulgare* [Mill.]), and dill (*Peucedanum graveolens* [Benth. et Hook.]). The lævo-rotatory form (b.p. 223°–224°; sp.gr. 0.9593 at 20°/4°; $[\alpha]_D - 62.41^\circ$) occurs in spear mint (*Mentha viridis* [Linn.]) and kuromoji (*Lindera sericea* [Blume]). The isolation of carvone from oils is effected by conversion into the compound with hydrogen sulphide ($\text{C}_{10}\text{H}_{14}\text{O}_2\text{S}$), and subsequent decomposition with alcoholic potash. When heated, carvone yields carvacrol $\text{C}_6\text{H}_5(\text{OH})(\text{CH}_3)(i\text{-C}_3\text{H}_7)$. The isomerisation to carvacrol by heating with hydrochloric acid (D. 1.19) at 120°–125° is said to involve the intermediate formation of 8-chloro- Δ^6 -menthene-2-one (Arno Müller, J. pr. Chem. 1916, ii, 93, 10). The active carvoximes melt at 72°, the inactive at 93°. Carvoxime was first obtained by Tilden by the action of alcoholic potash on limonene nitrosochloride (J. 1877, 428). *d*- α - and *d*- β -Limonene nitrosochlorides correspond to *l*-carvone, the *la*- and *lb*-nitrosochlorides to *d*-carvone, whilst α - and β -dipentene nitrosochlorides give the oxime of *r*-carvone (Wallach, Annalen, 1888, 245, 256; 246, 226; 1891, 270, 171).

Harries has described a method for preparation of the carvoximes (Meyer-Jacobson's Lehrbuch, 1902, II, 939).

Hydrochlorocarvoxime $\text{C}_{10}\text{H}_{15}\text{Cl} : \text{NOH}$ melts at 135° (*d*- or *l*-) or 125.5° (*r*-). The melting-points of the hydrobromocarvoximes

are 133°–134° (*d*- or *l*-) and 128°–129° (*r*-).

d-Carvone yields *m*- and *p*-nitrophenylhydrazones $\text{C}_{10}\text{H}_{14} : \text{N} \cdot \text{NH} \cdot \text{C}_6\text{H}_4 \cdot \text{NO}_2$, which melt at 105°–106° and 174°–175° respectively (W. Borsche, Annalen, 1908, 359, 49).

Carvelone $\text{C}_{20}\text{H}_{30}\text{O}_2$ is obtained on reduction (Harries, Ber. 1899, 32, 1316). A second carvelone is known (Law, Chem. Soc. Trans. 1912, 101, 1028). Dihydrocarvone is produced on electrolytic reduction in aqueous alcoholic solution, using a copper cathode (Law, *ibid.* 1549).

Suberone $\text{C}_7\text{H}_{12}\text{O}$ (Preparation, General Method 1), smells like peppermint; b.p. (742 mm.) 178.5° sp.gr. 0.9685 at 0°.

Oxime $\text{C}_7\text{H}_{13} : \text{NOH}$, m.p. 23.3°, b.p. 230°; semicarbazone $\text{C}_7\text{H}_{12} : \text{N} \cdot \text{HN} \cdot \text{CO} \cdot \text{NH}_2$, m.p. 163°; dibenzal derivative $\text{C}_7\text{H}_9\text{O} : \text{CH} \cdot \text{C}_6\text{H}_5)_2$, m.p. 107°–108°; sulphonol $\text{C}_7\text{H}_{12}(\text{SO}_2\text{C}_2\text{H}_5)_2$ (by the action of mercaptan in presence of hydrogen chloride and oxidation of the resultant mercaptol), m.p. 136°–139°. Suberone gives ζ -hydroxybenzoic acid by oxidation with Caro's acid (v. Baeyer, Ber. 1900, 33, 962). Further derivatives are described by Tarbouriech (Compt. rend. 1913, 156, 75).

Willstätter obtained suberone as a degradation product of ecgonine:

(Ber. 1898, 31, 2498). Tropinone and *r*-ecgonine have been completely synthesised by Willstätter and Bommer (Annalen, 1921, 422, 15).

Tropilene $\begin{array}{c} \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}_2 \\ | \\ \text{CH}_2 \cdot \text{CH} \cdot \text{CH} \end{array} \text{CO}$, an oil of high

refractive power and odour of bitter almonds, is difficultly soluble in water, and boils at 186° – 188° . It is obtained from tropine by exhaustive methylation (Ladenburg, Ber. 1881, 14, 2403; Annalen, 1883, 217, 132, 138; Merling, Ber. 1891, 24, 3123); its constitution was correctly recognised by Willstätter (Ber. 1898, 31, 1545; 1901, 34, 133).

cycloOctanone $\text{C}_8\text{H}_{14}\text{O}$ was obtained by Mager (Annalen, 1893, 275, 363) by distilling the calcium salt of azelaic acid, b.p. about 205° .

pseudoPelletierine or **methylgranatonine** is an alkaloid obtained from the pomegranate tree (*Punica Granatum* [Linn.]). Its constitution has been determined as:

by Willstätter and Veraguth (Ber. 1905, 38, 1975, 1984).

II. Bicyclic Monoketones.

Of the numerous monoketones derived from bicyclic hydrocarbons only a few can be mentioned.

Thujone (Tanacetone) $\text{C}_{10}\text{H}_{16}\text{O}$ is known in stereoisomeric forms, it occurs in *Arbor vitae* (*Thuja occidentalis* [Linn.]), tansy (*Tanacetum vulgare* [Linn.]), *Artemisia* and *Salvia*. α -Thujone predominates in thuja oil, $[\alpha]_D -10.23^\circ$; *oxime* $\text{C}_{10}\text{H}_{16}:\text{NOH}$, $[\alpha]_D -25.25^\circ$ in ethereal solution, *semicarbazone* $\text{C}_{10}\text{H}_{16}:\text{N}\cdot\text{NH}\cdot\text{CO}\cdot\text{NH}_2$, $[\alpha]_D +59.9^\circ$ in methyl alcoholic solution. β -Thujone is found in tansy oil $[\alpha]_D$ about $+70^\circ$, *oxime*, m.p. 54° – 55° , $[\alpha]_D +105.1^\circ$ in methyl alcoholic solution; *semicarbazone*, dimorphic, hexagonal, m.p. 174° – 175° , rhombic, m.p. 170° – 172° . Other derivatives v. Kijner, J. Russ. Phys. Chem. Soc. 1910, 42, 1198; 1911, 43, 577, 951, 1132.

Artemisia oil seems to contain a third feebly dextro-rotatory thujone (Wallach, Annalen, 1893, 275, 179; 1894, 279, 383; 1895, 286, 90; 1904, 336, 247). Thujone probably possesses the structure:

(Tschugaeff, Ber. 1900, 33, 3122; Semmler, *ibid.* 1900, 33, 275; 1903, 36, 4367; D. Thomson, Chem. Soc. Trans. 1910, 97, 1502).

Carone $\text{C}_{10}\text{H}_{16}\text{O}$, obtained by the action of alcoholic potash on the hydrobromide of dihydrocarvone, is also probably bicyclic (v. Baeyer, Ber. 1894, 27, 2715; 1895, 28, 639, 1586; 1896, 29, 3, 2796; 1898, 31, 1401, 2067).

Camphor $\text{C}_{10}\text{H}_{16}\text{O}$ (*q.v.*) occurs in the dextro-rotatory form ($[\alpha]_D +44.22^\circ$ in 20 p.c. alcoholic solution) in *Cinnamomum Camphora* (Nees and Eberm.) and other plants, m.p. 178.4° , b.p. 209° . The *lævo*-forms occurs in the oils of *Matricaria*, *Salvia*, and *Tanacetum*. Bredt gives the follow-

ing formulæ for camphor and its oxidation product, camphoric acid (Ber. 1893, 26, 3047; Annalen, 1896, 292, 55):—

Camphor has been obtained by distillation of the lead (Haller) and calcium (Bredt and Rosenberg) salts of homo-camphoric acid: respecting the synthesis of camphoric acid, see Kommpa (Ber. 1903, 36, 4332), Blanc and Thorpe (Chem. Soc. Trans. 1910, 97, 836), and Kommpa (Chem. Soc. Trans. 1911, 99, 29).

In *Epicanphor* $[\alpha]_D -58.2^\circ$, m.p. 182° , the positions of the carbonyl and adjacent methylene group are interchanged (Lankshear and Perkin, Proc. Chem. Soc. 1911, 27, 167; Bredt and Perkin, Trans. Chem. Soc. 1913, 103, 2182; Furness and Perkin, *ibid.* 1914, 105, 2024; Perkin and Titley, *ibid.* 1921, 119, 1089).

Fenchone $\text{C}_{10}\text{H}_{16}\text{O}$ occurs in nature as optical antipodes. The dextro-rotatory modification was found by Wallach and Hartmann (Annalen, 1890, 259, 324) in the portion of fennel oil boiling at 190° – 195° , whilst *l*-fenchone is a constituent of the corresponding fraction of thuja oil. The two fenchones melt at 5° – 6° , boil at 192° – 193° ; sp.gr. 0.9465 at 19° . *d*-Fenchone gives $[\alpha]_D +71.97^\circ$, the *l*-fenchone a slightly lower value (see also Bartram and Helle, J. pr. Chem. 1900, [ii.] 61, 293). Fenchone does not combine with sodium bisulphite; the *oximes* melt at 161° . Many derivatives have been prepared by Wallach; much *m*-cymene is produced on heating to 115° – 130° with phosphorus pentoxide (Annalen, 1891, 263, 129; 1892, 269, 326; 1893, 272, 99; 1893, 275, 145; 1895, 284, 324; 1901, 315, 291).

Of the following formulæ for fenchone:

the first was proposed by Wallach, the other two by Semmler (Ber. 1906, 39, 2577). L. Bouveault and F. Levallois prefer formula II. above (Semmler's first formula), and have brought forward considerable evidence in its favour (Compt. rend. 1908, 146, 180; 1909, 148, 1399, 1524; Bull. Soc. chim. 1910, [iv.] 7, 542, 683, 736, 807, 963, 968; Wallach, Annalen, 1911, 379, 182, 215). Other bicyclic ketones are described by Godchot and Taboury (Compt. rend. 1919, 169, 1168).

III. Monocyclic Diketones, &c.

1 : 3-cycloButanedione $\begin{array}{c} \text{CH}_2 \text{--- CO} \\ | \\ \text{CO} \text{--- CH}_2 \end{array}$. This is

possibly the dimeric form of ketene (Chick and Wilsmore, Chem. Soc. Trans. 1908, 93, 946;

1910, 97, 1978). One ketone group may be enolised, in which case the substance is really Δ^1 -cyclobuten-1-ol-3-one (Staudinger and Bereza, Ber. 1909, 42, 4908). Derivatives are described Schroeter, Ber. 1916, 49, 2697).

1 : 2-cycloPentanedione

(preparation, *v.s.*) is easily soluble in water, the solution reddens litmus, and is coloured violet by ferric chloride. In some respects it behaves as if one CH_2CO group were enolised, giving a phenylurethane $\text{C}_6\text{H}_5\text{O} \cdot \text{O} \cdot \text{CO} \cdot \text{NH} \cdot \text{C}_6\text{H}_5$, m.p. 122°, and benzoyl ester $\text{C}_6\text{H}_5\text{O} \cdot \text{O} \cdot \text{CO} \cdot \text{C}_6\text{H}_5$, m.p. 72°–73°. As a 1 : 2-diketone it yields a *dioxime* $\text{C}_5\text{H}_6(\text{:NOH})_2$, m.p. 210°; an *osazone* $\text{C}_5\text{H}_6(\text{:N} \cdot \text{NH} \cdot \text{C}_6\text{H}_5)_2$, m.p. 146°; and a *quinoxaline* $\text{CH}_2 \begin{array}{l} \diagup \text{CH}_2 - \text{C} = \text{N} \\ \diagdown \text{CH}_2 - \text{C} = \text{N} \end{array} \text{C}_6\text{H}_4$, m.p. 102°–103°.

1 : 3-cycloHexanedione (Dihydroresorcinol)

$\text{C}_6\text{H}_8\text{O}_2$ was obtained by Merling by the reduction of resorcinol in boiling alcoholic solution with sodium amalgam, carbon dioxide being led in during the operation (Annalen, 1894, 278, 28). Vorländer synthesised the diketone by the action of sodium on ethyl γ -acetobutyrate (Ber. 1895, 28, 3428); barium hydroxide breaks the ring, giving γ -acetobutyric acid :

m.p. 104°–106°; *dioxime*, m.p. 154°–157°; *monophenylhydrazone*, m.p. 176°–177°. Alkyl and aryl derivatives, see Borsche, Ber. 1909, 42, 4496.

Dimethyldihydroresorcinol (1 : 1 dimethylcyclohexanedione-3 : 5) has been obtained by D. Vorländer (Annalen, 1897, 294, 253, 300; 1898, 304, 15) and A. W. Crossley (Chem. Soc. Trans. 1899, 75, 771); the latter chemist has examined it exhaustively (see later papers).

An *O*-acetyl derivative is known (Dieckmann and Stein, Ber. 1904, 37, 338); in presence of a small amount of sodium acetate the acetyl group enters into the ring. For the resulting *O*-acetyl derivative, Crossley and Renouf (Chem. Soc. Trans. 1912, 101, 1524) consider the structure

The tautomerism of trimethyldihydroresorcin is dealt with by Crossley and Renouf (Chem. Soc. Trans. 1911, 99, 1101; 1912, 101, 1524).

Both Vorländer and Crossley condensed ethyl sodiomalonate with mesityl oxide thus obtaining ethyl 1 : 1-dimethylcyclohexane-3 : 5-dione-2-carboxylate from which 'dimethyldihydroresorcinol' was prepared by hydrolysis and elimination of carbon dioxide. M.p. 148.5°.

Norris and Thorpe (Trans. Chem. Soc. 1921, 119, 1199) find that cyclohexenylacetone (Wallach, Annalen, 1912, 394, 362) and cyclopentenylacetone (Kon, Trans. Chem. Soc. 1921, 119, 823)

may also be condensed with ethyl sodiomalonate yielding esters which furnish respectively on hydrolysis and loss of carbon dioxide.

Cyclohexane spirocyclohexane-3 : 5-dione, m.p. 170.5° and **cyclopentane spirocyclohexane-3 : 5-dione**, m.p. 135°–136.5°. Other *spiroketonic* compounds, Ingold and Thorpe, (Trans. Chem. Soc. 1919, 115, 320); Farmer and Ingold (Trans. Chem. Soc. 1920, 117, 1362).

1 : 4-cycloHexanedione $\text{C}_6\text{H}_8\text{O}_2$ is obtained in small quantity by the dry distillation of calcium succinate (Feist, Ber. 1895, 28, 738). v. Baeyer (Annalen, 1894, 278, 91) obtains a good yield of the ketone in the following manner : 100 grams of diethyl diacetosuccinate are dissolved in 420 c.c. of concentrated sulphuric acid, the solution being meanwhile cooled and then poured on to ice (1450 grams). After addition of 40 c.c. of alcohol the mixture is boiled for 16 hours, the alcohol distilled off and the residue nearly neutralised with calcined sodium carbonate. The sodium sulphate is frozen out, the filtrate saturated with ammonium sulphate, and the diketone extracted with chloroform, m.p. 78°; *dioxime*, m.p. 192°; *dicyanhydrin*, m.p. 180°.

Phloroglucinol $\text{C}_6\text{H}_3(\text{OH})_3$ 1 : 3 : 5 behaves tautomerically as cyclohexanetrione, giving a *trioxime* $\text{C}_6\text{H}_3(\text{:NOH})_3$, m.p. 155°. See, further, Heller, Ber. 1912, 45, 418; Göschke and Tambor, *ibid.* 1237; Sonn, Ber. 1919, 52, 255; Fuchs and Elsner, Ber. 1919, 52, 2281; 1920, 53, 886; 1921, 54, 245; Bucherer, Ber. 1920, 53, 1457; Herzig and Zeisel, *ibid.* 1518.

A few cyclic polyketones may be mentioned. The potassium carboxide $(\text{KCO})_n$ prepared by Liebig (Annalen, 1834, 11, 182), and which forms a by-product in Brunner's method of manufacturing potassium (Brodie, Annalen, 1860, 113, 358), is the potassium derivative of hexahydroxybenzene (Nietzki and Benckiser, Ber. 1885, 18, 499; 1886, 19, 293, 772). Treatment with dilute alcohol gives rhodizonic acid $\text{C}_6\text{H}_4\text{O}_6$ (Heller, Annalen, 1837, 24, 1; 1840, 34, 252; 1862, 124, 32; Will, *ibid.* 1861, 118, 189). Rhodizonic acid, as well as hexahydroxybenzene, when oxidised, give triquinoyl $\text{C}_6\text{H}_4\text{O}_{14}$ or $\text{C}_6\text{H}_6 \cdot 8\text{H}_2\text{O}$. Alkalis convert rhodizonic acid into croconic acid $\text{C}_6\text{H}_2\text{O}_5$ (see Zincke, Ber. 1887, 20, 1267, footnote), and the latter compound can be oxidised to leuconic acid. All four compounds appear to be cyclic polyketones :

3-Ethylcyclopentane-1 : 2 : 4-trione, m.p. 173° (E. Koenigs and W. Ottmann, Ber. 1921, 54, 1343).

IV. Aromatic Cyclic Ketones.

Only the briefest reference can be made to the cyclic ketones, in which both ends of the closed chain containing carbonyl groups are united to aromatic nuclei.

Coumaran $C_6H_4<\overset{CH_2}{O}>CH_2$ gives rise to two ketones, coumaranone $C_6H_4<\overset{CO}{O}>CH_2$, and coumarandione $C_6H_4<\overset{CO}{O}>CO$. The latter compound, despite its name, is really a monoketone, the second carbonyl is lactonic.

Coumaranone $C_6H_4<\overset{CO}{O}>CH_2$ is obtained by the hydrolysis of the esters of coumaranone-carboxylic acid (Friedländer, Ber. 1899, 32, 1868); by boiling ω -bromo-*o*-acetoxyacetophenone with water and calcium carbonate (F. Ber. 1897, 30, 1081) and by the action of phosphorus pentoxide on phenoxyacetic acid (Störmer and Bartsch, Ber. 1900, 33, 3177). White needles, m.p. 101°–102°. *Oxime*, m.p. 159°; *isonitroso* derivative, m.p. 172°; this can be regarded as the monoxime of the dione.

Coumaranone is the oxygen analogue of indoxyl and forms a series of 'oxindogenides' (Fries, Ber. 1911, 44, 114, 124). Numerous coumaranone derivatives have been prepared (Merriman, Chem. Soc. Trans. 1911, 99, 911; 1913, 103, 1838, 1845; von Auwers, Annalen, 1912, 393, 338; Ber. 1914, 47, 2334; 1919, 52, 77, 92; 1920, 53, 2271; Higginbotham and Stephen, Trans. Chem. Soc. 1:20, 117, 1534).

Coumarandione $C_6H_4<\overset{CO}{O}>CO$ is obtained by dehydration of *o*-hydroxyphenylglyoxylic acid. The carbonyl group in position 2 condenses easily with amino-compounds (Fries and Pfaffendorf, Ber. 1912, 45, 154; Stoermer, *ibid.* 162. See also Staudinger, Schlenker and Goldstein, Hb. Chim. Acta, 1921, 4, 334; Stollé and Knebel, Ber. 1921, 54, 1213).

Closely related is 2:2'-diketo- $\Delta^1:1'$ -dicoumaran $C_6H_4<\overset{CO}{O}>\dot{C}:C<\overset{CO}{O}>C_6H_4$, the so-called 'oxindigo' (Fries, Hasselbach and Schröder, Annalen, 1914, 405, 346).

Benzocoumaranones are described by K. Fries and R. Frellstedt (Ber. 1921, 54, 715).

Hydrindene $C_6H_4<\overset{CH_2}{CH_2}>CH_2$ gives rise to two hydrindones, two diketohydrindenes, and one triketohydrindene. The properties of these compounds are those to be expected of monoketones, α - and β -diketones and triketones respectively.

α -Hydrindone $C_6H_4<\overset{CH_2}{CO}>CH_2$. Prepared in several ways. Gently warm ethyl *o*-cyanohydrocinnamate with concentrated hydrochloric acid

(Gabriel and Hausmann, Ber. 1889, 22, 2018). Distil *o*-carboxyhydrocinnamic acid (König, Annalen, 1893, 275, 342). By the action of aluminium chloride on phenylpropionyl chloride dissolved in petroleum spirit (Kipping, Chem. Soc. Trans. 1894, 65, 485; also Ingold and Thorpe, Trans. Chem. Soc. 1919, 115, 1419), m.p. 40°, b.p. 243°–245°. *Oxime*, m.p. 146°; *semicarbazone*, m.p. 239°.

The methylene group adjacent to carbonyl reacts with the aldehyde group and nitrous acid. The *isonitroso*-compound produced in the latter

case is the monoxime of $\alpha\beta$ -diketohydrindene. Many derivatives are known.

β -Hydrindone $C_6H_4<\overset{CH_2}{CH_2}>CO$ is obtained by distillation of calcium *o*-phenylenediacetate (Schad, Ber. 1893, 26, 222; Benedikt, Annalen, 1893, 275, 353), and by heating hydrindene glycol with dilute sulphuric acid (Heusler and Schieffer, Ber. 1899, 32, 30), m.p. 58° or 60°, b.p. 220°–225°. *Oxime*, m.p. 155°.

$\alpha\beta$ -Diketohydrindene $C_6H_4<\overset{CO}{CH_2}>CO$ results when *iso*-nitroso- α -hydrindone is hydrolysed by hydrochloric acid in presence of formaldehyde (Perkin, Roberts and Robinson, Chem. Soc. Trans. 1912, 101, 232). Golden-yellow plates, m.p. 95°–115°. The *oxime*, *semicarbazone*, *quinoxaline*, and *osazone* have been prepared. (See, further, Chem. Soc. Trans. 1914, 105, 2405; and von Braun, Ber. 1913, 46, 3641; 1916, 49, 1268.)

$\alpha\gamma$ -Diketohydrindene $C_6H_4<\overset{CO}{CO}>CH_2$. Phthalic ester and acetic ester are condensed by sodium ethoxide, the resulting diketohydrindene carboxylic ester hydrolysed, and carbon dioxide eliminated from the resulting acid (Gabriel and Neumann, Ber. 1893, 26, 954), m.p. 129°–131°.

The methylene group is very reactive, and anhydroidiketohydrindene is produced by elimination of water between two molecules (Wislicenus and Kötze, Annalen, 1889, 252, 76). According to Hantzsch (Annalen, 1912, 392, 322), anhydroidiketohydrindene is

Phenyldiazonium salts give triketohydrindene- β -phenylhydrazones.

Tautomerism is observed in the derivatives, and whilst the *anil* (m.p. 208°) is probably $C_6H_4<\overset{CO}{C}\equiv N\cdot C_6H_5$ in the free state, the salts produced with acids and alkalis are probably derived from the forms $C_6H_4<\overset{CO}{C}\equiv\overset{CH}{NH}\cdot C_6H_5$

The enolisation of 2-monoacylindane-1:3-diones may give compounds of the type $C_6H_4<\overset{CO}{CO}>C:CR\cdot OH$ (Scheiber and Hopper, Ber. 1920, 53, 697).

Numerous homologues of the type

have been synthesised by Freund and Fleischer (Annalen, 1913, 399, 182; 1913, 402, 51; 1915, 409, 268; 1917, 414, 1; Das and Ghosh, J. Amer. Chem. Soc. 1919, 41, 1221; Fleischer, Annalen, 1921, 422, 231, 265, 272, 317).

Triketohydrindene $C_6H_4<\overset{CO}{CO}>CO$ results on oxidising an alkaline solution of $\alpha\gamma$ -diketohydrindene, with 3–3½ p.c. hydrogen peroxide solution, m.p. 190°–206° (with decomposition)

(Kaufmann, Ber. 1897, 30, 387; cf. Ruhemann, Chem. Soc. Trans. 1910, 97, 1438, 2025).

Bis- α -Hydrindene-2 : 2)-spiran

is obtained in small amount by distilling dibenzylmalonyl chloride with 2 p.c. of aluminium chloride under reduced pressure, m.p. 174° , b.p. $255^\circ\text{--}257^\circ$ (Leuchs and Radulesen, Ber. 1912, 45, 189).

1 : 2-Naphthindandione, m.p. 180° (Noto, Gazz. chim. ital. 1915, 45, ii. 126).

Perinaphthindandione

m.p. 265° (Errera, Gazz. chim. ital. 1911, 41, i. 190, ii. 807; 1913, 43, ii. 625; Calderaro, *ibid.* 1916, 46, i. 261).

Fluorene ketone

the distillation of calcium diphenate with lime (Fittig and Ostermayer, Annalen, 1873, 166, 373); by oxidation of phenanthraquinone with alkaline permanganate (Anschütz and Japp, Ber. 1878, 11, 212); and by oxidation of fluorene alcohol.

Yellow rhombic tablets, m.p. $83.5^\circ\text{--}84^\circ$.

A supposed pseudo-form is non-existent (Pummerer, Ber. 1914, 45, 294).

Pyrene ketone C_{10}H_6

tained by Bamberger and Philip by distillation of pyrenic acid $\text{C}_{15}\text{H}_8\text{O}_5$ with slaked lime, m.p. 83° , b.p. $235^\circ\text{--}250^\circ$ (Annalen, 1887, 240, 178).

Benzanthrone $\text{C}_{17}\text{H}_{10}$. These contain benzene and naphthalene residues united directly and also through a carbonyl group.

1 : 9-Benzanthrone

is obtained by heating phenyl- α -naphthyl ketone with 5 parts of aluminium chloride for 5 hours at 150° (Scholl, Annalen, 1912, 394, 111), or by elimination of water from α -naphthylbenzoic acid by means of sulphuric acid (Schaarschmidt, Ber. 1917, 50, 294).

The ketonic properties of the carbonyl group are usually profoundly modified when it forms one of the members of a heterocyclic chain. This is observed in the following well-known examples:—

Pyridone. Pyrone. Chromone. Xanthone.

KETONIC ACIDS AND ESTERS.

Whilst a few ketonic acids (*e.g.* pyruvic and lœvulic) are obtained by special reactions, these

substances are generally obtained as esters by condensation of simpler esters or esters and ketones under the influence of sodium, sodium ethoxide, &c.

α -Ketonic Monobasic Acids.

Pyruvic acid (*Pyroracemic* or *Propanonic acid*) $\text{CH}_3\cdot\text{CO}\cdot\text{CO}_2\text{H}$ can be obtained by the distillation of tartaric or racemic acids (Berzelius, Pogg. Ann. 1835, 36, 1); of glyceric acid (Moldenhauer, Annalen, 1864, 131, 338); and from α -dichloro- or α -dibromopropionic acids or their esters by the action of moist silver oxide (Beckurts and Otto, Ber. 1877, 10, 264; 1885, 18, 228). Claisen and Shadwell hydrolysed acetyl cyanide with hydrochloric acid (Ber. 1878, 11, 620, 1563), and Beilstein and Wiegand oxidised calcium lactate with potassium permanganate (*ibid.* 1884, 17, 840) (*v.* PYRUVIC ACID).

Pyruvic acid is prepared by distilling 500 grams of tartaric acid and 780 grams of commercial potassium bisulphate from a copper retort of 2 litres capacity. The process is complete in 30 minutes, and a 60 p.c. yield is obtained after rectifying the product under reduced pressure, b.p. $59^\circ\text{--}60^\circ$ at 12 mm. (A. Wohl and R. Maag, Ber. 1910, 43, 2188).

The decomposition of tartaric acid on distillation under reduced pressure and at a temperature not much exceeding 180° gives rise to much acetic and less pyruvic acid (Chattaway and Ray, Trans. Chem. Soc. 1920, 119, 34).

The salts crystallise when prepared in the cold; the solutions, if boiled, only yield gummy masses.

The esters hydrolyse very readily (Sudborough, Chem. Soc. Trans. 1912, 101, 1227).

Condensation with benzaldehyde gives keto-acetylphenyl paracone

(Mumm, Ber. 1912, 45, 3236). This compound had been previously described by Ruhemann (Chem. Soc. Trans. 1906, 89, 1236).

Pyruvic acid shows the reaction of a (methyl) ketone as well as an acid, *e.g.*

and $\text{CH}_3\cdot\text{C}(\text{OH})(\text{SO}_2\text{Na})\text{CO}_2\text{Na}\cdot\text{H}_2\text{O}$ are known.

The possibility of the enolisation of derivatives of pyruvic acid is raised by the isolation of an *O*-acetyl derivative of phenylpyruvic acid $\text{C}_6\text{H}_5\cdot\text{CH}:\text{C}(\text{OCOCH}_3)\cdot\text{CO}_2\text{H}$ (Bougault and Hemmerlé, Compt. rend. 1915, 160, 100).

Pyruvic acid phenylhydrazone

forms shining needles, m.p. 192° . The *ethyl ester* $\text{C}_9\text{H}_9\text{O}_2\text{N}_2\cdot\text{C}_2\text{H}_5$, m.p. $116^\circ\text{--}117^\circ$, when heated 3 or 4 minutes with its own weight of zinc chloride, yields ethyl indole carboxylate (E. Fischer, Annalen, 1886, 236, 142):

Tetronic acids, α - and β - These are lactones of γ -hydroxyketobutyric acids, and are probably to be represented as true enols:

(Wolff and Schwabe, *Annalen*, 1896, 291, 226; Lapworth, *Chem. Soc. Trans.* 1915, 107, 135, 1254).

Benzoylformic acid $\text{C}_6\text{H}_5\cdot\text{CO}\cdot\text{CO}_2\text{H}$ is obtained by the hydrolysis of benzoyl cyanide with hydrochloric acid (Claisen, *Ber.* 1877, 10, 845), m.p. 65° – 66° ; easily soluble in water; reduced by sodium amalgam to mandelic acid, and by hydriodic acid and amorphous phosphorus to α -toluic acid. *Phenylhydrazone*

m.p. 153° (with decomposition into carbon-dioxide and benzalphenylhydrazone).

Phenylpyruvic acid $\text{C}_6\text{H}_5\cdot\text{CH}_2\cdot\text{CO}\cdot\text{COOH}$. Three forms of the ethyl ester are known, to which the following structures are assigned:—

Ethyl β -phenylpyruvate reacts with acid anhydrides and chlorides yielding ethyl acyloxy-cinnamates, e.g.

m.p. 33° – 34° . Such derivatives do not form additive compounds with bromine, but immediately discolorise alkaline permanganate (H. Gault and R. Weick, *Compt. rend.* 1920, 170, 1392; 1920, 171, 395; 1921, 173, 391).

β -Ketonic Monobasic Acids.

The β -ketonic acids are extremely unstable, decomposing very readily into carbon dioxide and a ketone:

Owing to the reactivity of the methylene group, the esters of these acids are valuable synthetic agents; they are prepared by the action of sodium (sodium ethoxide, &c.) on esters or mixtures of esters and decomposition of the resultant sodium derivatives with dilute acetic acid:

Ethyl acetoacetate $\text{CH}_3\cdot\text{CO}\cdot\text{CH}_2\cdot\text{COOC}_2\text{H}_5$ is obtained by the action of sodium on ethyl acetate (Geuther, *J.* 1863, 233; *Zeitsch. Chem.* 1866, 5; Wislicenus, *Annalen*, 1877, 186, 161; Matthews and Hodgkinson, *Ber.* 1882, 15, 2679); b.p. 180.6° – 181.2° ; sp. gr. at $20^\circ/4^\circ$ 1.0256 (Brühl, *Annalen*, 1880, 203, 27); b.p. 71° at 12.52 mm. (Kahlbaum). Preparation on large scale (Cobenzl, *Chem. Zeit.* 1914, 38, 665). Free acetoacetic acid is described by Ceresole as a thickish liquid, miscible with water, reacting strongly acid, and decomposing violently below 100° into carbon dioxide and acetone. Ceresole

obtained the acid by allowing 4.5 parts of ethyl acetoacetate, 2.1 parts of caustic potash, and 80 parts of water to stand for 24 hours, then acidifying with sulphuric acid and extracting with ether (*Ber.* 1882, 15, 1327, 1872).

In addition to the use of acetoacetic ester in the laboratory, it is employed in the preparation of pyrazolone derivatives, e.g. antipyrine and pyrazolone dyestuffs (*see* *Farbenfab. vorm. Fr. Bayer & Co.*, *Eng. Pat.* 532 of 1910 (*v.* PYRAZOLONE).

Ethyl acetoacetate reacts tautomerically as $\text{CH}_3\cdot\text{C}(\text{OH})\cdot\text{CH}\cdot\text{CO}_2\text{C}_2\text{H}_5$ and

Knorr, Rothe, and Averbek (*Ber.* 1911, 44, 1138) have isolated the two forms, the ketonic ester being sparingly soluble in organic solvents at low temperatures. Both forms may be distilled in a high vacuum with little change.

Ketonic ester, b.p. 40° – $41^\circ/2$ mm., n_D^{10} 1.4225; enolic ester, b.p. 33° , n_D^{10} 1.4480. For the equilibrium mixture, b.p. 39° – $40^\circ/2$ mm., n_D^{10} 1.4230 to 1.4232.

K. H. Meyer and V. Schoeller find that when ethyl acetoacetate is distilled from a glass vessel at 2 mm. pressure, the distillate is far richer in the enolic form (about 70 p.c.), whilst the residue contains only 5 p.c. of enol. The enolisation is due to the catalytic action of the glass, for on distilling from a silica flask, three fractions and a residue, all of equal volume, gave 22, 11, 2.5 and 0 p.c. respectively. Hence the best way of obtaining the pure ketonic form is to distil under "aseptic" conditions (*Ber.* 1920, 53, 1410).

The pure enol may be obtained by distilling the equilibrium ester from a Jena glass vessel in presence of a trace of phthalic acid. The distillate, containing 88 p.c. enol, is collected in a quartz vessel and immediately refractionated from a silica apparatus, the pure enol forming the first fraction; n_D^{10} 1.4475. The method has also been applied to the preparation of enolic acetylacetone, which was obtained with about 1 p.c. of the ketone; n_D^{10} 1.4625 (K. H. Meyer and H. Hopff, *Ber.* 1921, 54, 579).

The question of this tautomerism has been much discussed, some of the papers bearing on this matter which have appeared since 1890 are as follows:—

J. U. Nef (*Annalen*, 1891, 266, 52; 1893, 276, 239); W. H. Perkin, *sen.* (*Chem. Soc. Trans.* 1892, 61, 800); J. W. Brühl (*Ber.* 1894, 27, 2378; *J. pr. Chem.* 1894, [ii.] 50, 119); L. Claisen (*Annalen*, 1893, 277, 162; *Ber.* 1892, 25, 1763); A. Michael (*Amer. Chem. J.* 1892, 14, 481; *Ber.* 1905, 38, 22; *cf.* H. Goldschmidt, *ibid.* 1096); A. Lapworth (*Chem. Soc. Trans.* 1902, 81, 1491, 1499; 1903, 83, 1114; 1904, 85, 30, 46; 1908, 93, 30; 1911, 99, 1882); E. C. Baly and C. H. Desch (*ibid.* 1904, 85, 1029; 1905, 87, 766); R. S. Morrell (*Chem. Soc. Proc.* 1898, 14, 121; *Chem. Soc. Trans.* 1903, 83, 1292); R. Schenck and E. Ellenberger (*Ber.* 1904, 37, 3443); F. Giolitti (*Gazz. chim. ital.* 1904, 34, ii. 208); S. F. Acree (*Amer. Chem. J.* 1907, 37, 71); A. E. Dunstan and J. A. Stubbs (*Chem. Soc. Trans.* 1908, 93, 1919); A. Hantzsch (*Ber.* 1910, 43, 3049; *ibid.* 1911, 44, 1771);

Dawson and co-workers (Chem. Soc. Trans. 1909, 95, 1860; 1910, 97, 2048; 1911, 99, 1, 1740; 1912, 101, 1503); Knorr (*ibid.* 1911, 44, 1138, 2767); Kurt Meyer (Annalen, 1911, 380, 212; Ber. 1911, 44, 2718, 2725, 2729; 1912, 45, 2843; Annalen, 1913, 398, 49).

A coloration with ferric chloride is produced by enolic modifications of ketones and ketonic esters, and not by the ketonic forms.

In arriving at a decision as to the proportion of ketone and enol in an equilibrium mixture, either physical or chemical methods may be employed. The β -ketonic esters and 1:3-diketones have been specially examined, and, of the physical methods, those depending on optical properties have received most attention. Thus, W. H. Perkin, sen., made use of magnetic rotation, Brühl of refraction and dispersion, whilst Hantzsch (Ber. 1915, 48, 1407) photographed absorption spectra. The results obtained by different methods have not always agreed, much depending on the interpretation of the measurements. A further complication is caused by the displacement of equilibrium when a solvent is employed, as in the case of photographing absorption spectra.

Of purely chemical methods of determining the proportion of enol in a mixture, that due to Kurt Meyer is important. The substance is dissolved in alcohol, alcoholic solution of bromine added until the colour is no longer discharged and the excess of bromine removed by alcoholic β -naphthol. The bromo-ketone derived from the enol is then reduced by excess of potassium iodide

$\cdot\text{CO}\cdot\text{CBr} < + 2\text{KI} + \text{H}_2\text{O} = \cdot\text{CO}\cdot\text{CH} < + \text{KOH} + \text{I}_2$
and the liberated iodine estimated with $N/10$ -thiosulphate

Ordinary ethyl acetoacetate consists of about 92.6 p.c. of the keto and 7.4 p.c. of the enol modification. Water favours the keto-form, whilst dilution with hexane enolises the ester.

The proportion of enol present in equilibrium mixtures as determined by refractometric and chemical methods do not always agree. When a simple ketone is in question, a decision between $\cdot\text{CO}\cdot\text{CHR}$ and $\text{C}(\text{OH})\cdot\text{CR}$ is easy to arrive at.

In the case of diketones, von Auwers (Annalen, 1918, 415, 169) shows that useful results may be obtained from refractometric measurements, if due allowance be made for the exaltation caused by conjugation when the grouping $\cdot\text{C}(\text{OH})\cdot\text{CR}\cdot\text{CR}\cdot\text{O}$ occurs.

This can be done if compounds containing the groupings

$\cdot\text{CH}\cdot\text{CH}\cdot\text{CR}\cdot\text{O}$ and $\cdot\text{CH}\cdot\text{CH}\cdot\text{C}(\text{OH})\cdot\text{O}$

as well as substitution derivatives are measured, and the results compared with those obtained from the substance under examination.

Deductions have also been drawn from a study of the products obtained on electrolytically reducing aceto-acetic ester and its derivatives. Tafel has considered constitutions such as

for the substitution derivatives of acetoacetic

ester (Ber. 1907, 40, 3312; 1909, 42, 2548; 1912, 45, 437). A useful account of tautomerism, including that of the ketones and ketonic esters, is given in the Presidential Address by W. H. Perkin, jun. (Chem. Soc. Trans. 1914, 105, 1176).

The electronic constitution of acetoacetic acid is discussed by Hauke and Noessler (J. Amer. Chem. Soc. 1918, 40, 1726).

Oxidation of sodium acetoacetate with potassium permanganate gives acetic, oxalic and glyoxylic acids (Engfeldt, Zeitsch. physiol. Chem. 1921, 112, 176).

Ethyl γ -chloroacetoacetate (J. F. Hamel, Bull. Soc. chim. 1921, [iv.] 29, 390) is converted by sodium ethoxide or phenoxide into ethyl succinylsuccinate, m.p. 126–127° (Sommelet, *ibid.* 402, 553).

γ -Ketonic Monobasic Acids.

Lævulic acid $\text{CH}_3\cdot\text{CO}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$ is obtained synthetically from diethyl acetosuccinate (b.p. 254°–256°, sp.gr. 1.08809 at 15°), produced from ethyl chloroacetate and the sodium derivative of ethyl acetoacetate by boiling with twice its volume of dilute hydrochloric acid (Conrad, Annalen, 1877, 188, 222):

It is obtained from various carbohydrates by boiling with acids e.g. lævulose, glucose, cane sugar, milk sugar, inulin (Tollens, Annalen, 1875, 175, 181; 1881, 206, 231; 1885, 227, 228); pine shavings, Carrageen moss and gum arabic (Bente, Ber. 1875, 8, 416, 1157). Conrad and Guthzeit (*ibid.* 1885, 18, 1442) recommend warming 20 grams of cane sugar with 50 grams of water containing 9.43 grams of hydrogen chloride for 17 hours on the water-bath. The liquid is filtered, evaporated on the water-bath, and extracted with ether; the ethereal extract is concentrated and distilled under reduced pressure.

W. A. van Ekenstein and J. J. Blanksma find the conversion of hexoses into lævulic acid takes place in two stages, hydroxyfurfuraldehyde which is first formed, giving lævulic and formic acids subsequently (Chem. Weekblad, 1910, 7, 387).

Lævulic acid has m.p. 33.5°, b.p. 250° (with slight decomposition); sp.gr. 1.135 at 15°. Optical constants (von Auwers and Heinze, Ber. 1919, 52, 584). Easily soluble in water, alcohol, and ether. Reduced by sodium amalgam in alcoholic solution to γ -hydroxyvaleric acid. Yields iodoform with iodine and caustic soda in the cold and forms oxime and phenylhydrazone, m.p. 108°. The latter compound loses water above 160°, giving phenylmethylpyridazolone $\text{CH}_3\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}\cdot\text{N}(\text{C}_6\text{H}_5)_2$.

The methyl and ethyl esters are liquid, and boil at 191°–191.5° (743 mm.) and 205.2° (corr. 756 mm.) respectively.

Lævulic acid is used in cotton printing.

γ -Ketonic acids condense in some cases with aldehydes; e.g. sodium benzoyl propionate, acetic anhydride and benzaldehyde give phenylbenzylidenecrotonolactone (W. Borsche, Ber. 1914, 47, 1108).

The synthesis of esters of δ -ketonic acids due to Kohler, has been extended by Hahn and Allbee (Amer. Chem. J. 1913, 49, 171).

A number of ϵ -ketonic acids have been prepared, starting with adipic acid (E. E. Blaise and A. Kochler, Bull. Soc. chim. 1910, [iv.] 7, 215).

Carboxylic acids of cyclic ketones are also known, e.g. cyclohexanone-2-carboxylic acid, and 1-methylcyclohexane-2-one-3-carboxylic acid (H. D. Gardner, W. H. Perkin, jun., and H. Watson, Chem. Soc. Trans. 1910, 97, 1756).

Dibasic Ketonic Acids.

Mesoxalic acid (dihydroxymalonic acid) $\text{C}(\text{OH})_2(\text{COOH})_2$ or $\text{CO}(\text{COOH})_2 \cdot \text{H}_2\text{O}$ was obtained by Liebig and Wöhler by the hydrolysis of alloxan (Annalen, 1838, 26, 298); from aminomalonic acid by Baeyer (*ibid.* 1864, 131, 298) and from dibromomalonic acid by Petrieu (J. Russ. Phys. Chem. Soc. 1878, 10, 72). M. Conrad and C. Brückner (Ber. 1891, 24, 2993) obtained the diethyl ester (m.p. 57°) by the action of bromine on diethyl acetyltartrate $\text{CH}_3\text{CO}\cdot\text{O}\cdot\text{CH}(\text{CO}_2\text{C}_2\text{H}_5)_2$, whilst H. Filippo, jun., obtained a practically quantitative yield of the ester by the action of bromine on diethyl tartrate (Rec. trav. chim. 1910, [ii.] 14, 113).

Mesoxalic acid melts at 119°–120° (E. Fischer), is easily soluble in water, fairly so in alcohol and ether. The aqueous solution, when boiled, gradually decomposes into carbon dioxide and glyoxylic acid.

The mesoxalic and oxomalic esters are obtained by acting on the corresponding malonic esters in admixture with acetic anhydride and ether with the nitrous gases evolved by the action of water on nitroxyl sulphate (Schmitt, *Compt. rend.* 1905, 140, 1400; Curtiss, *Amer. Chem. J.* 1906, 35, 477; *J. Amer. Chem. Soc.* 1908, 30, 1264; Meyer, *Bull. soc. chim.* 1911, iv, 9, 423).

Another example of the conversion of a malonic into a mesoxalic derivative is afforded by the formation of dithiommesoxanilide from malonanilide and sulphur monochloride (Naik, Trans. Chem. Soc. 1921, 119, 382, 1231).

Diethyl oxalacetate

is obtained by Claisen's method from diethyl oxalate and ethyl acetate, and by the action of concentrated sulphuric acid on diethyl acetonedicarboxylate. It is a colourless oil giving an intense dark red coloration with ferric chloride, and is sufficiently acid in character to be titrated with phenolphthalein as indicator (H. Gault, *Compt. rend.* 1910, 150, 1608; L. J. Simon, *ibid.* 1760).

Hydrolysis with dilute sulphuric acid gives alcohol, carbon dioxide, and pyruvic acid (ketonic fission); with alkalis, salts of oxalic and acetic acids are produced.

The sensitiveness of esters of oxaloacetic ester to alkalis is considerable, traces being sufficient to bring about marked decomposition. The dimethyl ester gives m.p. 87° – 90° in Jena glass, but only 77° if heated in a soft glass tube (Dieckmann, Ber. 1916, 49, 2213).

On lactonisation, oxalacetic ester gives oxalocitrolactone (Gault, *Compt. rend.* 1914, 158, 711).

The ester reacts with phenyldiazonium

chloride, giving a product identical with the monophenylhydrazone of diethyl diketosuccinate (m.p. 72° – 73°):

The action of phenylhydrazine on this compound yields an osazone (m.p. 119°-120°) $\text{C}_6\text{H}_5\cdot\text{NH}\cdot\text{N}:\text{C}:\text{CO}_2\text{C}_2\text{H}_5$, identical with the $\text{C}_6\text{H}_5\cdot\text{NH}\cdot\text{N}:\text{C}:\text{CO}_2\text{C}_2\text{H}_5$ product obtained by Anschütz and Geldermann from phenylhydrazine and diethyl diketosuccinate (Annalen, 1891, 261, 130). When this osazone is boiled with three or four parts of glacial acetic acid, ethyl alcohol is eliminated, and ethyl phenylketopyrazolonephenylhydrazine carboxylate

is produced (W. Wislizenus and A. Jensen, Ber. 1892, 25, 3448). Orange needles, m.p. 152°-153°; also obtained by Anschütz and Parlato (*ibid.* 1892, 25, 1975).

The pyrazolone compound described is of tartrazine type, and it is evident that mixed tartrazines may be prepared from ethyl oxalacetate, using hydrazines and diazo compounds derived from different aromatic amines. The constitution of the original tartrazine derived from phenylhydrazine-*p*-sulphonic and dihydroxytartaric acids has been fully investigated by Anschütz (Annalen, 1897, 294, 219), who recognised definitely the existence of the pyrazolone ring in the dyestuff. In the preparation of this colouring matter from diethyl oxalacetate, 9·4 kilos. of the ester, 9·5 kilos. of phenylhydrazine sulphonic acid, and 7·5 kilos. of crystallised sodium acetate are stirred with 50 litres of water at 50° until complete solution is effected. The solution is cooled to ordinary temperature, 8–10 kilos. of calcined soda are added (reaction alkaline), and after completion of the pyrazolone condensation, the tartrazinen ester sulphonic acid precipitated by dilute sulphuric acid, pressed and dried. After the hydrolysis with caustic soda, diazotised sulphonic acid is added, and the tartrazine salted out when coupling is completed (B. A. S. F., Eng. Pats. 5693 of 1893 and 765 of 1897; *cp. R.* Grehm and L. Benda, Annalen, 1898, 299, 100, and Farbenfab. vorm. Fr. Bayer & Co., Eng. Pat. 532 of 1910).

Dihydroxytartaric acid (Diketosuccinic acid)

was first obtained from protocatechuic acid (Gruber, Ber. 1879, 12, 514) and catechol (Barth, Monatsh. 1880, 1, 869) by the action of nitrous gases (N_2O_3). Kekulé obtained it from dinitrotartaric acid

acid is obtained by dissolving tartaric acid in $4\frac{1}{2}$ parts of fuming nitric acid, shaking with an equal volume of concentrated sulphuric acid, and drying the precipitate on porous earthen ware. This compound is then mixed with an equal amount of ether, some crude ethyl nitrite added, and the mixture allowed to stand for some days. On shaking with water and adding sodium carbonate, the nearly insoluble sodium dihydroxytartrate is precipitated.

H. J. H. Fenton and E. S. St. B. Sladen (Eng. Pat. 27032 of 1897) obtain the acid by adding to a mixture of 1 part of dihydroxymaleic acid and 4 parts of glacial acetic acid, bromine and water drop by drop in quantities slightly greater than that required by the equation

During the addition the mixture is well cooled.

Dihydroxytartaric acid generally reacts as diketosuccinic acid, and is very unstable; its employment in the production of tartrazines has already been mentioned.

Acetonedicarboxylic acid

is obtained by heating citric and sulphuric acids on the water-bath until carbon dioxide begins to be evolved:

The mixture is then diluted with water, and the acetonedicarboxylic acid extracted with ether (v. Pechmann, Ber. 1884, 17, 2543). By using hydrated citric acid and forming sulphuric acid (20 p.c. SO_3), Willstätter and Pfannenstiel have obtained yields of 53 to 66 p.c. (Annalen, 1921, 422, 1).

Acetonedicarboxylic acid is obtained crystalline from ethyl acetate; it decomposes on fusion into carbon dioxide and acetone, the same reaction occurring on boiling with water or warming with acids or alkalis. Ferric chloride gives a violet coloration. M.p. 138° .

Heated with phenylhydrazine and hydrochloric acid in aqueous solution, methylphenylpyrazolone carboxylic acid is produced. The latter compound, when heated to 160° , and then distilled under reduced pressure, gives Knorr's phenylmethylpyrazolone (Ber. 1883, 16, 2597; Annalen, 1887, 238, 147; v. Pechmann and Jenisch, Ber. 1891, 24, 3252).

Condensations with aldehydes, ammonia and amines (Petrenko-Kritschenko, J. pr. Chem. 1912, ii, 85, 1).

Electrolysis of ethyl potassio-acetone dicarboxylate after neutralisation with 1.2N. oxalic acid at 0° gives ethyl $\beta\beta'$ -diketo suberate (succinyldiacetate), m.p. 46° - 47° . The corresponding free acid melts at 117° .

Diethyl diketosuccinate

is obtained by the action of iodine on the sodium derivative of ethyl acetoacetate (Rugheimer, Ber. 1874, 7, 892; Harrow, Annalen, 1880, 201, 144); rhombic tables, m.p. 78° . The free acid seems incapable of existence; when

boiled with 20 p.c. sodium carbonate solution carbon dioxide escapes and acetylacetonone is produced. Like the latter compound, the ester readily condenses with ammonia, giving pyrrol-derivatives.

Ethyl oxalyl-succinate, b.p. 170° - $175^\circ/12$ -13 mm. (Blaise a. Gault, Bull. Soc. Chim. 1911, 9, 451, 458, 588; see also Wislicenus and Waldmüller, Ber. 1911, 44, 1564).

Ethyl diketobutyrate is obtained by the action of nitrous gases on ethyl isonitrosoacetoacetate. B.p. $70^\circ/13$ mm. Forms a crystalline hydrate $\text{C}_8\text{H}_{14}\text{O}_4\cdot\frac{1}{2}\text{H}_2\text{O}$, m.p. 120° (Bouveault and Wahl, Compt. rend. 1904, 138, 1221; Wahl, *ibid.* 1907, 144, 212; 1911, 152, 95; 1912, 154, 1237). The *dimethylamino-anil*, m.p. 63.5° , is obtained by the action of nitrosodimethylaniline on ethyl acetoacetate (Sachs, Ber. 1903, 36, 3221). Formation of lactones (Gault, Compt. rend. 1911, 153, 107).

ALDEHYDE-KETONES.

Compounds are known containing carbonyl in both aldehyde and ketone groups; the two simplest compounds of this class are methylglyoxal and mesoxal dialdehyde.

Methylglyoxal $\text{CH}_3\cdot\text{CO}\cdot\text{CHO}$ was first obtained as a dipolymeride together with acetone peroxide by gently warming mesityl oxide ozonide (Harries and Türk, Ber. 1905, 38, 1630). The acetal $\text{CH}_3\cdot\text{CO}\cdot\text{CH}(\text{OC}_2\text{H}_5)_2$ is obtained from ethyl diethoxyacetate and methyl magnesium iodide (Wohl and Lange, Ber. 1908, 41, 3612), and when hydrolysed by dilute sulphuric acid gives the tripolymeride of methylglyoxal. The monomolecular form is obtained by distilling the tripolymeride under reduced pressure; it is an intensely yellow liquid with a pungent odour. It begins to boil at 72° , but polymerises (Meisenheimer, Ber. 1912, 45, 2635).

Methylglyoxal is an intermediary product of sugar degradation by weak alkalis (sodium carbonate or phosphate), in presence of phenylhydrazine the osazone is obtained, a particularly good yield being obtained when fructose is the sugar employed (Neuberg and Oetzel, Biochem. Zeitsch. 1913, 55, 495).

For preparation of glyoxals of the type $\text{R}\cdot\text{CO}\cdot\text{CHO}$ and their acetals, see Dakin and Dudley (Chem. Soc. Trans. 1914, 105, 2453).

Mesoxal dialdehyde $\text{CHO}\cdot\text{CO}\cdot\text{CHO}$ is obtained as a hydrate by the decomposition of phorone diozonide with ice water. The anhydrous compound forms a pale yellow, brittle, hygroscopic mass (Harries and Türk, Ber. 1905, 38, 1630). A solution may also be obtained by passing nitrous fumes into an ice-cold aqueous suspension of diisonitrosoacetone (Henle and Schupp, Ber. 1905, 38, 1372).

The *triphenylhydrazine* prepared from mesoxal dialdehyde melted at 156° (Harries and Türk), though when obtained from acetonedicarboxylic acid and phenyldiazonium chloride the m.p. was found to be 175° - 176° (von Pechmann and Jenisch, Ber. 1891, 24, 3255).

J. T. H.

KETOXIMES. Substances formed by the action of hydroxylamine on ketones.

KHARSIVAN. Syn. for Salvarsan.

KHAYA or **KAYA** v. CALCEDRA.

KIDNEY-IRON-NORE v. HEMATITE and IRON.

KIESELGUHR v. DIATOMITE.

KIESERITE. Hydrated magnesium sulphate $MgSO_4 \cdot H_2O$, of rare occurrence as colourless monoclinic crystals; but as finely granular to compact masses of a greyish-white colour it is abundant in the potash-salt deposits of Stassfurt in Prussia. It is also found at Hallstadt in Austria, and Kalusz in Poland. Sp.gr. 2.57; H. 3-3½. On exposure to air it gradually becomes opaque and falls to a white powder, due to the absorption of water and conversion into epsomite. The 'kieserite zone,' about 60 metres in thickness and consisting of kieserite, together with carnallite, bischofite, rock-salt, and anhydrite, lies immediately below the 'carnallite zone' (v. POTASSIUM). (On the artificial production of kieserite, see van 't Hoff, Sitz.-Ber. Akad. Wiss. Berlin, 1901, 1034.)

L. J. S.

KILLAS. A local name used by Cornish miners for the clay-slates of their country (v. SLATE).

KINETATE v. EXPLOSIVES.

KINETINE. A combination of quinine and hedine.

KINEURINE. Trade name for quinine glycerophosphate.

KING'S BLUE, KING'S YELLOW v. PIGMENTS.

KINO of the B. P. and U.S. P. is the juice, dried by heat, which is obtained from incisions in the trunk of *Pterocarpus Marsupium* (Roxb.) (Corom. Pl. plate 116; Benth. a. Trim. plate 81), a tall tree of Southern India and Ceylon, the felling of which is restricted by the Government in the Madras Presidency. This *East Indian, Malabar, Madras, or Cochin* kino forms small, angular, glistening, opaque, reddish black, brittle fragments, transparent and ruby-red in thin laminae. It has a very astringent taste, colours the saliva blood-red, and dissolves almost entirely in 90 p.c. alcohol, slowly and incompletely in cold water; in hot water at least 75 p.c. dissolves. The ash does not exceed 2.5 p.c. (B. P.). Fused with potash it gives about 9 p.c. of phloroglucinol (Hlasiwetz, Annalen, 134, 122) and protocatechuic acid. Dry distillation yields catechol, and ether also extracts a little of this substance. Dilute mineral acids precipitate from the aqueous solution *kinoannic acid*, the principal constituent (75-80 p.c.), which is coloured green by ferric chloride and has not been obtained pure. By boiling kino with dilute hydrochloric acid (1 in 5) a colourless crystalline compound *kinoïn* $C_{14}H_{12}O_6$ is extracted, which can be removed from the acid solution by ether and crystallised from water; about 1.5 p.c. is present (Etti, Ber. 1878, 11, 1879; 1884, 17, 2241). Kinoïn gives with ferric chloride a red colour and is decomposed by concentrated hydrochloric acid at 120°-130° into methylchloride, gallic acid, and catechol, which indicates that it is perhaps guaiac gallate $C_6H_3(OH)_3CO \cdot OC_6H_4 \cdot OMe$. Heated by itself at 120°-130° it forms the anhydride *kino red* $C_{28}H_{22}O_{11}$, which is also obtained from the residues after extracting kinoïn from kino by means of acid.

Another variety of Indian kino is obtained from *Butea frondosa* (Roxb.), and is known as *Butea gum, Butea gurr, Bengal kino, Palas or Pulas kino, or Dhak gum*. Only about 40 p.c. is

soluble in 90 p.c. alcohol, but in other respects it closely resembles kino from *Pterocarpus Marsupium*, for which the B. P. allows it to be substituted in India and the East, under the name *Butea Gummi*.

Australian, Botany Bay or Eucalyptus kino, Eucalyptus gum or red gum is derived from various species of *Eucalyptus* (Mueller, Pharm. J. [iii.] 16, 898; Maiden, J. Soc. Chem. Ind. 1888, 38; Pharm. J. [iii.] 20, 221, 321), and is also included in the B. P. (*Kino eucalypti*). G. B.

KINO RED, KINOÏN, KINOTANNIC ACID, v. KINO.

KIRSCHWASSER or **KIRSCH** is a strong spirituous liquor made by distillation of the fermented juice of ripe Morella or wild cherries. It is prepared chiefly in Germany (particularly in the Black Forest), in Switzerland, and in the Vosges district in France.

The cherries are crushed and the juice collected in vats, the kernels added and the whole allowed to ferment for about 5 days, when the liquor is drawn off and distilled by steam.

The strength of the spirit is usually about 50 p.c. alcohol by volume or approximately 10 under proof; and its peculiar taste and flavour are due largely to the presence of hydrocyanic (prussic) acid derived from the kernels of the cherry stones.

In properly made kirschwasser, the hydrocyanic acid does not exceed 0.015 gram per litre, but in crude varieties, made by prolonged fermentation of unripe or unsound fruit, and distilled over an open fire, it occasionally reaches almost poisonous proportions.

Kirschwasser is sometimes made from grain, grape, molasses, or other spirit flavoured with 'essence of kirschwasser' or with peach blossom, oil of bitter almonds or its substitute, nitrobenzene. Traces of copper are frequently found as an impurity, due no doubt to the copper vessels used for distillation.

Genuine kirschwasser improves greatly by keeping, either in flasks or bottles with porous stoppers or in casks. The latter are made of ash in preference to oak, as the liquor should remain perfectly bright and colourless.

Various imitations of kirschwasser are made, the characteristic flavour being derived from the kernels of stone fruit, apricots, peach kernels or oil of bitter almonds. The following recipe (Spon's Encyclopædia) is one of the best: cherry seeds, 9 kilos.; apricot seeds, 3 kilos.; dried peach leaves, 625 grams; myrrh, 150 grams; alcohol at 85°, 62 litres. The seeds are bruised and digested with about 30 litres of water for 24 hours, and the whole distilled until about 60 litres have come over, when the distillate is reduced to about 50° alcohol. A little glycerin or sugar (not more than 15 grams per 100 litres) is usually added to soften the flavour.

Kirschwasser is occasionally heavily sweetened, when it greatly resembles 'noyau' (v. LIQUEURS AND CORDIALS).

J. C.

KISH. An ironworker's name for the masses of impure graphite which are occasionally found in blast furnaces, and which separate out from molten cast iron.

KLIACHITE v. BAUXITE.

KOHLRABI. *Brassica oleracea* f. *caulo-rapa*. A plant of the cabbage tribe producing a great

enlargement on the stem. This 'bulb,' which sometimes weighs as much as 12 or 15 lbs., is the valued portion of the crop, and furnishes an excellent substitute for swedes or turnips as food for cattle and sheep.

It is very hardy and more resistant to drought and frost than the turnip.

König gives as the average composition of the 'bulb'—

Water	Protein	Fat	Sugar	Other N-free subst.	Crude fibre	Ash	Organic sulphur
86.9	2.9	0.2	0.4	7.8	1.7	1.2	0.06

Of the total nitrogen, from which the 'protein' in the above analysis is calculated, only about 44 p.c. is present as true proteid, about 8 p.c. as amides, and the remainder in other forms of combination.

The leaves and stalks contain—

Water	Protein	Fat	Sugar	Other N-free subst.	Crude fibre	Ash	Organic sulphur
86.0	3.0	0.4	0.5	6.8	1.6	1.7	0.08

The ash contains—

	K ₂ O	Na ₂ O	CaO	MgO	Fe ₂ O ₃	P ₂ O ₅	SO ₃	SiO ₂	Cl
'Bulb'	35.3	6.5	11.0	6.8	3.0	21.9	8.8	2.5	4.9 p.c.
Leaves	18.5	4.9	30.1	4.6	6.0	8.3	10.9	9.0	8.0 „

H. I.

KOLA. Kola nuts, the fruit of *Cola acuminata* (Schott and Endl.), are imported from the West Coast of Africa, and are made into a paste which contains about 2 p.c. of caffeine, in addition to betaine (Polstorff, Chem. Zentr. 1909, ii, 1014; cf. Desvignes, J. Pharm. Chim. 1910, 2, 20; Allard, *ibid.* 2, 122). According to Heckel and Schlagdenhauffen, the fruit of *Herstiera littoralis* (Dryand), a tree growing in India, in the Philippines, and Molucca, is often found mixed with kola nuts. This fruit belongs to the same family (*Steruliaceæ*) as those which give the kola nuts, and is said to possess the same waste-repairing properties as the kola nut, although it contains no caffeine. It is used as a foodstuff in India.

KONDANG WAX *v.* *Figtree Wax*, art. WAXES.

KORALLENERZ *v.* CINNABAR.

KORONIUM BROMIDE. A trade name for strontium bromide.

KOSIN or **KOUSSEIN RESIN** *v.* RESINS.

KOUMISS *v.* MILK.

KOUSSO or **CUSSO**, B.P. The dried panicles of pistillate flowers of *Brayera anthelmintica* (Kunth.) *v.* RESINS.

KRAMERIA ROOT *v.* PEHATANY ROOT.

KRANTZITE. A variety of retinite (*v.* RESINS).

KREMS or **KREMSER WHITE**, **CREMNITZ WHITE**, *v.* PIGMENTS.

KREOLIN. Trade name for a preparation of crude carbolic acid. Used as an antiseptic.

KREOSAL, **KREOTOSAL**, **KRESÁLOL**, **KYROGENOL**, *v.* SYNTHETIC DRUGS.

KREOSOL *v.* *Guaiacum*, art. RESINS.

KRESAMINE. Ethylene diamine tricresol.

KRESAPOLIN, **KRESOLIN.** Preparations of crude carbolic acid. Used as disinfectants.

KRESATIN. *m.*-Cresol acetate.

KRYOFINE. Trade name for phenetidine-methyl-glycollate $\text{CH}_3\text{OCH}_2\text{CONH}\cdot\text{C}_6\text{H}_4\text{OC}_2\text{H}_5$.

Used as an antipyretic and anti-neuralgic. White, crystalline needles, m.p. 98°, odourless and tasteless, sparingly soluble in water (*v.* SYNTHETIC DRUGS).

KRYPTON. Sym. Kr. At.wt. 82.9 (Moore, Watson, *v. infra*).

An inert gas, discovered by Ramsay and Travers (Proc. Roy. Soc. 1898, 63, 405; British Assoc. Rep. 1898, 828) in the last portions of gas collected after evaporating considerable quantities of liquid air. When the latter is allowed to evaporate quietly in a vacuum vessel, the last traces of liquid consist almost entirely of oxygen, with small quantities of nitrogen, argon, krypton, and xenon. The liquid is allowed to evaporate, the gas is mixed with hydrogen and passed through a heated iron tube to remove oxygen. Nitrogen is absorbed by means of lime and magnesium (*cf.* ARGON), and after removing traces of hydrogen and carbon monoxide by means of heated copper oxide, the mixture of argon, krypton, and xenon is separated into its components by liquefaction and fractional evaporation. At the temperature of liquid air, krypton has a vapour pressure of 17 mm., whilst that of xenon is only 0.17 mm. (*v.* Travers, Study of Gases, 218; Ladenburg and Krügel, Sitzungber. K. Preuss. Akad. Wiss. 1900, 212, 727; Ramsay and Travers, Proc. Roy. Soc. 1901, 67, 329; Moore, Chem. Soc. Trans. 1908, 93, 2181). The separation of a mixture of argon, krypton, and xenon has been effected by absorbing the gases in charcoal cooled in liquid air, allowing the temperature to rise slowly and collecting the evolved gas in fractions (Valentiner and Schmidt, Sitzungber. K. Akad. Wiss. Berlin, 1905, 38, 816).

The proportion of krypton in the atmosphere is about 1 part in twenty millions by volume (Ramsay, Proc. Roy. Soc. 1903 71, 421; 1908, 80, A. 599); 50+10⁻⁹ by volume, 140+10⁻⁹ by weight (Leduc Bureau, Int. Poids et Mes. Mem. 16, 1917). Krypton also occurs in the gases evolved from many thermal springs (Moureu and Lepape, Compt. rend. 1909, 149, 1171).

Krypton is a colourless, odourless, tasteless gas. It is only slightly soluble in water, the absorption coefficient at 0°, 0.1095; 10°, 0.0807; 20°, 0.0626; 30°, 0.0511 (Antropoff, Zeitsch. Elektrochem. 1919, 25, 269). One litre of the gas at N. T. P. weighs 3.708 grams; its density is therefore 41.506 (O=16) (Moore, Chem. Soc. Trans. 1908, 93, 2181; Watson, *ibid.* 1910, 97, 833). Krypton boils at -151.7° and melts at -169°; its critical temperature is -62.5°, and the critical pressure is 54.3 atmospheres. One cub. cm. of liquid krypton at its boiling-point weighs 2.155 grams; the molecular volume is 37.84 (Ramsay and Travers, Proc. Roy. Soc. 1901, 67, 329). At N. T. P. the refractive index of the gas for the green mercury line ($\lambda=5461$) is 1.0004287 (Cuthbertson and Cuthbertson, Proc. Roy. Soc. 1908, 81, A. 440; 1910, 84, A. 13). (For the viscosity of krypton, *v.* Rankine, *ibid.* 1910, 83, A. 516; for its spectrum, *v.* Baly, Phil. Trans. 1903, 202, A. 183; Living and Dewar, Proc. Roy. Soc. 1901, 68, 389; Page, Proc. Physical Soc. 1912, 24, 138.)

Krypton is completely inactive, no compounds of the element being known. The gas

is monatomic, since the ratio of its specific heats is 1.66 (Ramsay and Travers).

KUNKUR. An argillaceous limestone used in India for the preparation of mortar. It forms an excellent hydraulic mortar (E. Nicholson, Chem. News, 32, 82).

KUNZITE. A transparent, violet, or lilac-coloured variety of the mineral spodumene $\text{LiAlSi}_2\text{O}_6$ (*q.v.*), used as a gem-stone. It is found with pink tourmaline in the gem-mines of San Diego Co., California, and in Madagascar.

L. J. S.

KUPFERNICKEL *v.* NICCOLITE.

KUS-KUS ROOT. The rhizome of *Andropogon squarrosus* (Linn.), a marsh plant of the Gramineæ, growing in India, the Philippines, &c., and cultivated in Jamaica; gives an ethereal oil, *oleum æther vetiveriæ*, used in perfumery.

KUTEERA GUM *v.* GUMS.

KYANISING. A process for preserving timber, due to Kyan, of New York, in which a solution of mercuric chloride is forced into the pores of the wood.

KYANITE or **CYANITE.** (Fr. *Disthène*.) Aluminium silicate $\text{Al}_2\text{O}_3\cdot\text{SiO}_2$ or Al_2SiO_5 , crystallised in the triclinic system. This compound is trimorphous and exists also as the minerals andalusite and sillimanite. Kyanite and andalusite are transformed at about 1300°

into sillimanite, which melts at 1816° . Kyanite occurs as bundles of bladed crystals in mica-schist and gneiss, and is not an uncommon mineral. There is a perfect cleavage parallel to the flat of the blades, and one less perfect at the sides; whilst at ends there is a glide-plane which gives rise to very characteristic cross markings on the broad surface. The colour is usually pale blue, hence the name, from *κυανός*, blue. A remarkable feature is the difference in hardness (H. 4-7) on different faces and in different directions on the same face. Sp.gr. 3.6. The mineral is not attacked by acids. Kyanite is occasionally used as a gem-stone. The best crystals come from Pizzo Forno, near Faido in Switzerland.

L. J. S.

KYANOL. Runge's term for aniline.

KYLINDRITE *v.* CYLINDRITE.

KYNITE *v.* EXPLOSIVES.

KYNURENIC ACID. An acid isolated from the urine of the dog by Liebig. Probably identical with 4-hydroxy-quinoline-2-carboxylic acid (Homer). Cf. Besthorn, Ber. 1921, 54 [B], 1330.

KYNURIN. Trade name for *p*-hydroxy-quinoline.

KYROFIN. Trade name for a substituted anilide $\text{C}_6\text{H}_5\text{O}\cdot\text{C}_6\text{H}_4\cdot\text{NH}\cdot\text{COCH}_2\text{OCH}_3$. Used as an antipyretic.
